Case Report

Chorea: Secondary to Non-Ketotic Hyperglycemia: A Case Report

Abstract

Chorea associated with non-ketotic hyperglycemia is an uncommon dyskinetic syndrome in uncontrolled or undiagnosed diabetes. Various theories are postulated but the underlying mechanism remains poorly understood. We report a 70-year-old man suffering from sudden choreodystonic movements and undiagnosed hyperglycemia. It always marks the importance of screening for diabetes as a cause of acute onset of hyperkinetic disorders.

Urine ketones were negative and urine glucose 3+. Complete blood picture showing Total WBC count 10,700/cmm. Serum Osmolarity was 326 mosmol/kg. A non contrast CT Brain showed no evidence of any pathology.

The patient was diagnosed with non-ketotic hyperosmolar hyperglycemic non-ketotic (HHNK) syndrome is a clinical syndrome of severe hyperglycemia, hyperosmolarity, and intracellular dehydration without ketoacidosis [1]. “Chorea is mostly seen in elderly patients with type 2 diabetes and has a better resolution of symptoms after glycaemia control, although persistent symptoms have been reported [2].”

Case Report

70 year old gentleman without any significant past medical history, presented to our emergency department with chief complaints of involuntary left arm and leg movement with associated slurring of speech for 5 days. The movements started suddenly, remitted during sleep, but were otherwise constant and progressively worsening. Upon review of his physical condition, the patient also noted the recent onset of polyuria and polydipsia. He denied significant past medical history, and denied a family history of Huntington’s chorea or other neurological disorder. Neurological examination revealed oculogyric crisis, orofacial dyskinesia, asymmetric axial and limbs left choreic movements with superimposed dystonic left-posturing of the neck muscle tone and strength. Deep tendon reflexes and sensation are intact and mental status within normal limits.

In the emergency department, serum glucose was elevated at 405 mg/dL. Glycosylated hemoglobin A1C was significantly elevated at 12.7%. FBS>140 and PPBS> 200 in the initial period which gradually decreased to FBS<110 and PPBS<160 on Insulin therapy over a period of 4 days. An Arterial blood gas showing pH 7.45 and HCO3 18mmol/L. BUN was 32mg/dL. Serum was negative for ketone bodies.

Introduction

Chorea associated with hyperglycemia is a rare dyskinetic syndrome usually characterised by unilateral involuntary movements in uncontrolled or undiagnosed diabetes. Hyperosmolar hyperglycemic non-ketotic (HHNK) syndrome is a clinical syndrome of severe hyperglycemia, hyperosmolarity, and intracellular dehydration without ketoacidosis [1]. “Chorea is mostly seen in elderly patients with type 2 diabetes and has a better resolution of symptoms after glycaemia control, although persistent symptoms have been reported [2].”

Discussion

Chorea (irregular, unpredictable, brief jerky involuntary movements) and hemballismus (ballistic flinging movements) could result from the number of causes namely, central nervous system infections, neoplasm, intracranial haemorrhage, neurodegenerative disorders, drugs, toxins, systemic disorders and metabolic imbalance.

Figure 1: MRI revealed A)T1 hyperintense signal abnormality and minimal enhancement of the Right putamen. B) Hypointensity in the same region was demonstrated on FLAIR and T2-weighted.
Hyperglycaemic stated associated chorea was first described by Bedwell in 1960 [3]. An exact mechanism behind the described phenomenon remains unclear, although a small number of theories have been proposed. It has been suggested that the presence of serum hyperosmolarity and hyperglycemia induces mild ischemia in the putamen via hypoperfusion. This theory is supported by a case series reporting caudate and putamen hypoperfusion on SPECT imaging in ten patients with hyperglycemia induced chorea [4]. Hyperglycemia creates an energy state at the cellular level favoring anaerobic metabolism, which in turn depletes gamma-aminobutyric acid (GABA), due to the fact that acetoacetate, a GABA substrate, is quickly depleted in the anerobic state [5]. It is plausible that depletion of GABA can contribute to the development of chorea via it’s interaction with dopamine. GABA acts to inhibit dopaminergic neurons in the nigrostriatal system, therefore the hyperglycemia-induced inhibition of GABA may create a hyperactive dopaminergic state, giving rise to the onset of choreic movements.

Conclusion

Hyperglycemia is an uncommon but reversible treatable cause of chorea. “Checking blood glucose is necessary whenever an elderly patient presents with the new onset hyperkinesias as fluid management and Blood sugar level monitoring can lead to rapid and complete recovery”.
