Brownian motors have been studied intensively since the early 1990s. This interest coincided with developments in bioengineering and nanotechnology, where understanding and designing a motor in the shape of a small biological or artificial device is an important issue. Most of the motors investigated in this context are powered by chemical energy. Brownian motors driven by a temperature gradient have a fundamental appeal, since their operation is directly related to basic questions such as Carnot efficiency, Maxwell demons and the foundations of statistical mechanics and thermodynamics. The additional significance of the thermal Brownian motor comes from the recent observation that it can operate as a refrigerator, see also [5]. In fact, this property is, at least in the regime of linear response, a direct consequence of Onsager symmetry: if a temperature gradient generates motion, an applied force will generate a heat flux. This principle is well known in its application to electro-thermal devices, displaying the Peltier, Seebeck and Thompson effects. At variance however with electro-thermal devices, rectification of nonequilibrium thermal fluctuations provide the driving mechanism for Brownian refrigeration. The latter become more prominent, and so do the resulting motor and cooling functions, as the apparatus becomes smaller.

Previous models for the Brownian refrigerator assume translational motion of the engine. This construction obviously poses difficulties in its technological implementation, while the resulting friction is expected to lower the efficiency. In this letter, we present a chiral rotational model, in which these problems do not occur, and which has the extra benefit that the choice of the axis of rotation provides an additional parameter that can be optimized. A related question, that will also be addressed, is the optimal chiral shape of the engine. The observed optimized rates of rotation and heat transfer are found to be significantly larger than in the translational counterpart, suggesting the technological implementation of such devices.

Since the properties of the Brownian heat pump follow by Onsager symmetry from those of the Brownian motor, we first focus on the latter. The basic construction is represented in Fig. 1(a). The engine consists of two parts linked by a rigid axis (which we take to be the \( z \)-axis), around which the whole construction is free to rotate as a single entity. This rotational motion is induced, following Newton’s laws, by the collisions with surrounding gas particles. The question of interest is under which conditions sustained rotational motion will arise. Following the Curie principle, the breaking of symmetry plays a crucial role. There are two obvious symmetries involved: the statistical symmetry of the microscopic dynamics and the chiral symmetry of the device. If the motor units are achiral, in the sense that clockwise and counterclockwise rotation cannot be distinguished, no sustained motion will appear. When both motor units reside in a single compartment at equilibrium, sustained rotational motion will not appear, even for chiral motor units, because it would violate the second law of thermodynamics, or referring to the basic underlying symmetry, because detailed balance should hold. Both symmetries will be broken if we consider chiral units residing in separate compartments at unequal temperatures \( T_i \). The index \( i \) runs over the different reservoirs, cf. Fig. 1(a) for a schematic rep-
The contour integral specifying \( \omega \) is the polar angle of the surface at impact, see Fig. 1(b). For three-dimensional cylindrical objects, as depicted in Fig. 1(a), the thermal speed of the gas particles \( v_T = \sqrt{8kT_i/\pi m} \), and the angular velocity increment \( \Delta \omega = \omega - \omega' \) in equilibrium, \( T_i = T \), one easily verifies that the Boltzmann distribution \( P^\rho(\omega) = \sqrt{T/(2\pi kT)} \exp[-I\omega^2/(2kT)] \) is the unique steady state solution of Eq. (1). As required by statistical mechanics, this solution satisfies detailed balance: \( W_{\omega|\omega'}^\rho (\omega') = W_{\omega'|\omega}^\rho (\omega) \).

A general solution away from equilibrium is not available, hence we resort to a perturbational technique. For small values of the parameter \( \epsilon = \sqrt{m/M} = r_0/\sqrt{m/I} \), where \( r_0 = \sqrt{T/M} \) is the radius of gyration of the device, the change in angular velocity upon collision with a gas particle is small and we can apply a Kramers-Moyal type of expansion. Note that this expansion is not uniform when performed in terms of the probability distribution, but has been found to converge very well when performed at the level of the moments. Here we only present the final results of this procedure, for more details see [8].

Up to first order in \( \epsilon \) the average angular speed of the motor obeys the following equation:

\[
\frac{\partial \langle \omega \rangle}{\partial t} = \frac{m}{M} \sum_i \rho_i \left[ -v_T \langle \omega \rangle \int dl_i (r_i/r_0)^2 \right. \\
+ \epsilon \left. \left( \sqrt{I/m} \langle \omega^2 \rangle - kT \right) \int dl_i (r_i/r_0)^3 + O(\epsilon^2) \right].
\] (4)

To lowest order in \( \epsilon \) we recognize a linear drag law, \( I \partial_i \langle \omega \rangle = -\gamma \langle \omega \rangle \), featuring a frictional torque which is proportional to the average rotational speed. The proportionality factor \( \gamma = \sum_i \gamma_i \) is equal to the sum of the friction coefficients \( \gamma_i \) contributed by each of the engine parts. From Eq. (4), one finds the following explicit expression for these friction coefficients:

\[
\gamma_i = m \rho_i v_T \int dl_i (r_i/r_0)^2.
\] (5)

Note that at this order of the perturbation, no systematic steady state motion appears \( \langle \omega \rangle^{st} = 0 \). This indicates that the “rectification of the fluctuations” leading to systematic motion appears at the level of nonlinear and non-Gaussian effects.

At the next order in \( \epsilon \), the equation for the first moment is coupled to the second moment, whose evaluation is thus needed to close the equation. Restricting ourselves to the steady state, one finds, not surprisingly, that (to lowest order) the average kinetic energy of the motor is given by the usual expression for equipartition, \( \frac{1}{2} I \langle \omega^2 \rangle = \frac{1}{2} kT_{eff} \), but at an effective temperature \( T_{eff} \). The latter is found to equal to the weighted geometric mean of the temperatures in the reservoirs: \( T_{eff} = (\sum_i \gamma_i T_i)/(\sum_i \gamma_i) \).

Combined with Eq. (1) we conclude that (up to first order \( \epsilon \)), the engine will develop an average steady state...
angular velocity given by
\[ \langle \omega \rangle = \frac{\sum_i \rho_i k (T_{\text{eff}} - T_i) \oint dl_i r_i^3}{I \sum_i \rho_i v_i T_i \oint dl_i r_i^2}. \] (6)

We proceed to discuss this first central result of our paper. The angular velocity is obviously zero at equilibrium, \( T_i = T_{\text{eff}} \), and also when \( \oint dl_i r_i^3 = 0 \), in agreement with the fact that the object then loses its chirality. As far as maximizing rotational frequency is concerned, a numerical procedure was employed to identify the optimum configuration (shape plus axis implantation) by deforming the contours in both compartments. This resulted in the spiral shape depicted in Fig. 1(b), with one engine part the enantiomorph of the other one. The same shape remains optimal, but appearing as the basis of a cylindrical object as depicted in Fig. 1(a), when turning to the case of dimension 3. The dependence of the rotational speed on the shape and axis implantation is very intricate. In fact even the direction of the net rotation is not at all obvious. In Fig. 2 we reproduce, for a specific triangular motor element (and its enantiomorph), the lines of equal amplitude for the rotational frequency as a function of the implantation of the rotation axis. The rotation is clockwise/counterclockwise in the dark/light shaded areas respectively. In view of the technological interest of this result, we include the corresponding properties of such engine calculated under physically realistic conditions, in Table I. Rotational frequencies in the kHz regime are obtained for a temperature gradient of .1 K. Such a sustained average rotation will dominate over the thermal Brownian motion, with typical frequency \( \sqrt{kT/I} = 1.81 \times 10^9 \) Hz, on a time scale of seconds or more.

We next turn to the analysis of the heat pump function. In the following, we will focus only on the linear response property, which can directly be obtained by invoking Onsager symmetry. To do so, one needs to write the result Eq. (6) in the framework of linear irreversible thermodynamics [6]. One identifies the flux \( J_1 = \langle \omega \rangle \) and the thermodynamic force \( X_1 = 1/T_2 - 1/T_1 \). For a small temperature difference \( \Delta T, T_1 = T + \Delta T/2, T_2 = T - \Delta T/2 \), a linear relation between flux \( J_1 \) and force \( X_2 = \Delta T/T_2 \) is observed, namely: \( J_1 = L_{12} X_2 \). The value of the coefficient \( L_{12} \) is found from Eq. (6) (for simplicity considering again enantiomorphs):
\[ L_{12} = \frac{2kT^2}{I v_T} \frac{\rho_1 \rho_2}{(\rho_1 + \rho_2)^2} \oint dl_i r_i^3. \] (7)

Following Onsager symmetry [7], there is a mirror relation \( J_2 = L_{21} X_1 \) with an identical proportionality coefficient \( L_{21} = L_{12} \), while \( J_2 \) is the flux associated to the temperature gradient \( X_2 \), i.e., it is a heat flux \( Q_{1\rightarrow2} \) (from reservoir 1 to reservoir 2), and \( X_1 \) is the thermodynamic force associated with the rotation, namely a mechanical torque divided by the temperature of the system, \( X_1 = \Gamma/T \). The relation \( J_2 = L_{21} X_1 \), with Eq. (7), implies that the heat flux \( Q_{1\rightarrow2} \) is given by
\[ Q_{1\rightarrow2} = \frac{2kT}{I v_T} \frac{\rho_1 \rho_2}{(\rho_1 + \rho_2)^2} \oint dl_i r_i^3 \Gamma. \] (8)

This is the second basic result of this letter. Note that the direction of heat transfer depends on the direction of the torque, in such a way that it activates an opposing Brownian motor in agreement with Le Chatelier’s principle [6]. For example, considering \( \oint dl_i r_i^3 > 0 \), the motor rotates clockwise \( \langle \omega \rangle < 0 \) for \( \Delta T < 0 \) (\( T_1 < T_2 \)). The application of a positive torque \( \Gamma > 0 \), inducing counterclockwise rotation, produces an energy flux \( Q_{1\rightarrow2} > 0 \), tending to activate the clockwise Brownian motor.

The Onsager coefficients \( L_{21} \) and \( L_{12} \) are the off-
We also note that under this condition, half of the rate of femtojoules per second, cf. Fig. 3(a) and Table I. The shape of the device is optimal for (a,b,c), while for (d) it corresponds with the 45° configuration of Fig. 3. Other properties as for Table I.

The diagonal elements $L_{11}$, the rotational mobility, and $L_{22}$, the thermal conductivity, can again be calculated from the above perturbational method [3], or from general arguments based on Langevin theory [3]. As we proceed to show, these terms, associated with Joule heating and heat conduction, specify the domain in which the heat pump can operate as a cooling device.

An external torque can induce a cooling flux, by pumping heat out of one reservoir (into the other). This effect is offset by a dissipative contribution in both reservoirs, resulting from frictional heating. The linear response term $L_{11} \dot{x}_1$ expresses that work is performed on the pump upon application of an external torque $\Gamma$, which leads to a power input $\gamma^2 \gamma_1 / \gamma^2$ in each reservoir $i$. The $\gamma^2$ dependency ensures that the cooling flux, which is proportional to $\Gamma$, will dominate for torques below a certain $\Gamma_{\text{lim}}$, as depicted in Fig. 3(b) for a concrete realization of the device. The formal condition $|L_{21} \dot{x}_1| > \gamma^2 \gamma_1 / \gamma^2$ enables us to quantify the limiting torque as $\Gamma_{\text{lim}} = \gamma^2 |L_{12}| / (\gamma_1 T)$, which is remarkably scale-independent. Maximum net cooling occurs for half the limiting torque $\Gamma_{\text{lim}} / 2$. Under this condition, a device of a few nanometer thickness is capable of a net rate of femtojoules per second, cf. Fig. 3(a) and Table I.

We also note that under this condition, half of the input power $P_{\text{in}}$ is used for cooling, yielding a coefficient of performance $\eta = Q_{\text{net}} / P_{\text{in}} = 0.5$. For lower values of the torque, $\Gamma < \Gamma_{\text{lim}} / 2$, a higher performance $\eta$ is feasible even though, as explained above, the net cooling flux is no longer maximal [see also Fig. 3(c)].

The fact that this term is proportional with $m/M$ indicates that the device may be better suited to transfer heat than to create a direct temperature difference.

In conclusion, a chiral molecular device, operating as a heat engine or heat pump, appears to be technologically feasible. It remains to be seen whether the simplifications assumed in this exact theoretical analysis (ideal gas reservoirs, frictionless rotation axis and lowest order approximation in $m/M$) lead to a realistic estimation of the performance, and whether alternative constructions (non-rigid coupling between units, vibrational instead of rotational units) offer an even better perspective.
