Abstract

We provide a general mechanism to design online learning algorithms based on a minimax analysis within a drifting-games framework. Different online learning settings (Hedge, multi-armed bandit problems and online convex optimization) are studied by converting into various kinds of drifting games. The original minimax analysis for drifting games is then used and generalized by applying a series of relaxations, starting from choosing a convex surrogate of the 0-1 loss function. With different choices of surrogates, we not only recover existing algorithms, but also propose new algorithms that are totally parameter-free and enjoy other useful properties. Moreover, our drifting-games framework naturally allows us to study high probability bounds without resorting to any concentration results, and also a generalized notion of regret that measures how good the algorithm is compared to all but the top small fraction of candidates. Finally, we translate our new Hedge algorithm into a new adaptive boosting algorithm that is computationally faster as shown in experiments, since it ignores a large number of examples on each round.

1 Introduction

In this paper, we study online learning problems within a drifting-games framework, with the aim of developing a general methodology for designing learning algorithms based on a minimax analysis. To solve an online learning problem, it is natural to consider game-theoretically optimal algorithms which find the best solution even in worst-case scenarios. This is possible for some special cases ([8,1,3,18]) but difficult in general. On the other hand, many other efficient algorithms with optimal regret rate (but not exactly minimax optimal) have been proposed for different learning settings (such as the exponential weights algorithm [14,15], and follow the perturbed leader [17]). However, it is not always clear how to come up with these algorithms. Recent work by Rakhlin et al. [21] built a bridge between these two classes of methods by showing that many existing algorithms can indeed be derived from a minimax analysis followed by a series of relaxations.

In this paper, we provide a parallel way to design learning algorithms by first converting online learning problems into variants of drifting games, and then applying a minimax analysis and relaxations. Drifting games [23] (reviewed in Section 2) generalize Freund’s “majority-vote game” [13] and subsume some well-studied boosting and online learning settings. A nearly minimax optimal algorithm is proposed in [23]. It turns out the connections between drifting games and online learning go far beyond what has been discussed previously. To show that, we consider variants of drifting games that capture different popular online learning problems. We then generalize the minimax analysis in [23] based on one key idea: relax a 0-1 loss function by a convex surrogate. Although this idea has been applied widely elsewhere in machine learning, we use it here in a new way to obtain a very general methodology for designing and analyzing online learning algorithms. Using
this general idea, we not only recover existing algorithms, but also design new ones with special useful properties. A somewhat surprising result is that our new algorithms are totally parameter-free, which is usually not the case for algorithms derived from a minimax analysis. Moreover, a generalized notion of regret (ε-regret, defined in Section 3) that measures how good the algorithm is compared to all but the top ε fraction of candidates arises naturally in our drifting-games framework. Below we summarize our results for a range of learning settings.

**Hedge Settings:** (Section 3) The Hedge problem [14] investigates how to cleverly bet across a set of actions. We show an algorithmic equivalence between this problem and a simple drifting game (DGv1). We then show how to relax the original minimax analysis step by step to reach a general recipe for designing Hedge algorithms (Algorithm 3). Three examples of appropriate convex surrogates of the 0-1 loss function are then discussed, leading to the well-known exponential weights algorithm and two other new ones, one of which (AbnormalHedge in Section 3) bears some similarities with the NormalHedge algorithm [11] and enjoys a similar ε-regret bound simultaneously for all ε and horizons. However, our regret bounds do not depend on the number of actions, and thus can be applied even when there are infinitely many actions. Our analysis is also arguably simpler and more intuitive than the one in [11] and easy to be generalized to more general settings. Moreover, our algorithm is more computationally efficient since it does not require a numerical searching step as in NormalHedge. Finally, we also derive high probability bounds for the randomized Hedge setting as a simple side product of our framework without using any concentration results.

**Multi-armed Bandit Problems:** (Section 4) The multi-armed bandit problem [6] is a classic example for learning with incomplete information where the learner can only obtain feedback for the actions taken. To capture this problem, we study a quite different drifting game (DGv2) where randomness and variance constraints are taken into account. Again the minimax analysis is generalized and the EXP3 algorithm [6] is recovered. Our results could be seen as a preliminary step to answer the open question [2] on exact minimax optimal algorithms for the multi-armed bandit problem.

**Online Convex Optimization:** (Section 4) Based the theory of convex optimization, online convex optimization [26] has been the foundation of modern online learning theory. The corresponding drifting game formulation is a continuous space variant (DGv3). Fortunately, it turns out that all results from the Hedge setting are ready to be used here, recovering the continuous EXP algorithm [12, 20] and also generalizing our new algorithms to this general setting. Besides the usual regret bounds, we also generalize the ε-regret, which, as far as we know, is the first time it has been explicitly studied. Again, we emphasize that our new algorithms are adaptive in ε and the horizon.

**Boosting:** (Section 5) Realizing that every Hedge algorithm can be converted into a boosting algorithm (DGv4), we propose a new boosting algorithm (AbnormalBoost) by converting AbnormalHedge. The adaptivity of AbnormalHedge is then translated into training error and margin distribution bounds that previous analysis in [24] using nonadaptive algorithms does not show. Moreover, our new boosting algorithm ignores a great many examples on each round, which is an appealing property useful to speeding up the weak learning algorithm. This is confirmed by our experiments.

**Related work:** Our analysis makes use of potential functions. Similar concepts have widely appeared in the literature [9, 5], but unlike our work, they are not related to any minimax analysis and might be hard to interpret. The justification and practical value of studying ε-regret were discussed in [11]. Boosting algorithms that ignore some examples on each round were studied in [16], where a heuristic was used to ignore examples with small weights and no theoretical guarantee is provided.

### 2 Reviewing Drifting Games

We consider a simplified version of drifting games similar to the one described in [24, chap. 13] (also called chip games). This game proceeds through T rounds, and is played between a player and an adversary who controls \( N \) chips on the real line. The positions of these chips at the end of round \( t \) are denoted by \( s_t \in \mathbb{R}^N \), with each coordinate \( s_{t,i} \) corresponding to the position of chip \( i \). Initially, all chips are at position 0 so that \( s_0 = 0 \). On every round \( t = 1, \ldots, T \): the player first chooses a distribution \( p_t \) over the chips, then the adversary decides the movements of the chips \( z_t \), so that the new positions are updated as \( s_t = s_{t-1} + z_t \). Here, each \( z_{t,i} \) has to be picked from a prespecified set \( B \subseteq \mathbb{R} \), and more importantly, satisfy the constraint \( p_t \cdot z_t \geq \beta \geq 0 \) for some fixed constant \( \beta \).
At the end of the game, each chip is associated with a nonnegative loss defined by $L(s_{T,t})$ for some nonincreasing function $L$ mapping from the final position of the chip to $\mathbb{R}_+$. The goal of the player is to minimize the average loss $\frac{1}{T} \sum_{t=1}^{N} L(s_{T,t})$ after $T$ rounds. So intuitively, the player aims to “push” the chips to the right by assigning appropriate weights on them so that the adversary has to move them to the right by $\beta$ in a weighted average sense on each round. This game captures many learning problems. For instance, binary classification via boosting can be translated into a drifting game by treating each training example as a chip (see [23] for details).

We regard a player’s strategy $D$ as a function mapping from the history of the adversary’s decisions to a distribution that the player is going to play with, that is, $p_t = D(z_{1:t-1})$ where $z_{1:t-1}$ stands for $z_1, \ldots, z_{t-1}$. The player’s worst case loss using this algorithm is then denoted by $L_T(D)$. The minimax optimal loss of the game is computed by the following expression:

$$\min_D L_T(D) = \min_{p_t \in \Delta_N} \max_{z_{1:t-1} \in \mathbb{Z}^N} \min_{p_T \in \Delta_N} \max_{z_T \in Z^N} L \left( \sum_{t=1}^{T} \min_{i} L_{t}(s_{t,i}) \right),$$

where $\Delta_N$ is the $N$ dimensional simplex and $Z^N = \{ z : p \cdot z \geq \beta \}$ is assumed to be compact. A strategy $D^*$ that realizes the minimum in $L_T(D)$ is called a minimax optimal strategy.

A nearly optimal strategy and its analysis is originally given in [23], and a derivation by directly tackling the above minimax expression can be found in [24, chap. 13]. Specifically, a sequence of potential functions of a chip’s position is defined recursively as follows:

$$\Phi_T(s) = L(s), \quad \Phi_{t-1}(s) = \min_{w \in \mathbb{R}_+} \max_{z \in B} (\Phi_t(s+z) + w(z - \beta)).$$

(1)

Let $w_{t,i}$ be the weight that realizes the minimum in the definition of $\Phi_{t-1}(s_{t-1,i})$, that is, $w_{t,i} \in \arg \min_{w} \max_{z} (\Phi_t(s_{t-1,i} + z) + w(z - \beta))$. Then the player’s strategy is to set $p_{t,i} \propto w_{t,i}$. The key property of this strategy is that it assures that the sum of the potentials over all the chips never increases, connecting the player’s final loss with the potential at time $0$ as follows:

$$\frac{1}{N} \sum_{i=1}^{N} L(s_{T,i}) \leq \frac{1}{N} \sum_{i=1}^{N} \Phi_T(s_{T,i}) \leq \frac{1}{N} \sum_{i=1}^{N} \Phi_{t-1}(s_{T-1,i}) \leq \cdots \leq \frac{1}{N} \sum_{i=1}^{N} \Phi_0(s_{0,i}) = \Phi_0(0).$$

(2)

It has been shown in [23] that this upper bound on the loss is optimal in a very strong sense.

Moreover, in some cases the potential functions have nice closed forms and thus the algorithm can be efficiently implemented. For example, in the boosting setting, $B$ is simply $\{-1, +1\}$, and one can verify $\Phi_t(s) = \frac{1+\beta}{1-\beta} \Phi_{t+1}(s+1) + \frac{1-\beta}{1+\beta} \Phi_{t+1}(s-1)$ and $w_{t,i} = \frac{1}{2} (\Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1))$. With the loss function $L(s)$ being $\mathbf{1}\{ s \leq 0 \}$, these can be further simplified and eventually give exactly the boost-by-majority algorithm [13].

3 Online Learning as a Drifting Game

The connection between drifting games and some specific settings of online learning has been noticed before ([23, 19]). We aim to find deeper connections or even an equivalence between variants of drifting games and more general settings of online learning, and provide insights on designing learning algorithms through a minimax analysis. We start with a simple yet classic Hedge setting.

3.1 Algorithmic Equivalence

In the Hedge setting [14], a player tries to earn as much as possible (or lose as little as possible) by cleverly spreading a fixed amount of money to bet on a set of actions on each day. Formally, the game proceeds for $T$ rounds, and on each round $t = 1, \ldots, T$: the player chooses a distribution $p_t$ over $N$ actions, then the adversary decides the actions’ losses $\ell_t$ (i.e. action $i$ incurs loss $\ell_{t,i} \in [0, 1]$) which are revealed to the player. The player suffers a weighted average loss $p_t \cdot \ell_t$ at the end of this round. The goal of the player is to minimize his “regret”, which is usually defined as the difference between his total loss and the loss of the best action. Here, we consider an even more general notion of regret introduced in [11, which we call $\epsilon$-regret. Suppose the actions are ordered according to their total losses after $T$ rounds (i.e. $\sum_{t=1}^{T} \ell_{t,i}$) from smallest to largest, and let $i_\epsilon$ be the index of the action that is the $[N\epsilon]$-th element in the sorted list ($0 < \epsilon \leq 1$). Now, $\epsilon$-regret is defined as $R^T_{\epsilon}(p_1:T, \ell_1:T) = \sum_{t=1}^{T} p_t \cdot \ell_t - \sum_{t=1}^{T} \ell_{t,i_\epsilon}$. In other words, $\epsilon$-regret measures the difference between the player’s loss and the loss of the $[N\epsilon]$-th best action (recovering the usual regret with
Algorithm 1: Conversion of a Hedge Algorithm $\mathcal{H}$ to a DGv1 Algorithm $\mathcal{D}_R$

| Input: A Hedge Algorithm $\mathcal{H}$ | Algorithm 2: Conversion of a DGv1 Algorithm $\mathcal{D}_R$ to a Hedge Algorithm $\mathcal{H}$ |
|----------------------------------|----------------------------------|
| **for** $t = 1$ to $T$ **do**   | **for** $t = 1$ to $T$ **do**   |
| Query $\mathcal{H}$: $p_t = \mathcal{H}(\ell_{1:t-1})$. | Query $\mathcal{D}_R$: $p_t = \mathcal{D}_R(z_{1:t-1})$. |
| Set: $D_1(R(z_{1:t-1}) = p_t)$. | Set: $\mathcal{H}(\ell_{1:t-1}) = p_t$. |
| Receive movements $z_t$ from the adversary. | Receive losses $\ell_t$ from the adversary. |
| Set: $z_{t,i} = z_{t,i} - \min_j z_{t,j}$, $\forall i$. | Set: $z_{t,i} = \ell_{t,i} - p_t \cdot \ell_{t,i}$, $\forall i$. |

Next we discuss how Hedge is highly related to drifting games. Consider a variant of drifting games where $B = [-1, 1]$, $\beta = 0$ and $L(s) = 1 \{ s \leq -R \}$ for some constant $R$. Additionally, we impose an extra restriction on the adversary: $|z_{t,i} - z_{t,j}| \leq 1$ for all $i$ and $j$. In other words, the difference between any two chips’ movements is at most 1. We denote this specific variant of drifting games by DGv1 (summarized in Appendix A) and a corresponding algorithm by $\mathcal{D}_R$ to emphasize the dependence on $R$. The reductions in Algorithm 1 and 2 and Theorem 1 show that DGv1 and the Hedge problem are algorithmically equivalent (note that both conversions are valid). The proof is straightforward and deferred to Appendix B. By Theorem 1, it is clear that the minimax optimal algorithm for one setting is also minimax optimal for the other under these conversions.

**Theorem 1.** DGv1 and the Hedge problem are algorithmically equivalent in the following sense:

1. Algorithm 1 produces a DGv1 algorithm $\mathcal{D}_R$ satisfying $L_T(\mathcal{D}_R) \leq i/N$ where $i \in \{0, \ldots, N\}$ is such that $R_T^{(i+1)/N}(\mathcal{H}) < R \leq R_T^{i/N}(\mathcal{H})$.

2. Algorithm 2 produces a Hedge algorithm $\mathcal{H}$ with $R_T^*(\mathcal{H}) < R$ for any $R$ such that $L_T(\mathcal{D}_R) < \epsilon$.

### 3.2 Relaxations

From now on we only focus on the direction of converting a drifting game algorithm into a Hedge algorithm. In order to derive a minimax Hedge algorithm, Theorem 1 tells us it suffices to derive minimax DGv1 algorithms. Exact minimax analysis is usually difficult, and appropriate relaxations seem to be necessary. To make use of the existing analysis for standard drifting games, the first obvious relaxation is to drop the additional restriction in DGv1, that is, $|z_{t,i} - z_{t,j}| \leq 1$ for all $i$ and $j$. Doing this will lead to the exact setting discussed in Appendix A where a near optimal strategy is proposed using the recipe in Eq. (1). It turns out that this relaxation is reasonable and does not give too much more power to the adversary. To see this, first recall that results from Appendix B, written in our notation, state that $\min_{\mathcal{D}_R} L_T(\mathcal{D}_R) \leq \frac{1}{2T} \sum_{j=0}^{T+\epsilon / \epsilon} \left( \frac{R+1)^2}{2(T+j)} \right)$, which, by Hoeffding’s inequality, is upper bounded by $2 \exp \left( \frac{R+1)^2}{2(T+j)} \right)$. Second, statement (2) in Theorem 1 clearly remains valid if the input of Algorithm 2 is a drifting game algorithm for this relaxed version of DGv1. Therefore, by setting $\epsilon > 2 \exp \left( -\frac{(R+1)^2}{2(T+j)} \right)$ and solving for $R$, we have $R_T^*(\mathcal{H}) \leq O \left( \sqrt{T \ln(\frac{1}{\epsilon})} \right)$, which is the known optimal regret rate for the Hedge problem, showing that we lose little due to this relaxation.

However, the algorithm proposed in Appendix A is not computationally efficient since the potential functions $\Phi_t(s)$ do not have closed forms. To get around this, we would want the minimax expression in Eq. (1) to be easily solved, just like the case when $B = \{-1, 1\}$. It turns out that convexity would allow us to treat $B = [-1, 1]$ almost as $B = \{-1, 1\}$. Specifically, if each $\Phi_t(s)$ is a convex function of $s$, then due to the fact that the maximum of a convex function is always realized at the boundary of a compact region, we have

$$
\min_{w \in \mathbb{R}_+} \max_{z \in [-1, 1]} (\Phi_t(s + z) + wz) = \min_{w \in \mathbb{R}_+} \max_{z \in [-1, 1]} (\Phi_t(s + z) + wz) = \frac{\Phi_t(s - 1) + \Phi_t(s + 1)}{2},
$$

with $w = (\Phi(s - 1) - \Phi(s + 1))/2$ realizing the minimum. Since 0-1 loss function $L(s)$ is not convex, this motivates us to find a convex surrogate of $L(s)$. Fortunately, relaxing the equality constraints in Eq. (1) does not affect the key property of Eq. (2) as we will show in the proof of
for some value

for computations show that all pick out that this will lead to the well-known exponential weights algorithm [14, 15]. Specifically, we has been widely used as the convex surrogate of the 0-1 loss function in the literature. It turns operation. The following lemma shows that this algorithm is Exponential Weights (EXP) Algorithm.

3.3 Designing Potentials and Algorithms

Now we are ready to recover existing algorithms and develop new ones by choosing an appropriate potential \( \Phi_T(s) \) as Algorithm 3 suggests. We will discuss three different algorithms below, and summarize these examples in Table 1 (see Appendix C).

Exponential Weights (EXP) Algorithm. Exponential loss is an obvious choice for \( \Phi_T(s) \) as it has been widely used as the convex surrogate of the 0-1 loss function in the literature. It turns out that this will lead to the well-known exponential weights algorithm [14, 15]. Specifically, we pick \( \Phi_T(s) \) to be \( \exp(-\eta(s + R)) \) which exactly upper bounds \( 1\{s \leq -R\} \). To compute \( \Phi_t(s) \) for \( t \leq T \), we simply let \( \Phi_t(s) = 0 \). On the other hand, by Eq. (3), we have \( \Phi_t(s_{t-1,i} + z_{t,i}) = \max_{z \in [-1,1]} (\Phi_t(s_{t-1,i} + z) + wz) = \frac{1}{2} (\Phi_t(s_{t-1,i} - 1) + \Phi_t(s_{t-1,i} + 1)) \), which is at most \( \Phi_{t-1}(s_{t-1,i}) \) by Algorithm 3. This shows \( \Phi_t(s_{t,i}) \leq \Phi_{t-1}(s_{t-1,i}) \) and Eq. (2) follows.

Theorem 2 tells us that if solving \( \Phi_0(0) < \epsilon \) gives \( R > R' \) for some value \( R \), then the regret of Algorithm 3 is less than any value that is greater than \( R \), meaning the regret is at most \( R \).

| Algorithm 3: A General Hedge Algorithm \( \mathcal{H} \) |
|---|
| **Input:** A convex, nonincreasing, nonnegative function \( \Phi_T(s) \). |
| **for** \( t = T \) **down to** 1 |
| Find a convex function \( \Phi_{t-1}(s) \) s.t. \( \forall s, \Phi_t(s - 1) + \Phi_t(s + 1) \leq 2\Phi_{t-1}(s) \). |
| Set: \( s_0 = 0 \). |
| **for** \( t = 1 \) **to** \( T \) |
| Set: \( \mathcal{H}(s_{t-1}) = p_t \) s.t. \( p_t \propto \Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1) \). |
| Receive losses \( \ell_t \) and set \( s_{t,i} = s_{t-1,i} + \ell_{t,i} - p_t \cdot \ell_t, \forall i \). |

**Theorem 2.** For Algorithm 3 if \( R \) and \( \epsilon \) are such that \( \Phi_0(0) < \epsilon \) and \( \Phi_T(s) \geq 1\{s \leq -R\} \) for all \( s \in \mathbb{R} \), then \( R'_{\mathcal{H}} < R \).

**Proof.** It suffices to show that Eq. (3) holds so that the theorem follows by a direct application of statement (2) of Theorem 1. Let \( w_{t,i} = (\Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1))/2 \). Then \( \sum_{i} \Phi_t(s_{t,i}) \leq \sum_{i} (\Phi_t(s_{t-1,i} - 1) + \Phi_t(s_{t-1,i} + 1))/2 \). On the other hand, by Eq. (3), we have \( \Phi_t(s_{t-1,i} + z_{t,i}) = \min_{z \in [-1,1]} (\Phi_t(s_{t-1,i} + z) + wz) = \frac{1}{2} (\Phi_t(s_{t-1,i} - 1) + \Phi_t(s_{t-1,i} + 1)) \), which is at most \( \Phi_{t-1}(s_{t-1,i}) \) by Algorithm 3. This shows \( \sum_{i} \Phi_t(s_{t,i}) \leq \sum_{i} \Phi_{t-1}(s_{t-1,i}) \) and Eq. (2) follows.

2-norm Algorithm. We next move on to another simple convex surrogate: \( \Phi_T(s) = a|s|^2 \geq 1\{s \leq -1/\sqrt{a}\} \), where \( a \) is some positive constant and \( |s| = \min(0, s) \) represents a truncating operation. The following lemma shows that \( \Phi_t(s) \) can also be simply described.

**Lemma 1.** If \( a > 0 \), then \( \Phi_t(s) = a (|s|^2 + T - t) \) satisfies \( \Phi_t(s - 1) + \Phi_t(s + 1) \leq 2\Phi_{t-1}(s) \).
Thus, Algorithm 3 can again be applied. The resulting algorithm is extremely concise:

\[ p_{t,i} \propto \Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1) \propto [s_{t-1,i} - 1]_+^2 - [s_{t-1,i} + 1]_+^2. \]

We call this the “2-norm” algorithm since it resembles the \( p \)-norm algorithm in the literature when \( p = 2 \) (see [10]). The difference is that the \( p \)-norm algorithm sets the weights proportional to the derivative of potentials, instead of the difference of them as we are doing here. A somewhat surprising property of this algorithm is that it is totally adaptive and parameter-free (since \( a \) disappears under normalization), a property that we usually do not expect to obtain from a minimax analysis. Direct application of Theorem 2 (\( \Phi_0(0) = aT < \epsilon \iff 1/\sqrt{a} > \sqrt{T/\epsilon} \)) shows that its regret achieves the optimal dependence on the horizon \( T \).

**Corollary 1.** Algorithm 3 with potential \( \Phi_t(s) \) defined in Lemma 7 produces a Hedge algorithm \( H \) such that \( R_T(H) \leq \sqrt{T/\epsilon} \) simultaneously for all \( T \) and \( \epsilon \).

**AbnormalHedge.** The regret for the 2-norm algorithm does not have the optimal dependence on \( \epsilon \). An obvious follow-up question would be whether it is possible to derive an adaptive algorithm that achieves the optimal rate \( O(\sqrt{T \ln(1/\epsilon)}) \) simultaneously for all \( T \) and \( \epsilon \) using our framework.

An even deeper question is: instead of choosing convex surrogates in a seemingly arbitrary way, is there a more natural way to find the right choice of \( \Phi_T(s) \)?

To answer these questions, we recall that the reason why the 2-norm algorithm can get rid of the dependence on \( \epsilon \) is that \( \epsilon \) appears merely in the multiplicative constant \( a \) that does not play a role after normalization. This motivates us to let \( \Phi_T(s) \) in the form of \( \epsilon F(s) \) for some \( F(s) \). On the other hand, from Theorem 2 we also want \( \epsilon F(s) \) to upper bound the 0-1 loss function \( 1\{s \leq -\Theta(\sqrt{T \ln(1/\epsilon)}) \} \). Taken together, this is telling us that the right choice of \( F(s) \) should be of the form \( \Theta(\exp(s^2/T)) \). Of course we still need to refine it to satisfy the monotonicity and other properties. We define \( \Phi_T(s) \) formally and more generally as:

\[ \Phi_T(s) = a \left( \exp \left( \frac{|s|^2}{dT} \right) - 1 \right) \geq 1 \left\{ s \leq -\sqrt{dT \ln \left( \frac{1}{a+1} \right)} \right\}, \]

where \( a \) and \( d \) are some positive constants. This time it is more involved to figure out what other \( \Phi_t(s) \) should be. The following lemma addresses this issue (proof deferred to Appendix C).

**Lemma 2.** If \( b_t = 1 - \frac{1}{2} \sum_{t'=t+1}^T \left( \exp \left( \frac{|s_{t'}|^2}{dT} \right) - 1 \right), a > 0, d \geq 3 \) and \( \Phi_t(s) = a \left( \exp \left( \frac{|s|^2}{dT} \right) - b_t \right) \) (define \( \Phi_0(s) = a(1 - b_0) \)), then we have \( \Phi_T(s-1) + \Phi_T(s+1) \leq 2\Phi_{t-1}(s) \) for all \( s \in \mathbb{R} \) and \( t = 2, \ldots, T \). Moreover, Eq. (2) still holds.

Note that even if \( \Phi_1(s-1) + \Phi_1(s+1) \leq 2\Phi_0(s) \) is not valid in general, Lemma 2 states that Eq. (2) still holds. Thus Algorithm 3 can indeed still be applied, leading to our new algorithm:

\[ p_{t,i} \propto \Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1) \propto \exp \left( \frac{|s_{t-1,i} - 1|^2}{dT} \right) - \exp \left( \frac{|s_{t-1,i} + 1|^2}{dT} \right). \]

Here, \( d \) seems to be an extra parameter, but in fact, simply setting \( d = 3 \) is good enough:

**Corollary 2.** Algorithm 3 with potential \( \Phi_t(s) \) defined in Lemma 2 and \( d = 3 \) produces a Hedge algorithm \( H \) such that the following holds simultaneously for all \( T \) and \( \epsilon \):

\[ R_T(H) \leq \sqrt{3T \ln \left( \frac{1}{\epsilon^3} (e^{4/3} - 1) \ln(T + 1) + 1 \right)} = O \left( \sqrt{T \ln(1/\epsilon) + T \ln T} \right). \]

We have thus proposed a parameter-free adaptive algorithm with optimal regret rate (ignoring the \( \ln \ln T \) term) using our drifting-games framework. In fact, our algorithm bears a striking similarity to the NormalHedge algorithm [11], the first algorithm that has this kind of adaptivity. We include NormalHedge in Table 1 for comparison. One can see that the main differences are: 1) On each round NormalHedge performs a numerical search to find out the right parameter used in the exponents; 2) NormalHedge uses the derivative of potentials as weights. While it seems that the adaptivity of NormalHedge comes from the online tuning of the parameter using the existing data, our algorithm shows that this is not necessary for adaptivity. The authors in [11] called their algorithm NormalHedge since the potential looks like a normal distribution. In fact, in our opinions they are quite different. We thus name our algorithm AbnormalHedge.
Compared to NormalHedge, the regret bound for AbnormalHedge has no explicit dependence on $N$, but has a slightly worse dependence on $T$ (indeed $\ln \ln T$ is almost negligible). We emphasize other advantages of our algorithm over NormalHedge: 1) AbnormalHedge is more computationally efficient especially when $N$ is very large, since it does not need a numerical search for each round; 2) our analysis is arguably simpler and more intuitive than the one in [11]; 3) as we will discuss in Section 4 AbnormalHedge can be easily extended to deal with the more general online convex optimization problem where the number of actions is infinitely large, while it is not clear how to do that for NormalHedge by generalizing the analysis in [11]. Indeed, the extra dependence on the number of actions $N$ for the regret of NormalHedge makes this generalization even seem impossible. Finally, we will later see that AbnormalHedge outperforms NormalHedge in experiments. Despite the differences, it is worth noting that both algorithms assign zero weight to some actions on each round, an appealing property when $N$ is huge. We will discuss more on this in Section 5

3.4 High Probability Bounds

We now consider a common variant of Hedge: on each round, instead of choosing a distribution $p_t$, the player has to randomly pick a single action $i_t$, while the adversary decides the losses $\ell_t$ at the same time (without seeing $i_t$). For now we only focus on the player’s regret to the best action: $R_T(i_t; \ell_T, \ell_t) = \sum_{t=1}^T \ell_t, i_t - \min_{\ell_t, i_t} \sum_{t=1}^T \ell_t, i_t$. Notice that the regret is now a random variable, and we are interested in a bound that holds with high probability. Using Azuma’s inequality, standard analysis (see for instance [10, Lemma 4.1]) shows that the player can simply draw $i_t$ according to $p_t = \mathcal{H}(\ell_{t-1})$, the output of a standard Hedge algorithm, and suffers regret at most $R_T(\mathcal{H}) + \sqrt{2T \ln(1/\delta)}$ with probability $1 - \delta$. Below we recover similar results as a simple side product of our drifting-games analysis without resorting to concentration results, such as Azuma’s inequality.

For this, we only need to modify Algorithm 3 by setting $z_{t,i} = \ell_{t,i} - \ell_{t,i}$. The restriction $p_t \cdot z_t \geq 0$ is then relaxed to hold in expectation. Moreover, it is clear that Eq. (2) also still holds in expectation. On the other hand, by definition and the union bound, one can show that $\sum_t \mathbb{E}(L_T(s_T, i)) = \sum_t \Pr[s_{T,i} \leq -R] \geq \Pr[R_T(i_t; \ell, \ell_t) \geq R]$. So setting $\Phi_0(t) = \delta$ shows that the regret is smaller than $R$ with probability $1 - \delta$. Therefore, for example, if EXP is used, then the regret would be at most $\sqrt{2T \ln(N/\delta)}$ with probability $1 - \delta$, giving basically the same bound as the standard analysis. One draw back is that EXP would need $\delta$ as a parameter. However, this can again be addressed by AbnormalHedge for the exact same reason that AbnormalHedge is independent of $\epsilon$. We have thus derived high probability bounds without using any concentration inequalities.

4 Generalizations

Multi-armed Bandit (MAB) Problem: The only difference between Hedge (randomized version) and the non-stochastic MAB problem [6] is that on each round, after picking $i_t$, the player only sees the loss for this single action $\ell_{t,i}$ instead of the whole vector $\ell_t$. The goal is still to compete with the best action. A common technique used in the bandit setting is to build an unbiased estimator $\hat{\ell}_t$ for the losses, which in this case could be $\hat{\ell}_{t,i} = 1\{i = i_t\} \cdot \ell_{t,i} / p_{t,i}$. Then algorithms such as EXP can be used by replacing $\ell_t$ with $\hat{\ell}_t$, leading to the EXP3 algorithm [6] with regret $O(\sqrt{TN \ln N})$.

One might expect that Algorithm 3 would also work well by replacing $\ell_t$ with $\hat{\ell}_t$. However, doing so breaks an important property of the movements $z_{t,i}$: boundedness. Indeed, Eq. (3) no longer makes sense if $z$ could be infinitely large, even if in expectation it is still in $[-1,1]$ (note that $z_{t,i}$ is now a random variable). It turns out that we can address this issue by imposing a variance constraint on $z_{t,i}$. Formally, we consider a variant of drifting games where on each round, the adversary has to pick a random movement $z_{t,i}$ for each chip such that: $z_{t,i} \geq -1, \mathbb{E}[z_{t,i}] \leq 1, \mathbb{E}[z_{t,i}^2] \leq 1/p_{t,i}$ and $\mathbb{E}_t[p_t \cdot z_t] \geq 0$. We call this variant DGv2 and summarize it in Appendix A. The standard minimax analysis and the derivation of potential functions need to be modified in a certain way for DGv2, as stated in Theorem 3 (Appendix D). Using the analysis for DGv2, we propose a general recipe for designing MAB algorithms in a similar way as for Hedge and also recover EXP3 (see Algorithm 3 and Theorem 5 in Appendix D). Unfortunately so far we do not know other appropriate potentials due to some technical difficulties. We conjecture, however, that there is a
potential function that could recover the poly-INF algorithm \cite{4, 5} or give its variants that achieve the optimal regret $O(\sqrt{TN})$.

**Online Convex Optimization:** We next consider a general online convex optimization setting \cite{26}. Let $S \subset \mathbb{R}^d$ be a compact convex set, and $\mathcal{F}$ be a set of convex functions with range $[0, 1]$ on $S$. On each round $t$, the learner chooses a point $x_t \in S$, and the adversary chooses a loss function $f_t \in \mathcal{F}$ (knowing $x_t$). The learner then suffers loss $l_t(x_t)$. The regret after $T$ rounds is $R_T(x_1:T, f_1:T) = \sum_{t=1}^T l_t(x_t) - \min_{x \in S} \sum_{t=1}^T l_t(x)$. There are two general approaches to OCO: one builds on convex optimization theory \cite{25}, and the other generalizes EXP to a continuous space \cite{12, 20}. We will see how the drifting-games framework can recover the latter method and also leads to new ones.

To do so, we introduce a continuous variant of drifting games (DGv3, see Appendix A). There are now infinitely many chips, one for each point in $S$. On round $t$, the player needs to choose a distribution over the chips, that is, a probability density function $p_t(x)$ on $S$. Then the adversary decides the movements for each chip, that is, a function $z_t(x)$ with range $[-1, 1]$ on $S$ (not necessarily convex or continuous), subject to a constraint $\mathbb{E}_{x \sim p_t}[z_t(x)] \geq 0$. At the end, each point $x$ is associated with a loss $L(x) = 1\{\sum_t z_t(x) \leq -\gamma\}$, and the player aims to minimize the total loss $\int_{x \in S} L(x) dx$.

OCO can be converted into DGv3 by setting $z_t(x) = f_t(x) - f_t(x_t)$ and predicting $x_t = \mathbb{E}_{x \sim p_t}[x] \in S$. The constraint $\mathbb{E}_{x \sim p_t}[z_t(x)] \geq 0$ holds by the convexity of $f_t$. Moreover, it turns out that the minimax analysis and potentials for DGv1 can readily be used here. See Appendix B for our general recipe for designing OCO algorithms. Note that the notion of $\epsilon$-regret, now generalized to the OCO setting, measures the difference of the player’s loss and the loss of a best fixed point in a subset of $S$ that excludes the top $\epsilon$ fraction of points (see Appendix B for formal definitions). With different potentials, we obtain versions of each of the three algorithms of Section 3 generalized to this setting, with the same $\epsilon$-regret bounds as before. Again, two of these methods are adaptive and parameter-free. To derive bounds for the usual regret $R_T(x_1:T, f_1:T)$, at first glance it seems that we have to set $\epsilon$ to be close to zero, leading to a meaningless bound. Nevertheless, this is addressed by Theorem 6 using similar techniques in \cite{7}, giving the usual $O(\sqrt{T \ln T})$ regret bound (see Appendix C).

5 Applications to Boosting

There is a deep and well-known connection between Hedge and boosting \cite{14, 24}. In principle, every Hedge algorithm can be converted into a boosting algorithm; for instance, this is how AdaBoost was derived from EXP. In the same way, AbnormalHedge can be converted into a new boosting algorithm that we call AbnormalBoost. See Appendix C for details and further background on boosting. The main idea is to treat each training example as an “action”, and to rely on the Hedge algorithm to compute distributions over these examples which are used to train the weak hypotheses. Typically, it is assumed that each of these has “edge” $\gamma$, meaning its accuracy on the training distribution is at least $1/2 + \gamma$. The final hypothesis is a simple majority vote of the weak hypotheses. To understand the prediction accuracy of a boosting algorithm, we often study the training error rate and also the distribution of margins, a well-established measure of confidence (see Appendix C for formal definitions). Thanks to the adaptivity of AbnormalHedge, we can derive bounds on both the training error and the distribution of margins after any number of rounds:

**Theorem 3.** After $T$ rounds, the training error rate of AbnormalBoost is of order $\tilde{O}(\exp(-T\gamma^2))$, and the fraction of training examples with margin at most $\theta(\leq 2\gamma)$ is of order $\tilde{O}(\exp(-T(\theta-2\gamma)^2))$.

Thus, the training error decreases at roughly the same rate as AdaBoost. In addition, this theorem implies that the fraction of examples with margin smaller than $2\gamma$ eventually goes to zero as $T$ gets large, which means AbnormalBoost converges to the optimal margin $2\gamma$; this is known not to be true for AdaBoost (see \cite{24}). Also, like AdaBoost, AbnormalBoost is an adaptive boosting algorithm that does not require $\gamma$ or $T$ as a parameter. However, unlike AdaBoost, AbnormalBoost has the striking property that it completely ignores many examples on each round (by assigning zero weight), which is very helpful for the weak learning algorithm in terms of computational efficiency.

To test this, we conducted experiments to compare the efficiency of AdaBoost, “NH-Boost” (an analogous boosting algorithm derived from NormalHedge) and AbnormalBoost. All details are in Appendix D. Here we only briefly summarize the results. While the three algorithms have similar performance in terms of training and test error, AbnormalBoost is always the fastest one in terms of
running time for the same number of rounds. Moreover, the average fraction of examples with zero
weight is significantly higher for AbnormalBoost than for NH-Boost (see Table 3). On one hand,
this explains why AbnormalBoost is faster (besides the reason that it does not require a numerical
step). On the other hand, this also implies that AbnormalBoost tends to achieve larger margins, since
zero weight is assigned to examples with large margin. This is also confirmed by our experiments.

A Summary of Drifting Game Variants

We study three different variants of drifting games throughout the paper, which corresponds to the Hedge setting, the multi-armed bandit problem and online convex optimization respectively. The protocols of these variants are summarized below.

| DGv1          | DGv2          | DGv3          |
|---------------|---------------|---------------|
| Given: a loss function \( L(s) = 1 \{ s \leq -R \} \). For \( t = 1, \ldots, T \): | Given: a loss function \( L(s) = 1 \{ s \leq -R \} \). For \( t = 1, \ldots, T \): | Given: a compact convex set \( S \), a loss function \( L(s) = 1 \{ s \leq -R \} \). For \( t = 1, \ldots, T \): |
| 1. The player chooses a distribution \( p_t \) over \( N \) chips. | 1. The player chooses a distribution \( p_t \) over \( N \) chips. | 1. The player chooses a density function \( p_t(x) \) on \( S \). |
| 2. The adversary decides the movement of each chip \( z_{t,i} \in [-1, 1] \) subject to \( p_t \cdot z_i \geq 0 \) and \( |z_{t,i} - z_{t,j}| \leq 1 \) for all \( i \) and \( j \). | 2. The adversary randomly decides the movement of each chip \( z_{t,i} \geq -1 \) subject to \( \mathbb{E}_t [z_{t,i}] \leq 1, \mathbb{E}_t [z_{t,i}^2] \leq 1/p_{t,i} \) and \( \mathbb{E}_t [p_t \cdot z_i] \geq 0 \). | 2. The adversary decides a function \( z_t(x) : S \to [-1, 1] \) subject to \( \mathbb{E}_{x \sim p_t} [z_t(x)] \geq 0 \). |
| The player suffers loss \( \sum_{i=1}^N L(\sum_{t=1}^T z_{t,i}) \). | The player suffers loss \( \sum_{i=1}^N L(\sum_{t=1}^T z_{t,i}) \). | The player suffers loss \( \int_{x \in S} L(\sum_{t=1}^T z_t(x)) \, dx \). |

B Proof of Theorem 1

**Proof.** We first show that both conversions are valid. In Algorithm 1 it is clear that \( \ell_{t,i} \geq 0 \). Also, \( \ell_{t,i} \leq 1 \) is guaranteed due to the extra restriction of DGv1. For Algorithm 2, \( z_{t,i} \) lies in \( \mathcal{B} = [-1, 1] \) since \( \ell_{t,i} \in [0, 1] \), and direct computation shows \( p_t \cdot z_t = 0 \geq \beta (= 0) \) and \( |z_{t,i} - z_{t,j}| = |\ell_{t,i} - \ell_{t,j}| \leq 1 \) for all \( i \) and \( j \).

(1) For any choices of \( z_t \), we have

\[
\sum_{i=1}^N L(s_{T,i}) = \sum_{i=1}^N L \left( \sum_{t=1}^N z_{t,i} \right) \leq \sum_{i=1}^N L \left( \sum_{t=1}^N (z_{t,i} - p_t \cdot z_i) \right),
\]

where the inequality holds since \( p_t \cdot z_i \) is required to be nonnegative and \( L \) is a nonincreasing function. By Algorithm 1, \( z_{t,i} - p_t \cdot z_i \) is equal to \( \ell_{t,i} - p_t \cdot \ell_t \), leading to

\[
\sum_{i=1}^N L(s_{T,i}) \leq \sum_{i=1}^N L \left( \sum_{t=1}^N (\ell_{t,i} - p_t \cdot \ell_t) \right) = \sum_{i=1}^N \left\{ R \leq \sum_{t=1}^N (p_t \cdot \ell_t - \ell_{t,i}) \right\},
\]
Since $R_T^{(i+1)/N}(\mathcal{H}) < R \leq R_T^{i/N}(\mathcal{H})$, we must have $\sum_{i=1}^{N} (p_t \cdot \ell_t - \ell_{t,i}) < R$ except for the best $i$ actions, which means $\sum_{i=1}^{N} L(s_{T,i}) \leq i$. This holds for any choices of $z_t$, so $L_T(D_R) \leq i/N$.

(2) By Algorithm 2 and the condition $L_T(D_R) < \epsilon$, we have

$$\frac{1}{N} \sum_{i=1}^{N} 1 \left\{ R \leq \sum_{i=1}^{N} (p_t \cdot \ell_t - \ell_{t,i}) \right\} = \frac{1}{N} \sum_{i=1}^{N} \sum_{i=1}^{N} L(s_{T,i}) \leq L_T(D_R) < \epsilon,$$

which means there are at most $\lceil N\epsilon \rceil - 1$ actions satisfying $R \leq \sum_{i=1}^{N} (p_t \cdot \ell_t - \ell_{t,i})$, and thus $\sum_{i=1}^{N} (p_t \cdot \ell_t - \ell_{t,i}) < R$. Since this holds for any choices of $\ell_t$, we have $R_T^{i}(\mathcal{H}) < R$. □

Proof of Lemma 1 It suffices to show $[s - 1]^2 + [s + 1]^2 \leq 2[s]^2 + 2$. When $s \geq 0$, LHS = $[s - 1]^2 \leq 1 < 2$ = RHS. When $s < 0$, LHS $\leq (s - 1)^2 + (s + 1)^2 = 2s^2 + 2 =$ RHS. □

Proof of Lemma 2 Let $F(s) = \exp \left( \frac{[s-1]^2}{dt} \right) + \exp \left( \frac{[s+1]^2}{dt} \right) - 2 \exp \left( \frac{[s]^2}{dt} \right)$. It suffices to show

$$F(s) \leq 2(b_t - b_{t-1}) = \exp \left( \frac{4}{dt} \right) - 1,$$

which is clearly true for the following 3 cases:

$$F(s) = \begin{cases} 0 & \text{if } s > 1; \\
\exp \left( \frac{(s-1)^2}{dt} \right) - 1 < \exp \left( \frac{s}{dt} \right) - 1 & \text{if } 0 < s \leq 1; \\
\exp \left( \frac{(s+1)^2}{dt} \right) + 1 - 2 \exp \left( \frac{s^2}{dt(t-1)} \right) < \exp \left( \frac{s}{dt} \right) - 1 & \text{if } -1 < s \leq 0. 
\end{cases}$$

For the last case $s \leq -1$, if we can show that $F(s)$ is increasing in this region, then the lemma follows. Below, we show this by proving $F'(s)$ is nonnegative when $s \leq -1$.

Let $h(s, c) = \frac{\partial \exp \left( \frac{c}{s} \right)}{\partial s} = \frac{2c}{s} \exp \left( \frac{c}{s} \right)$. $F'(s)$ can now be written as

$$F'(s) = h(s - 1, c) + h(s + 1, c) - 2h(s, c) + 2(h(s, c) - h(s, c')),$$

where $c = dt$ and $c' = dt(t-1)$. Next we apply (one-dimensional) Taylor expansion to $h(s - 1, c)$ and $h(s + 1, c)$ around $s$, and $h(s, c)$ around $c$, leading to

$$F'(s) = \sum_{k=1}^{\infty} \frac{(-1)^k}{k!} \frac{\partial^k h(s, c)}{\partial s^k} + \sum_{k=1}^{\infty} \frac{1}{k!} \frac{\partial^k h(s, c)}{\partial s^k} - 2 \sum_{k=1}^{\infty} \frac{(c' - c)^k}{k!} \frac{\partial^k h(s, c)}{\partial c^k}$$

$$= 2 \sum_{k=1}^{\infty} \left( \frac{1}{(2k)!} \frac{\partial^{2k} h(s, c)}{\partial s^{2k}} - \frac{(-d)^k}{k!} \frac{\partial^k h(s, c)}{\partial c^k} \right).$$
Therefore, with initial values $\alpha_0$ and $\beta_0$, we need a much weaker statement:

\[
\alpha_{k+1,j} = \alpha_{k,j-1} + (k + j + 1)\alpha_{k,j},
\]

\[
\beta_{k+1,j} = 4\beta_{k,j-1} + (8j + 6)\beta_{k,j} + (2j + 3)(2j + 2)\beta_{k,j+1},
\]

with initial values $\alpha_{0,0} = \beta_{0,0} = 2$ (when $j \not\in \{0, \ldots, k\}$, $\alpha_{k,j}$ and $\beta_{k,j}$ are all defined to be 0). Therefore, $F'(s)$ can be further simplified as

\[
F'(s) = 2 \exp \left( \frac{s^2}{c} \right) \sum_{k=1}^{\infty} \sum_{j=0}^{k-1} \frac{s^{2j+1}}{c^{k+j+1} (2k)!} \left( \frac{2^{2k+1} \alpha_{k,j}}{k!} \right).
\]

Since $s$ is negative, it suffices to show that $\frac{\beta_{k,j}}{2^{2k+1}} \leq \frac{d^k \alpha_{k,j}}{k!}$ holds for all $k$ and $j$, which turns out to be true as long as $d \geq 3$, as shown by induction in the technical lemma 4 below. To sum up, $\Phi_t(s - 1) + \Phi_t(s + 1) \leq 2\Phi_t(s)$ for all $s \in \mathbb{R}$ and $t = 2, \ldots, T$.

Finally, we need to show that Eq. (2) still holds. The inequality we just proved above implies $\sum \Phi_t(s_i) \leq \sum \Phi_t(s_{i-1})$ for $t = 2, \ldots, T$, as shown in Theorem 2. Thus the only thing we need to show here is the case when $t = 1$. Note that $\Phi_t(s - 1) + \Phi_t(s + 1) \leq 2\Phi_t(s)$ does not hold for all $s$ apparently. However, in order to prove $\sum \Phi_t(s_{i-1}) \leq \sum \Phi_t(s_{0,i})$, we in fact only need a much weaker statement: $\Phi_t(s - 1) + \Phi_t(s + 1) \leq 2\Phi_0(0)$ since $s_{0,i} = 0$. This is equivalent to $\exp(1/d) - 1 \leq \exp(4/d) - 1$, which is true trivially.

**Lemma 3.** Let $h(s, c) = \frac{2s}{c} \exp \left( \frac{s^2}{c} \right)$. The partial derivatives of $h(s, c)$ satisfy Eq. (4) and (5).

**Proof.** The base case holds trivially. Assume Eq. (4) holds for a fixed $k$. Then we have

\[
\frac{\partial^{k+1} h(s, c)}{\partial c^{k+1}} = \exp \left( \frac{s^2}{c} \right) \sum_{j=0}^{k} (-1)^k \alpha_{k,j} \cdot \left( \frac{s^2}{c} - (k + j + 1) \frac{s^{2j+1}}{c^{k+j+2}} \right)
\]

\[
= \exp \left( \frac{s^2}{c} \right) \sum_{j=0}^{k} (-1)^{k+1} \alpha_{k,j} \cdot \left( \frac{s^{2(j+1)+1}}{c^{(k+1)+(j+1)+1}} + (k + j + 1) \frac{s^{2j+1}}{c^{(k+1)+(j+1)+1}} \right)
\]

\[
= \exp \left( \frac{s^2}{c} \right) \sum_{j=0}^{k+1} (-1)^{k+1} \alpha_{k,j-1} + (k + j + 1) \alpha_{k,j} \cdot \frac{s^{2j+1}}{c^{(k+1)+j+1}},
\]

and

\[
\frac{\partial^{2(k+1)} h(s, c)}{\partial s^{2(k+1)}} = \partial \left[ \exp \left( \frac{s^2}{c} \right) \sum_{j=0}^{k} \beta_{k,j} \cdot \frac{2s^{2j+2}}{c^{k+j+2}} + (2j + 1) \frac{s^{2j}}{c^{k+j+1}} \right] / \partial s
\]

\[
= \exp \left( \frac{s^2}{c} \right) \sum_{j=0}^{k} \beta_{k,j} \cdot \left( \frac{4s^{2j+3}}{c^{k+j+3}} + (8j + 6) \frac{s^{2j+1}}{c^{k+j+2}} + (2j + 1)2j \frac{s^{2j-1}}{c^{k+j+2}} \right)
\]

\[
= \exp \left( \frac{s^2}{c} \right) \sum_{j=0}^{k+1} (4\beta_{k,j-1} + (8j + 6)\beta_{k,j} + (2j + 3)(2j + 2)\beta_{k,j+1}) \cdot \frac{s^{2j+1}}{c^{k+j+2}}.
\]
completing the induction.

concluding the proof. \qed

Lemma 4. Let $\alpha_{k,j}$ and $\beta_{k,j}$ be defined as in Eq. (5). Then $\frac{\beta_{k,j}}{(2k)!} \leq \frac{d^k \alpha_{k,j}}{k!}$ holds for all $k \geq 0$ and $j \in \{0, \ldots, k\}$ when $d \geq 3$.

Proof. We prove the lemma by induction on $k$. The base case $k = 0$ is trivial. Assume $\frac{\beta_{k,j}}{(2k)!} \leq \frac{d^k \alpha_{k,j}}{k!}$ holds for a fixed $k$ and all $j \in \{0, \ldots, k\}$, then we have $\forall j$,

$$\frac{\beta_{k+1,j}}{(2k+2)!} = \frac{4\beta_{k,j-1} + (8j + 6)\beta_{k,j} + (2j + 3)(2j + 2)\beta_{k,j+1}}{(2k+2)!} \leq \frac{d^k (4\alpha_{k,j-1} + (8j + 6)\alpha_{k,j} + (2j + 3)(2j + 2)\alpha_{k,j+1})}{(2k+2)(2k+1)!}.$$  

We need to show that the above expression is at most $\frac{d^{k+1} \alpha_{k+1,j}}{(k+1)!}$, which, after arrangements, is equivalent to $2\alpha_{k,j-1} + (4j + 3)\alpha_{k,j} + (2j + 3)(j + 1)\alpha_{k,j+1} \leq d(2k + 1)\alpha_{k+1,j}$. We will prove this by another induction on $k$. Then the lemma follows.

The base case ($k = 0$) is simplified to $6 \leq 2d$, which is true by our assumption $d \geq 3$. Assume the inequality holds for a fixed $k$, then by the definition of $\alpha_{k,j}$, one has

$$2\alpha_{k+1,j-1} + (4j + 3)\alpha_{k+1,j} + (2j + 3)(j + 1)\alpha_{k+1,j+1}$$

$$= (2\alpha_{k,j-2} + (4j + 3)\alpha_{k,j-1} + (2j + 3)(j + 1)\alpha_{k,j}) +$$

$$(2k + j)\alpha_{k,j-1} + (4j + 3)(k + j + 1)\alpha_{k,j} + (2j + 3)(j + 1)(k + j + 2)\alpha_{k,j+1}$$

$$= (2\alpha_{k,j-2} + (4j + 1)\alpha_{k,j-1} + (2j + 1)\alpha_{k,j}) +$$

$$(k + j + 2) (2\alpha_{k,j-1} + (4j + 3)\alpha_{k,j} + (2j + 3)(j + 1)\alpha_{k,j+1})$$

$$\leq d(2k + 1)(\alpha_{k+1,j-1} + (k + j + 2)\alpha_{k+1,j})$$

(by induction)

$$= d(2k + 1)\alpha_{k+2,j}$$

$$\leq d(2k + 3)\alpha_{k+2,j},$$

completing the induction. \qed

Proof of Corollary. Recall that $\Phi_T(s) \geq 1 \left\{ s \leq -\sqrt{dT \ln \left( \frac{1}{n} + 1 \right)} \right\}$. So by setting $\Phi_0(0) = \alpha(1 - b_0) < \epsilon$ and applying Theorem, we arrive at

$$R_T(H) \leq \sqrt{dT \ln \left( \frac{1 - b_0}{\epsilon} + 1 \right)}.$$  

It suffices to upper bound $1 - b_0$, which, by definition, is $\frac{1}{2} \sum_{t=1}^{T} \left( \exp \left( \frac{4}{dt} \right) - 1 \right)$. Since $e^x - 1 \leq \frac{e^x - 1}{x}$ for any $x \in [0, c]$, we have

$$\sum_{i=1}^{T} \left( \exp \left( \frac{4}{dt} \right) - 1 \right) \leq (e^{4/d} - 1) \sum_{i=1}^{T} \frac{1}{i} \leq (e^{4/d} - 1)(\ln T + 1).$$  

Plugging $d = 3$ gives the corollary. \qed
\section{A General MAB Algorithm and Regret Bounds}

\begin{algorithm}
\textbf{Input:} A convex, nonincreasing, nonnegative function $\Phi_T(s) \in \mathbb{C}^2$, with nonincreasing second derivative.

\textbf{for} $t = T$ \textbf{down to} 1 \textbf{do}

\hspace{1em} Find a convex function $\Phi_{t-1}(s)$ s.t. the conditions of Theorem 4 hold.

Set: $s_0 = 0$.

\textbf{for} $t = 1$ \textbf{to} $T$ \textbf{do}

\hspace{1em} Set: $p_{t,i} \propto \Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1)$.

\hspace{1em} Draw $i_t \sim p_t$ and receive loss $\ell_{t,i_t}$.

\hspace{1em} Set: $z_{t,i} = 1 \{ i = i_t \} \cdot (\ell_{t,i_t}/p_{t,i_t} - \ell_{t,i_t}, \forall i$.

\hspace{1em} Set: $s_t = s_{t-1} + z_t$.

\end{algorithm}

\textbf{Algorithm 4:} A General MAB Algorithm

\begin{theorem}
Suppose $\Phi_t(s)$ is convex, twice continuously differentiable (i.e. $\Phi_t(s) \in \mathbb{C}^2$), have nonincreasing second derivative, and satisfies:

$$
\frac{1}{2} + N\alpha_t \frac{\Phi_t(s - 1) + (\frac{1}{2} - N\alpha_t) \Phi_t(s + 1) \leq \Phi_{t-1}(s), \forall s \in \mathbb{R} (6)
$$

where $\alpha_t = \frac{1}{T} \max_s \frac{\Phi''(s-1)}{\Phi_t(s-1) - \Phi_t(s+1)}$. If the player’s strategy is such that $p_{t,i} \propto \Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1)$, then Eq. (2) holds in expectation.

\end{theorem}

\textbf{Proof of Theorem 4:} As discussed before, the main difficulty here is the unboundedness of $z_{t,i}$. However, the expectation of $z_{t,i}$ is still in $[-1, 1]$ as in DGv1. To exploit this fact, we apply Taylor’s theorem to $\Phi_t(s_{t-1,i} + z_{t,i})$ to the second order term:

$$
\Phi_t(s_{t,i}) = \Phi_t(s_{t-1,i} + z_{t,i})
$$

$$
= \Phi_t(s_{t-1,i}) + \Phi'_t(s_{t-1,i})z_{t,i} + \frac{1}{2}\Phi''_t(\xi_{t,i})z_{t,i}^2
$$

$$
\leq \Phi_t(s_{t-1,i}) + \Phi'_t(s_{t-1,i})z_{t,i} + \frac{1}{2}\Phi''_t(s_{t-1,i} + 1)z_{t,i}^2,
$$

where $\xi_{t,i}$ is between $s_{t-1,i} + z_{t,i}$ and $s_{t-1,i}$, and the inequality holds because $\Phi'_t(s)$ is nonincreasing and $z_{t,i} \geq -1$ by assumption. Now taking expectation on both sides with respect to the randomness of $z_{t,i}$, using the convexity of $\Phi_t(s)$, and plugging the assumption $E_t[z_{t,i}^2] \leq 1/p_{t,i}$ give:

$$
E_t[\Phi_t(s_{t,i})] \leq \Phi_t(s_{t-1,i}) + \Phi'_t(s_{t-1,i})E_t[z_{t,i}] + \frac{1}{2}\Phi''_t(s_{t-1,i} - 1)E_t[z_{t,i}^2]
$$

$$
\leq \Phi_t(s_{t-1,i} + E_t[z_{t,i}]) + \frac{1}{2}\Phi''_t(s_{t-1,i} - 1)/p_{t,i}.
$$

Let $w_{t,i} = \frac{1}{2}(\Phi_t(s_{t-1,i} - 1) - \Phi_t(s_{t-1,i} + 1))$. Further plugging $p_{t,i} \propto w_{t,i}$ and summing over all $i$, we arrive at

$$
\sum_{i=1}^{N} E_t[\Phi_t(s_{t,i})] \leq \sum_{i=1}^{N} \left( \Phi_t(s_{t-1,i} + E_t[z_{t,i}]) + \frac{\Phi''_t(s_{t-1,i} - 1)}{2w_{t,i}} \cdot \sum_{i=1}^{N} w_{t,i} \right)
$$

$$
\leq \sum_{i=1}^{N} \left( \Phi_t(s_{t-1,i} + E_t[z_{t,i}]) + 2\alpha_t \sum_{i=1}^{N} w_{t,i} \right) \quad \text{(by the definition of } \alpha_t)
$$

$$
= \sum_{i=1}^{N} (\Phi_t(s_{t-1,i} + E_t[z_{t,i}]) + 2N\alpha_tw_{t,i}) .
$$

Since $E_t[p_t \cdot z_t] \geq 0$ implies $\sum_{i=1}^{N} w_{t,i}E_t[z_{t,i}] \geq 0$, we thus have

$$
\sum_{i=1}^{N} E_t[\Phi_t(s_{t,i})] \leq \sum_{i=1}^{N} \left( \Phi_t(s_{t-1,i} + E_t[z_{t,i}]) + w_{t,i}E_t[z_{t,i}] + 2N\alpha_tw_{t,i} \right)
$$

$$
\leq \sum_{i=1}^{N} \left( \max_{z \in [-1,1]} (\Phi_t(s_{t-1,i} + z) + w_{t,i}z) + 2N\alpha_tw_{t,i} \right)
$$

15
\[
\sum_{i=1}^{N} \left( \max_{z \in \{-1,+1\}} \left( \Phi_t(s_{t-1,i} + z) + w_{t,i}z \right) + 2N \alpha_t w_{t,i} \right)
\]
(by the convexity of \(\Phi_t(s)\))
\[
\sum_{i=1}^{N} \left( \left( \frac{1}{2} + N \alpha_t \right) \Phi_t(s_{t-1,i} - 1) + \left( \frac{1}{2} - N \alpha_t \right) \Phi_t(s_{t-1,i} + 1) \right)
\]
\[
\leq \sum_{i=1}^{N} \Phi_{t-1}(s_{t-1,i}).
\]
(by assumption)

The theorem follows by taking expectation on both sides with respect to the past (i.e. the randomness of \(z_1, \ldots, z_{t-1}\)). \(\square\)

**Theorem 5.** For Algorithm 4 if \(R \) and \(\epsilon \) are such that \(\Phi_0(0) < \epsilon \) and \(\Phi_T(s) \geq 1 \{ s \leq -R \} \) for all \(s \in \mathbb{R} \), then \(\mathbb{E}[\sum_{t=1}^{T} \ell_{t,i} - \sum_{t=1}^{T} \ell_{t,i}] < R \) for any non-oblivious adversary. Moreover, using \(\Phi_T(s) = \exp(-\eta(s + R))\) (and let Eq. (6) hold with equality) gives exactly the EXP3 algorithm with regret \(O(\sqrt{TN \ln(1/\epsilon)})\).

**Proof of Theorem 5.** We first show that Algorithm 4 converts the multi-armed bandit problem to a valid instance of DGv2. It suffices to prove that \(z_{t,i} = 1\{i = i_t\} \cdot \ell_{t,i}/p_{t,i} - \ell_{t,i} \) satisfies all conditions defined in DGv2, as shown below (\(z_{t,i} \geq -1 \) is trivial):
\[
\mathbb{E}[z_{t,i}] = \ell_{t,i} - p_t \cdot \ell_t \leq 1,
\]
\[
\mathbb{E}[z_{t,i}^2] = p_{t,i} \left( \frac{\ell_{t,i}}{p_t,i} - \ell_{t,i} \right)^2 + \sum_{j \neq i} p_{t,j} \ell_{t,j} \leq p_{t,i} \left( \frac{1}{p_t,i} - 1 \right)^2 + \sum_{j \neq i} p_{t,j} = \frac{1}{p_t,i} - 1 \leq \frac{1}{p_t,i},
\]
\[
\mathbb{E}[\mathbb{E}[\ell_{t,i}] = \ell_{t,i} - \sum_{j=1}^{N} p_{t,j} \ell_{t,i}] = 0.
\]
Therefore, we can apply Theorem 4 directly, arriving at:
\[
\frac{1}{N} \sum_{i=1}^{N} \mathbb{E}[\Phi_T(s_{T,i})] \leq \cdots \leq \frac{1}{N} \sum_{i=1}^{N} \mathbb{E}[\Phi_0(s_{0,i})] = \Phi_0(0) \leq \epsilon.
\]
On the other hand, by applying Jensen’ inequality, we have
\[
\mathbb{E}[\Phi_T(s_{T,i})] \geq \Phi_T(\mathbb{E}[s_{T,i}]) \geq 1 \{ \mathbb{E}[s_{T,i}] \leq -R \}.
\]
Note that \(\mathbb{E}[s_{T,i}] \) is equal to \(\mathbb{E}\left[ \sum_{t=1}^{T} (\ell_{t,i} - \ell_{t,i}) \right] \). We thus know
\[
\frac{1}{N} \sum_{i=1}^{N} \mathbb{E}\left[ \sum_{t=1}^{T} (\ell_{t,i} - \ell_{t,i}) \right] \leq -R \}
\]
which implies \(\mathbb{E}\left[ \sum_{t=1}^{T} \ell_{t,i} - \sum_{t=1}^{T} \ell_{t,i} \right] < R \) for any non-oblivious adversary for the exact same argument used in the proof of Theorem 2.

Finally, we show how to recover EXP3 using Algorithm 4 with input \(\Phi_T(s) = \exp(-\eta(s + R))\). To compute \(\Phi_t(s)\) for \(t < T\), we simply use Eq. (6) with equality. One can verify using induction that
\[
\Phi_t(s) = \exp\left(-\eta(s + R)\right)\left(\frac{e^\eta + e^{-\eta} + N e^{\eta} \eta^2}{2}\right)^{T-t},
\]
\[
\alpha_t = \frac{1}{2} \max_{s} \frac{\eta^2 \Phi_t(s-1)}{\Phi_t(s-1) - \Phi_t(s+1)} = \frac{e^\eta \eta^2}{2(e^\eta - e^{-\eta})},
\]
\[
\Phi_t''(s) = -\eta^3 \Phi_t(s) \leq 0.
\]
Theorem 6. Next consider a shrunk version of setting, the “sum” of potentials never increases:

Proof of Theorem 6. Let \( w_t(x) = \frac{1}{2} (\Phi_t(s_{t-1}(x) - 1) - \Phi_t(s_{t-1}(x) + 1)) \). Similarly to the Hedge setting, the “sum” of potentials never increases:

\[
\int_{x \in S} \Phi_t(s_t(x)) dx \leq \int_{x \in S} (\Phi_t(s_{t-1}(x) + z_t(x)) + w_t(x) z_t(x)) dx \leq \int_{x \in S} \Phi_{t-1}(s_{t-1}(x)) dx.
\]

Here, the first inequality is due to \( \operatorname{E}_{x \sim p_t} [z_t(x)] \geq 0 \), and the second inequality holds for the exact same reason as in the case for Hedge. Therefore, we have

\[
\int_{x \in S} 1 \{ s_T(x) \leq -R \} dx \leq \int_{x \in S} \Phi_T(s_T(x)) dx \leq \cdots \leq \int_{x \in S} \Phi_0(0) dx < eV,
\]

where \( V \) is the volume of \( S \). Recall the construction of \( S' \). There must exist a point \( x' \in S' \) such that \( s_T(x') > -R \), otherwise \( \int_{x' \in S} 1 \{ s_T(x) \leq -R \} dx \) would be at least \( eV \). Unfolding \( s_T(x') \), we arrive at \( \sum_i f_i(x_i) - \sum_i f_i(x') < R \). Using the fact \( \sum f_i(x') \leq \inf_{x \in S'} \sum f_i(x) \) gives the bound for \( \epsilon \)-regret.

Next consider a shrunk version of \( S' \): \( S'_\epsilon = \{ (1 - \epsilon^\frac{2}{3}) x^* + \epsilon^\frac{2}{3} x : x \in S \} \) where \( x^* \in \arg \min_x \sum_i f_i(x) \). Then \( \int_{x \in S} 1 \{ s_T(x) \leq -R \} dx = \epsilon \int_{x \in S} 1 \{ s_T((1 - \epsilon^\frac{2}{3}) x^* + \epsilon^\frac{2}{3} x) \leq -R \} dx \).
which, by the convexity and the boundedness of $f_t(x)$, is at least

$$
\epsilon \int_{x \in S} 1 \left\{ \sum_{i=1}^{T} \left( (1 - \epsilon^\frac{1}{2}) f_t(x^*) + \epsilon^\frac{1}{2} f_t(x) - f_t(x_i) \right) \right\} dx 
$$

$$
\geq \epsilon \int_{x \in S} 1 \left\{ \sum_{i=1}^{T} (f_t(x^*) - f_t(x_i)) \right\} dx 
$$

$$
= \epsilon V \cdot 1 \left\{ \sum_{i=1}^{T} (f_t(x^*) - f_t(x_i)) \right\} 
$$

Following the previous discussion, the expression in the last line above is strictly less than $\epsilon V$, which means that the value of the indicator function has to be 0, namely, $R_{T}(x_{1:T}, f_{1:T}) < R + T \epsilon^{1/d}$.

\[\square\]

### F AbnormalBoost, NH-Boost and Proof of Theorem 3

**Algorithm 6: AbnormalBoost**

**Input** : Training examples $(x_i, y_i) \in \mathbb{R}^d \times \{-1,+1\}, i = 1, \ldots, N$.
**Input** : A weak learning algorithm.
**Input** : Number of rounds $T$.
**Output** : A Hypothesis $H(x) : \mathbb{R}^d \rightarrow \{-1,+1\}$.

Set: $s_0 = 0$.

for $t = 1$ to $T$ do

Set: $p_{t,i} \propto \exp \left( \frac{[s_{t-1,i} - 1]^2}{3t} \right) - \exp \left( \frac{[s_{t-1,i} + 1]^2}{3t} \right), \forall i$.

Invoke the weak learning algorithm to get $h_t$ with edge $\gamma_t = \frac{1}{2} \sum_i p_{t,i} y_i h_t(x_i)$.

Set: $s_{t,i} = s_{t-1,i} + \frac{1}{T} y_i h_t(x_i) - \gamma_t, \forall i$.

Set: $H(x) = \text{sign}(\sum_{t=1}^{T} h_t(x))$.

**Algorithm 7: NH-Boost**

In the boosting setting for binary classification, we are given a set of training examples $(x_i, y_i)_{i=1,\ldots,N}$ where $x_i \in \mathbb{R}^d$ is an example and $y_i \in \{-1,+1\}$ is its label. A boosting algorithm proceeds for $T$ rounds. On each round, a distribution $p_t$ over the examples is computed and fed into a weak learning algorithm which returns a “weak” hypothesis $h_t : \mathbb{R}^d \rightarrow \{-1,+1\}$ with a guaranteed small edge, that is, $\gamma_t = \frac{1}{2} \sum_i p_{t,i} y_i h_t(x_i) \geq \gamma > 0$. At the end, a linear combination of all $h_t$ is computed as the final “strong” hypothesis which is expected to have low training error and potentially low generalization error.

The conversion of a Hedge algorithm into a boosting algorithm is to treat each example as an “action” and set $\ell_{t,i} = 1\{h_t(x_i) = y_i\}$ so that the booster tends to increase weights for those “hard”
implies:

Therefore, if

where

be at most

θ

is again at most

γ > R

For the margin bound, by plugging

temporarily playing a Hedge game using AbnormalHedge with loss

of example

implies

where sign

G Experiments in a Boosting Setting

margin bound for the Hedge setting together with the assumption on the weak learning algorithm implies:

∀j ∈ {1, . . . , N},

\[ \frac{1}{2} + \gamma \leq \frac{1}{T} \sum_{t=1}^{T} \sum_{i=1}^{N} \mathbf{p}_{t,i} \mathbf{1}\{h_t(x_i) = y_i\} \leq \frac{1}{T} \sum_{t=1}^{T} \sum_{i=1}^{N} 1\{h_t(x_j) = \tilde{y}_j\} + \frac{R_{j/N}^{T}}{T}, \]  

\[ (7) \]

where \( R_{j/N}^{T} = \tilde{O}(\sqrt{T \ln(N/j)}) \) is the \( j/N \)-regret bound for AbnormalHedge. So if \( j \) is such that

\[ \gamma > \frac{R_{j/N}^{T}}{T}, \]

we have

\[ \sum_{t=1}^{T} 1\{h_t(x_j) = \tilde{y}_j\} > \frac{1}{T}, \]

which is saying that example \((\hat{x}_j, \hat{y}_j)\) will eventually be classified correctly by \( H(x) \) due to the fact that \( H(x) \) is taking a majority vote of all \( h_t \). This is in fact true for all examples \((\hat{x}_j, \hat{y}_j)\) such that \( i \geq j \) and thus the training error rate will be at most \((j-1)/N\), which is of order \( \tilde{O}(\exp(-T\gamma^2)) \).

For the margin bound, by plugging \( 1\{h_t(x_j) = \tilde{y}_j\} = (\hat{y}_j h_t(x_j) + 1)/2 \), we rewrite Eq. (7) as:

\[ 2 \left( \gamma - \frac{R_{j/N}^{T}}{T} \right) \leq \frac{1}{T} \sum_{t=1}^{T} \hat{y}_j h_t(x_j). \]

Therefore, if \( j \) is such that \( \theta < 2(\gamma - \frac{R_{j/N}^{T}}{T}) \), then the fraction of examples with margin at most \( \theta \) is again at most \((j-1)/N\), which is of order \( \tilde{O}(\exp(-T(\theta - 2\gamma)^2)) \).

\[ \square \]

G Experiments in a Boosting Setting

We conducted experiments to compare the performance of three boosting algorithms for binary classification: AdaBoost [14], NH-Boost (Algorithm 2) and AbnormalBoost (Algorithm 6), using a set of benchmark data available from the UCI repository and LIBSVM datasets. Some datasets are preprocessed according to [22]. The number of features, training examples and test examples can be found in Table 2.

All features are binary. The weak learning algorithm is a simple (exhaustive) decision stump (see for instance [24]). On each round, the weak learning algorithm enumerates all features, and for each feature computes the weighted error of the corresponding stump on the weighted training examples. Therefore, if the number of examples with zero weight is relatively large, then the weak learning algorithm would be faster in computing the weighted error and thus faster in finding the best feature.

All boosting algorithms are run for two hundred rounds. The results are summarized in Table 3 with bold entries being the best ones among the three (AB, NB and ANB stand for AdaBoost, NH-Boost and AbnormalBoost respectively). As we can see, in terms of training error and test error, all three algorithms have similar performance. However, our AbnormalBoost algorithm is always the fastest one. The average fraction of examples with zero weights for AbnormalBoost is significantly higher than the one for NH-Boost (note that AdaBoost does not assign zero weight at all). We plot the change of this fraction over rounds in Figure 1 (using three datasets). As both algorithms proceed, they tend to ignore more and more examples on each round, but AbnormalBoost consistently ignores more examples than NH-Boost.

Since \( s_{t,i} \) is positively correlated to the margin of example \( i \) (\( \frac{1}{T} \sum_{t=1}^{T} y_i h_t(x_i) \)) and large \( s_{t,i} \) leads to zero weight, the above phenomenon in fact implies that the examples’ margins should be larger

\[ \text{http://archive.ics.uci.edu/ml/} \]
\[ \text{http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/} \]
for AbnormalBoost than for NH-Boost. This is confirmed by Figure 2, where we plot the final cumulative margins on three datasets (i.e. each point represents the fraction of examples with at most some fixed margin). One can see that the lines for AbnormalBoost are below the ones for NH-Boost (and even AdaBoost) for most time, meaning that AbnormalBoost achieves larger margins in general. This could explain AbnormalBoost’s better test error on some datasets.

Table 2: Description of datasets

| Data  | #feature | #training | #test  |
|-------|----------|-----------|--------|
| a9a   | 123      | 32,561    | 16,281 |
