ABSTRACT

Transcription-coupled DNA repair (TCR) is a sub-pathway of nucleotide excision repair (NER) dedicated to rapid removal of DNA lesions in the transcribed strand of actively transcribed genes. The precise nature of the TCR signal and how the repair machinery gains access to lesions imbedded in stalled RNA polymerase II (RNAP II) complexes in eukaryotic cells are still enigmatic. RNAP II has an intrinsic capacity for transcription bypass of DNA lesions by incorporation or misincorporation of nucleotides across the lesions. It has been suggested that transcription bypass of lesions, which exposes the lesions, may be required for TCR. Here, we show that E1103G mutation of Rpb1, the largest subunit of RNAP II, which promotes transcription bypass of UV-induced cyclobutane pyrimidine dimers (CPDs), increases survival of UV irradiated yeast cells but attenuates TCR. The increased cell survival is independent of any NER subpathways. In contrast, G730D mutation of Rpb1, which impairs transcription bypass of CPDs, enhances TCR. Our results suggest that transcription bypass of lesions attenuates TCR but enhances cell tolerance to DNA lesions. Efficient stalling of RNAP II is essential for efficient TCR.

INTRODUCTION

Nucleotide excision repair (NER) is a multi-step process that removes bulky and/or helix-distorting lesions, such as ultraviolet (UV)-induced cis-syn cyclobutane pyrimidine dimers (CPDs) and bulky chemical adducts that generally obstruct DNA replication and transcription (1,2). NER has two subpathways: transcription coupled repair (TCR) and global genomic repair (GGR). TCR is dedicated to rapid removal of lesions in the transcribed strand of actively transcribed genes. On the other hand, GGR is responsible for removal of lesions throughout the whole genome, including the non-transcribed strand of actively transcribed genes. In eukaryotic cells, the two NER subpathways rely on different proteins in the early damage recognition step but share common factors in the later steps of the repair process. CSA, CSB, UVSSA and USP7 in mammalian cells (3,4) and Rad26 (homolog of mammalian CSB) in Saccharomyces cerevisiae (2) are involved in TCR but dispensable for GGR. On the other hand, XPC in mammalian cells (1), and Rad7, Rad16 and Elc1 in S. cerevisiae (2) are specifically required for GGR but play no role in TCR.

RNA polymerase (RNAP) is an ideal proxy damage sensor because its selectivity is higher than any known DNA damage recognition proteins (5). A mammalian RNAP II complex stalled at a CPD has a half-life of ~20 h, which is more stable than any complex formed between a damage-recognition protein and its substrate (6). TCR is generally assumed to be triggered by stalling of an RNAP at a lesion in the transcribed strand, as DNA lesions that can stably stall RNAP are generally good substrates for TCR (7,8). Up to date, however, no direct evidence has been available to prove this assumption and the precise nature of the TCR signal is still enigmatic.

In Escherichia coli, Mfd, a DNA translocase, binds to the β subunit of a lesion-stalled RNAP, displaces the RNAP complex by pushing it forward and concurrently recruits UvrA to the exposed lesion site to facilitate TCR (9–12). Upon binding to ATP, Mfd also binds to DNA in a manner that the DNA wraps around the protein (13). The DNA binding activity may anchor Mfd downstream from the transcription stop site to carry out its transcription-repair coupling function (14). In addition to promoting repair of lesions that stall the RNAP, Mfd may facilitate TCR downstream of the site that stalls RNAP (15). UvrD, a DNA helicase, has also been shown to play an important role in TCR in E. coli (16). Unlike Mfd, UvrD forces RNAP to backtrack, thereby exposing DNA lesions for access of the repair machinery.

How the TCR machinery gains access to a lesion initially trapped by a stalled RNAP II in eukaryotic cells is...
still mysterious (7,8). Multiple scenarios have been suggested, including (i) ubiquitination and degradation of the largest subunit (Rpb1) of the 12 subunit (Rpb1–12) RNAP II, (ii) displacement of the transcription elongation complex through forced back- or forward-tracking and (iii) remodeling of the complex without removal from the arrest site. To date, however, none of these scenarios has been proven to be required for TCR in eukaryotic cells. In mammalian cells, CSB interacts loosely with the elongating RNAP II and stimulates transcription (17) but becomes more tightly bound following transcription arrest (18). CSB may also push the RNAP II forward, such that an additional nucleotide is incorporated opposite a CPD (19). However, unlike the bacterial Mfd, which displaces a lesion-stalled RNAP from the DNA, CSB does not seem to displace a lesion-stalled RNAP II (19). In S. cerevisiae, the elongating RNAP II complex, which is stabilized by Spt5 and other associated transcription elongation factors, is intrinsically repressive to TCR (20). Rad26 appears to facilitate TCR by antagonizing the repression, as it becomes dispensable for TCR in the absence of Spt4 (21,22), Rpb4 (23), the RNAP II associated factor 1 complex (PAF1c) (24) and certain domains of Spt5 (20,21).

An RNAP has an intrinsic capacity for transcription bypass of lesions by incorporation or misincorporation of nucleotides across the lesions (25,26). In vitro studies with a DNA template containing a T-T CPD showed that the S. cerevisiae RNAP II catalyzes a non-templated insertion of AMP opposite the CPD 3’-T following the A-rule, followed by a very slow and templated AMP or UMP incorporation opposite the CPD 5’-T (27,28). AMP incorporation opposite the CPD 5’-T enables lesion bypass, whereas UMP misincorporation opposite the 5’-T results in irreversible stalling of RNAP II (27,28).

Two domains of Rpb1, the trigger loop and bridge helix, play key roles in the nucleotide addition cycle during RNA synthesis. Upon binding of a matched nucleotide, the trigger loop of RNAP II switches from an inactive open state to an active closed state (Figure 1) (29,30). Mutations of Rpb1 near the RNAP II active center and secondary pore (through which nucleotides reach the catalytic center) have been shown to affect the fidelity of transcription in S. cerevisiae (31–34). Two yeast Rpb1 mutations, G730D (rpb1G730D) and E1103G (rpb1E1103G) (Figure 1), have been shown to affect transcription bypass of CPDs in vitro (28). The rpb1G730D mutation is located in the α21 helix, which forms a part of the secondary pore and contacts the trigger loop. This mutation abolishes transcription bypass of a T-T CPD by preventing incorporation of nucleotides opposite the CPD 3’- and 5’-Ts. The rpb1E1103G mutation is located at the base of the trigger loop. In contrast to the rpb1G730D mutation, the rpb1E1103G mutation increases transcription bypass of T-T CPDs by enabling incorporation of two AMPs opposite the CPD 3’- and 5’-Ts (28). The rpb1E1103G mutation was also observed to increase resistance of RAD26 (wild-type) cells but not rad26Δ cells to UV irradiation, suggesting that the increased UV resistance is dependent on Rad26-dependent TCR (28). An appealing new model of TCR mechanism was therefore proposed: transcription bypass of lesions may expose the lesions to the TCR proteins after their Rad26-dependent recruitment to the lesion-stalled RNAP II and this exposure may be required for TCR (28,35). However, if and/or how transcription bypass of lesions is implicated in TCR remains to be determined.

We found that increased transcription bypass of CPDs by RNAP II enhances survival of UV-irradiated S. cerevisiae cells but attenuates TCR. The enhanced cell survival is independent of Rad26 or other NER factors. In contrast, impairment of transcription bypass of CPDs by RNAP II decreases survival of UV-irradiated GGR-deficient S. cerevisiae cells but enhances TCR. Our results suggest that transcription bypass of lesions may enhance lesion tolerance but attenuate TCR. Efficient stalling of RNAP II is essential for efficient TCR.

MATERIALS AND METHODS

Yeast strains and plasmids

All yeast strains used in this study are derivatives of the wild-type strain Y452 (MATa, ura3–52, his3–1, leu2–3,112, cir+)Deletions of RAD16, RPB1, RAD26 and RAD14 genes were conducted as previously described (23).

Plasmid pRS416-RPB1 was created by inserting the whole RPB1 gene including the promoter, coding sequence and 3’ terminator sequences into the multiple cloning site of the centromericURA3 plasmid pRS416 (36). Plasmids pRS415-RPB1, pRS415-RPB1E1103G and pRS415-RPB1G730D were created by inserting the whole RPB1 gene encoding the wild-type and E1103G and G730D mutant Rpb1, respectively, into the XhoI and ApaI sites of the centromeric LEU2 plasmid pRS415 (36).

Plasmids pRS415-RPB1, pRS415-RPB1E1103G and pRS415-RPB1G730D were transformed into yeast strains...
whose genomic RPB1 gene was deleted and complemented with pRS416-RPB1. The transformed cells were selected with 5-fluoroorotic acid, which is toxic to cells with a functional URA3 gene, to select for cells that had lost the pRS416-RPB1 plasmid.

**Measurement of RNA synthesis in yeast cells**

To measure total RNA synthesis, yeast cells were grown at 30°C in synthetic dextrose medium to late log phase (A_{600} ≈ 1.0). The harvested cells were washed twice with ice-cold H_{2}O, resuspended in ice-cold 2% dextrose and split into two aliquots. One aliquot was kept on ice and the other was irradiated with 360 J/m² of 254 nm UV (by using a 15 W UV germicidal bulb, General Electric). Treatment of genomic DNA with T4 endonuclease V, followed by denaturing agarose gel analysis indicates that this dose of UV induces ∼1 CPD per 1 kb of DNA. After addition of one-tenth volume of a stock solution (6.7% yeast nitrogen base without amino acids, 1.6% yeast synthetic drop-out media supplement without uracil, 1 mM uracil), [2–14C]uracil (56.0 mCi/mmol; Moravek Biochemicals) was added to a final concentration of 2 μM. The samples were incubated at 30°C in the dark and aliquots were collected at different times of the incubation. Total RNA was isolated using a hot acidic phenol method as previously described (37), and quantified by using the Qubit® RNA HS assay kit and a Qubit® 2.0 Fluorometer (Invitrogen, Life Technologies). The isolated total RNA was fractionated on formaldehyde agarose gels (38), and transferred onto Hybond-N+ membranes (GE Healthcare Life Sciences). The membranes were exposed to Phosphorimagery screens for 7 days and scanned with Molecular Imager FX (Bio-Rad).

For northern blot analysis of galactose-induced GAL10 transcription, yeast cells were grown at 30°C in synthetic medium containing 2% glycerol, 2% lactate and 2% ethanol to late log phase (A_{600} ≈ 1.0). The harvested cells were washed and resuspended in ice-cold H_{2}O, and split into two aliquots. One aliquot was kept on ice and the other was irradiated with 120 J/m² of 254 nm UV (the dose we used for TCR analysis). The unirradiated and UV-irradiated cells were pelleted by centrifugation and resuspended in YPG (1% yeast extract, 2% peptone and 2% galactose) medium and incubated at 30°C. At different times of the incubation, aliquots were collected. Total RNA was isolated, fractionated on formaldehyde agarose gels and transferred onto Hybond-N+ membranes. The GAL10 transcripts on the membranes were probed with a 150 nucleotide long [α-32P]-UTP-labeled riboprobe that is complementary to the 5’ end of the GAL10 transcripts.

**Repair analysis of UV-induced CPDs**

Yeast cells were cultured at 30°C in synthetic dextrose medium to late log phase (A_{600} ≈ 1.0), washed twice with ice-cold ddH_{2}O, resuspended in 2% dextrose and irradiated with 120 J/m² of 254 nm UV. After addition of one-tenth volume of a stock solution (10% yeast extract, 20% peptone), the yeast samples were incubated at 30°C in the dark. At different times of the repair incubation, aliquots were collected and the genomic DNA was isolated as described previously (23).

The transcribed and non-transcribed strands of the RPB2 gene (39,40) were 3’-end labeled with [α-32P]-dATP by using a method described previously (41,42). Briefly, ∼1 μg of total genomic DNA was digested with Drai and released the RPB2 fragments and incubated at CPD sites with an excess amount of T4 endonuclease V (Epicentre). Excess copies of a biotinylated oligonucleotide, which is complementary to the 3′ end of the transcribed or non-transcribed strand of the RPB2 gene, were mixed with the samples. The mixtures were heated at 95°C for 5 min to denature the DNA and then cooled to an annealing temperature of around 50°C. The annealed molecules were attached to streptavidin magnetic beads, labeled with [α-32P]-dATP and resolved on DNA sequencing gels. The gels were exposed to Phosphorimagery screens. The intensities of gel bands corresponding to CPD sites were quantified using Quantity One (Bio-Rad).

**UV sensitivity assay**

Yeast cells were cultured at 30°C in synthetic dextrose medium to saturation. Sequential 10-fold dilutions of the cultures were made. For spotting assay, the diluted cells were spotted onto YPD (1% yeast extract, 2% peptone and 2% dextrose) plates and irradiated with different doses of 254 nm UV. After 3–5 days of incubation at 30°C in the dark, the plates were photographed. For colony formation assay, the diluted cells were spread onto YPD plates and irradiated with different doses of 254 nm UV. After 3–5 days of incubation at 30°C in the dark, the colonies were counted. Three repeats were performed and the means and standard deviations were calculated.

**Detection of cellular levels of Rpb1 by western blot**

Late log phase yeast cells were harvested and the whole cell extracts were prepared as described previously (43). Proteins were resolved on an sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) gel and transferred onto a polyvinylidene difluoride membrane. The samples were incubated with a monoclonal anti-Rpb1 antibody (Thermol Scientific). Blots were incubated with SuperSignal West Femto Maximum Sensitivity Substrate (Thermo Scientific), and the protein bands were detected using ChemiDoc™ XRS+ System (Bio-Rad).

**Measurement of RNAP II densities on the RPB2 gene by chromatin immunoprecipitation (ChIP) assay**

The ChIP assay was performed as described previously (44). Briefly, yeast cells were grown in synthetic dextrose medium to late log phase, cross-linked with 1% formaldehyde and lysed by vortexing with glass beads. The cell lysates were sonicated by using a Bioruptor (Diagenode) to shear the chromatin DNA to an average size of 200 bp and clarified by centrifugation at 4°C. An aliquot from each of the clarified lysates was saved as an input. The remaining lysates were immunoprecipitated with the anti-Rpb1 antibody 8WG16 or...

(A–C) Northern blots showing GAL10 transcripts in UV-irradiated and unirradiated rad14Δ cells expressing wild-type Rpb1, and rpb1E1103G and rpb1G730D mutants. Note that the 18S rRNA has certain level of cross-hybridization with the GAL10 riboprobe. Numbers on top of the blots indicate time (min) of incubation in galactose medium at 30°C. (D–F) Plots showing scans of signal intensities along the lanes of the blots shown in A–C, respectively. Numbers on the top of the plots indicate relative signal intensity (arbitrary units). Numbers on the left of the plots indicate relative locations on the gel (arbitrary units). Brackets on the right panels indicate the predominant GAL10 transcripts.
Figure 4. Effects of rpb1E1103G and rpb1G730D mutations on TCR. (A–C) Sequencing gel showing TCR of CPDs in rad16Δ cells expressing wild-type Rpb1, and rpb1E1103G and rpb1G730D mutants. (D–F) Sequencing gel showing TCR of CPDs in rad16Δ rad26Δ cells expressing wild-type Rpb1, and rpb1E1103G and rpb1G730D mutants. Unirradiated (U) and irradiated samples after different times (in minutes) of repair incubation are indicated at the top of the gel lanes. Nucleotide positions shown on the left are relative to the TSS.

mock immunoprecipitated. DNA fragments corresponding to different regions of the RPB2 gene in the input, immunoprecipitated and mock immunoprecipitated samples were quantified in triplicates by using real-time polymerase chain reaction (PCR). Primers used for amplifying the different regions of the RPB2 gene were described previously (20). The number of molecules in each immunoprecipitated sample was subtracted by that in the corresponding mock immunoprecipitated sample (generally ∼5% of the immunoprecipitated sample) and then normalized to that in the corresponding input. The levels of RNAP II association with the different regions of RPB2 gene in cells expressing the rpb1E1103G and rpb1G730D mutants were normalized to
those in cells expressing the wild-type Rpb1. The Student’s
t-test was used for statistical analysis.

RESULTS

rpb1E1103G mutation promotes transcription of UV-
damaged templates, whereas rpb1G730D mutation impairs
transcription of the damaged templates in vivo

In vitro studies with purified yeast RNAP II have shown that
the rpb1E1103G mutation promotes transcription bypass
of CPDs, whereas the rpb1G730D mutation abolishes trans-
scription bypass of the DNA lesions (28). RNAP II tran-
scription is affected by chromatin structure and regulated by
a plethora of transcription elongation factors in the cell. To
determine if the Rpb1 mutations also affect transcription
bypass of lesions in vivo, we measured RNAP II transcription
by detecting incorporation of radioactive \(^{14}\)C uracil
into total RNA in yeast cells. To prevent removal of UV-
duced DNA lesions, we utilized \(\Delta\) rad14 cells, which are
completely deficient in NER (2). Late log phase yeast cells
were irradiated with 360 J/m\(^2\) of 254 nm UV to induce \(~1\)
CPD per 1 kb of DNA. Unirradiated and the UV-irradiated
cells were then incubated in the presence of \(^{14}\)C uracil. To-
tal RNA was isolated from the cells at different times of the
incubation, fractionated on formaldehyde agarose gels and
migrated as smears. \(^{14}\)C uracil was rapidly incorporated
shorter transcripts were elongated into longer transcripts,
thus reflect a more proficient transcription elongation.
After 120 min of incubation, the ratios were 5.9 and 1.8
in unirradiated and UV-irradiated \(\Delta\) rad14 cells, re-
spectively (Figure 2H and I). These results suggest that the
rpb1E1103G and rpb1G730D mutations respectively promotes and impairs transcription elongation of mRNAs on UV-damaged templates. These results agree well with the in vitro observations that the Rpb1E1103G and G730D mutations respectively promotes and abolishes transcription bypass of DNA lesions (28).

To specifically analyze the effects of the rpb1E1103G and
rpb1G730D mutations on RNAP II transcription and rule
out the interference by transcripts of other RNAPs, we
measured \(GAL10\) transcripts in UV-irradiated cells. The
\(GAL10\) gene is not transcribed in glycerol/lactate/ethanol
media, but can be rapidly induced upon switching of the
cells to galactose media (46). Yeast cells were grown in a
glycerol/lactate/ethanol medium to late log phase, irradi-
ated with 120 J/m\(^2\) of UV (the dose we used for TCR analy-

Figure 5. Percent of CPDs remaining in the transcribed strand of the \(RPB2\) gene in \(\Delta\) rad16 and \(\Delta\) rad16 \(\Delta\) rad26 cells expressing wild-type Rpb1, and
rpb1E1103G and rpb1G730D mutants. Data are represented as mean ± SD.
Figure 6. No repair of CPDs occurred in the non-transcribed strand of the RPB2 gene in rad16Δ cells expressing wild-type Rpb1, and rpb1E1103G and rpb1G730D mutants.

galactose) and switched to a galactose medium. For unknown reason(s), the rpb1G730D mutant cells grow almost as quickly as wild-type cells in glycerol/lactate/ethanol or galactose media (not shown). Total RNA was isolated from the cells at different times of incubation in the galactose medium. The GAL10 transcripts were detected on northern blots using a riboprobe that is complementary to the 5′ end of the GAL10 transcripts.

GAL10 transcripts could be easily detected in all the yeast cells analyzed after 10 min of galactose induction and leveled off after ~40 min of the induction (Figure 3). UV irradiation impaired the transcription of GAL10 gene. The rad14Δ rpb1E1103G cells had a higher level of the GAL10 transcripts than rad14Δ RPB1 cells, whereas the rad14Δ rpb1G730D cells showed a lower level of the transcripts.

Also, the predominant GAL10 transcripts were longest in the rad14Δ rpb1E1103G cells and shortest in the rad14Δ rpb1G730D cells (Figure 3D and E). A higher level of longer transcripts will indicate more proficient transcription elongation, and vice versa. Taken together, our results indicate that the rpb1E1103G and rpb1G730D mutations respectively promote and impair transcription elongation of the UV-damaged GAL10 gene. However, full-length GAL10 transcripts were rare in all the cells analyzed, indicating that even the rpb1E1103G mutation may not enable full transcription bypass of UV lesions.

rpb1E1103G mutation attenuates TCR, whereas rpb1G730D mutation enhances TCR

To determine the implication of transcription bypass of DNA lesions in TCR, we directly measured repair of UV-induced CPDs in the RPB2 gene in rad16Δ RPB1, rad16Δ rpb1E1103G and rad16Δ rpb1G730D yeast cells. The reason for using rad16Δ cells for the measurement is to eliminate GGR so that TCR can be unambiguously analyzed. Indeed, repair could not be seen in the region of the transcribed strand that is 40 nucleotides upstream of the transcription start site (TSS) (where TCR does not operate) (Figure 4A–F), or in the non-transcribed strand of the RPB2 gene (Figure 6A–C). TCR could be easily seen in rad16Δ RPB1 cells (Figure 4A). As expected, additional deletion of RAD26 decreased TCR (Figure 4D). Surprisingly, the rpb1E1103G mutation caused attenuation of TCR in both rad16Δ and rad16Δ rad26Δ cells (Figure 4, compare panels A and B, and D and E; Figure 5). In contrast, the rpb1G730D mutation enhanced TCR in both rad16Δ and rad16Δ rad26Δ cells (Figure 4, compare panels A and C, and D and F; Figure 5).

Our results indicate that enhanced transcription bypass of DNA lesions attenuates TCR regardless the presence of Rad26. On the other hand, impaired transcription bypass of DNA lesions enhances Rad26-dependent and independent TCR.

rpb1E1103G mutation increases cell resistance to UV regardless the presence of any NER subpathways, whereas rpb1G730D mutation decreases cell resistance to UV only in the absence of GGR

The rpb1E1103G mutation was observed to increase UV resistance of RAD26 cells but not that of rad26Δ cells, suggesting that the increased resistance is dependent on Rad26-dependent TCR (28). Our direct analysis of TCR showed that the mutation actually attenuate TCR regardless of the presence of Rad26. To determine if the increased UV resistance is dependent on Rad26-dependent TCR or other subpathway of NER, we measured epistatic interactions of the rpb1E1103G and rpb1G730D mutations with RAD26, which plays an important role in TCR, and with RAD16 and RAD14, which are essential for GGR and the entire NER, respectively. The rpb1E1103G mutation increases UV resistance of the otherwise wild-type, rad26Δ (Figure 7A), rad16Δ, rad16Δ rad26Δ (Figure 7B and D) and rad14Δ
Figure 7. Epistatic interactions of *rpb1E1103G* and *rpb1G730D* mutations with different NER genes. (A–C) Spotting assay showing the effects of *rpb1E1103G* and *rpb1G730D* mutations on UV sensitivities of yeast cells with different NER subpathways operative. (D) Colony formation assay showing the effects of *rpb1E1103G* and *rpb1G730D* mutations on UV sensitivities of *rad16Δ* and *rad16Δ rad26Δ* cells. The values of the survival fractions are the means of three repeats. Standard error bars are within the symbols of the data points.
DISCUSSION

We showed here that increased transcription bypass of CPDs attenuates TCR but enhances cell survival, whereas impairment of the bypass enhances TCR but decreases cell survival in the absence of GGR. Our results do not support the proposition that the bypass, which may expose the lesions, is required for TCR (28,35). Rather, the bypass may actually weaken the recognition of lesions during TCR.

Transcription bypass of a DNA lesion could have serious repercussions on the cell, particularly if the lesion has miscoding properties, resulting in the insertion of incorrect nucleotides into the mRNA and generation of a mutant protein (25). However, the bypass may allow the completion of the ongoing mRNA synthesis to provide a steady supply of the housekeeping and repair proteins in the presence of the lesions, thereby enhancing cell survival. Therefore, the bypass may serve as a DNA damage tolerance mechanism that is alternative to TCR. The survival benefit of the damage tolerance appears to outweigh the survival deficiency of TCR attenuation caused by enhanced transcription bypass of DNA lesions.
Our results offer direct evidence for the long-standing but unproven notion that TCR requires sufficient stalling of an RNAP. Incorporation of one or two nucleotides opposite a CPD, especially misincorporation of a nucleotide opposite the 5’ nucleotide of a CPD appears to be necessary to induce RNAP II stalling and potentially invoke TCR (28,47–48).

This suggests that sufficient stalling of RNAP II, regardless of incorporation or misincorporation of nucleotides opposite a lesion, may be sufficient for eliciting TCR. However, transcription is regulated by a plethora of transcription elongation factors in the cell, if the rpb1G730D mutant RNAP II can catalyze incorporation of nucleotides across CPDs that leads to transcription stalling in vivo has not been tested. Therefore, if the enhanced TCR caused by the rpb1G730D mutation requires the incorporation or misincorporation of nucleotide(s) across CPDs in living yeast cells remains to be determined. Besides enhancing TCR, stalling of RNAP II blocks ongoing transcription and may also impair replication, resulting in reduced resistance to DNA damage especially in the absence of GGR. In this case, the survival deficiency caused by impaired transcription bypass of DNA lesions outweighs the survival benefit of enhanced TCR.

Previous studies have ruled out the roles of ubiquitination and degradation of Rpb1 (49–51) and back-tracking of RNAP II by TFIIS (52) in TCR. A number of transcription elongation factors, such as Spt4 (22), Spt5 (20,21) and PAFc (24), which stabilize and promote forward-tracking of the RNAP II elongation complex, have been shown to repress TCR. Here, we show that transcription bypass of lesions attenuates TCR, although the bypass may expose the lesions to DNA repair machinery. Taken together, these studies appear to support the model that the RNAP II complex stalled at a lesion may be remodeled, rather than removed from the stalled site, to initiate TCR in eukaryotic cells. How RNAP II complex is remodeled during TCR remains to be elucidated.
