Au+Au Collisions at RHIC and implications for ultra-relativistic astrophysical A+A collisions

Jens Sören Lange a *

a Johann Wolfgang Goethe-Universität Frankfurt am Main, Institut für Kernphysik

Presented at the XIII International Symposium on Very High Energy Cosmic Ray Interactions Pylos, Greece, 09/6-12/2004

Results from ultra-relativistic Au+Au collisions at RHIC are reviewed. Emphasis is put upon (a) measured properties of an Au+Au collision, which might be used as input to cosmic air shower Monte-Carlo event generators, (b) production of anti-matter, and (c) forward physics.

1. RHIC

The Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory, New York, USA, has a circumference of 3833 m and uses 1740 superconducting magnets [1]. Fig. 1 shows the RHIC accelerator complex. The main objective of RHIC is the investigation of novel QCD phenomena at high density and high temperature in ultra-relativistic Au+Au collisions. The highest center-of-mass energy $\sqrt{s}=200$ GeV is a factor $\approx 10$ higher than past fixed target nucleus-nucleus collision experiments (e.g. CERN SPS $E_{beam}=160$ GeV, equivalent to $\sqrt{s} \approx 17.3$ GeV). With a cross section of $\sigma_{Au+Au}=7.04$ barn (see Tab. 2), the design luminosity of $L=2 \cdot 10^{26}$ cm$^{-2}$ s$^{-1}$ means an interaction rate of $\approx 1.4$ kHz. Four experiments are located at RHIC interaction points, i.e. the STAR, PHENIX, PHOBOS and BRAHMS experiments. The STAR experiment consists of

- a large scale midrapidity ($|\eta| \leq 1.6$) Time Projection Chamber (TPC, $R=2$ m, $L=4$ m) with $\approx 48,000,000$ pixels (momentum resolution $\Delta p_T/p_T=3\%$ at $p_T=1$ GeV/c in a solenoidal magnetic field of $B=0.5$ T) [2]
- 2400 lead-scintillator electromagnetic calorimeter modules ($|\eta| \leq 1.0$), and
- a 3-layer silicon drift detector with $\approx 13,000,000$ pixels ($|\eta| \leq 1.0$)

*Current Address: GSI, Planckstraße 1, 64291 Darmstadt, Germany, Email <soeren@bnl.gov>

2Throughout this paper, $\sqrt{s}$ denotes the center-of-mass energy in the nucleon-nucleon system $\sqrt{s_{NN}}$.
Au+Au collisions create a system of hot nuclear matter, \( d+Au \) collisions a system of cold nuclear matter. The \( p+p \) data set serves as reference for \( Au+Au \), but at the same time is also used for the RHIC spin program, as protons in RHIC can be polarized vertical or longitudinal.

As an illustration of the amount of data, the raw data set collected at STAR experiment in 2004 compares to \( \sim 60 \) times the combined raw data set of the \( B \) meson factories BELLE and BABAR.

STAR also utilizes a level-3 trigger system \([6]\), performing full event reconstruction of a central \( Au+Au \) collision within \( t \leq 100 \text{ ms} \). Fig. 2 shows a central \( Au+Au \) collision at \( \sqrt{s}=200 \text{ GeV} \), recorded by the level-3 trigger system at STAR, and consisting of \( \sim 6,500 \) charged particle tracks and \( \sim 130,000 \) TPC clusters. The level-3 trigger was used for realtime rare probe detection, such as events with anti-Helium (described in detail in Ch. 5).

2. The RHIC \( Au+Au \) Collision

There are four basic stages of an \( Au+Au \) collision, which are also schematically depicted in Fig. 3.

- \( t=0 \text{ fm/c} \): The nuclei are Lorentz contracted in the laboratory frame (“pancake shape”). Hard parton scattering occurs (\( qq, qg, gg \) scatterings).
- \( t \sim 1 \text{ fm/c} \): A hot cylinder is formed. The temperature in the cylinder exceeds \( 10^{12} \text{ K} \).
- \( t \sim 4 \text{ fm/c} \): Soft partons, thermally produced, emerge from the center of the collision. Beam remnant particles are peaked in the forward and backward directions.
- \( t \sim 10 \text{ fm/c} \): Hadronic freeze-out occurs. All partons confine into particles.

Figure 2. RHIC \( Au+Au \) collision at \( \sqrt{s}=200 \text{ GeV} \), recorded at the STAR experiment.

| \( \sqrt{s} \) | \( \# \) of Events | Year |
|----------------|-----------------|------|
| \( Au+Au \) 130.0 GeV | 0.7 Mill. | 2000 |
| \( Au+Au \) 200.0 GeV | 3.2 Mill. | 2001 |
| \( Au+Au \) 19.6 GeV | \( \sim 20,000 \) | 2001 |
| \( d+Au \) 200.0 GeV | 35 Mill. | 2003 |
| \( Au+Au \) 200.0 GeV | 77.9 Mill. | 2004 |
| \( Au+Au \) 62.4 GeV | 13.3 Mill. | 2004 |
| \( p+p \) 200 GeV | 19.8 Mill. | 2004 |

Table 1
Recorded STAR data set.

| \( \sqrt{s} \) | \( \# \) of Events | Year |
|----------------|-----------------|------|
| \( Au+Au \) 130.0 GeV | 0.7 Mill. | 2000 |
| \( Au+Au \) 200.0 GeV | 3.2 Mill. | 2001 |
| \( Au+Au \) 19.6 GeV | \( \sim 20,000 \) | 2001 |
| \( d+Au \) 200.0 GeV | 35 Mill. | 2003 |
| \( Au+Au \) 200.0 GeV | 77.9 Mill. | 2004 |
| \( Au+Au \) 62.4 GeV | 13.3 Mill. | 2004 |
| \( p+p \) 200 GeV | 19.8 Mill. | 2004 |

Table 2
Measured parameters of a RHIC \( Au+Au \) collision. For details see Ch. 2

| Parameter | Value | Reference |
|-----------|-------|-----------|
| \( \sigma_{Au+Au} \) | \( (7.05 \pm 0.05) \text{ barn} \) | 130 [7] |
| \( N_{part} \) | \( 352 \pm 3 \) | 200 [5] |
| \( N_{bin} \) | \( 1051 \pm 72 \) | 200 [8] |
| \( R_{out} \) | \( (5.39 \pm 0.18 \pm 0.28) \text{ fm} \) | 130 [9] |
| \( R_{long} \) | \( (5.99 \pm 0.19 \pm 0.36) \text{ fm} \) | 130 [9] |
| \( R_{side} \) | \( (5.48 \pm 0.15 \pm 0.30) \text{ fm} \) | 130 [9] |
| \( E_T \) | \( (620 \pm 33) \text{ GeV} \) | 200 [8] |
| \( E_{T_{em}} \) | \( (216 \pm 14) \text{ GeV} \) | 200 [8] |
| \( \beta \) | \( 0.56c \) | 130 [10] |
| \( T_{chem} \) | \( (181 \pm 8) \text{ MeV} \) | 130 [10] |
| \( T_{kin} \) | \( (89 \pm 10) \text{ MeV} \) | 200 [11] |
| \( \mu_b/T \) | \( 0.18 \pm 0.03 \) | 130 [12] |
| \( p/p \) ratio | \( 0.71 \pm 0.002 \pm 0.05 \) | 130 [13] |
| \( \varepsilon_{Bjorken} \) | \( (4.2 \pm 0.3) \text{ GeV/fm}^3 \) | 130 [14] |

Tab. 2 lists the measured parameters of a RHIC collision. \( \sigma_{Au+Au} \) denotes the total cross section. \( N_{part} \) denotes the number of participant nucleons. \( N_{bin} \) denotes the number of binary nucleon-nucleon collisions. The size of the system can be concluded from the radii \( R_{out} \), \( R_{long} \) and \( R_{side} \), which are measured by quantum-mechanical Hanbury-Brown-Twiss (HBT) interferometry of \( \pi^+\pi^- \) pairs, close in phase space. \( R_{out} \) denotes the radius perpendicular to the
beam axis, $R_{long}$ parallel to the beam axis. $R_{side}$ denotes a radius perpendicular to $R_{out}$, but not necessarily measured from the origin (0,0,0). $R_{out}$ can be interpreted as the size of the particle wave front, while freezing out. In particular, the ratio $R_{out}/R_{side} \approx 1$ indicates that RHIC freeze-out has a surprisingly short duration, an evidence which is supported by the measured high expansion velocity, given as the fraction of the speed of light $\beta = 0.56$.

$E_T$ denotes the total transverse energy, defined as the sum of the electromagnetic transverse energy $E_{em}^T$ (i.e. leptons and photons) and the hadronic transverse energy $E_{had}^T$. The ratio $E_{em}^T/E_T$ was determined to be $0.348 \pm 0.019$ [8]. So far, there is no indication for Centauro type events with an anomalous ratio $E_{em}^T/E_{had}^T \approx 1/6$ [15].

The $\bar{p}/p$ ratio visualizes how many baryons from the beam projectiles remain in the collision zone. A complete baryon-free zone would lead to a $\bar{p}/p$ ratio $\approx 1$, i.e. all baryons and anti-baryons are created by pair production. The measured $\bar{p}/p$ ratio of 0.71 indicates that a significant excess of baryons over anti-baryons is still present at RHIC. As a comparison, the measured ratio is much higher than 0.00025 \pm 10\% at the AGS ($\sqrt{s} \approx 4.9$ GeV) and 0.07 \pm 10\% at the SPS ($\sqrt{s} \approx 17.3$ GeV), i.e. RHIC collisions represent for the first time an opportunity to advance into the almost baryon free regime.

The baryo-chemical potential $\mu_B$ denotes the energy which is necessary to add one nucleon to the system. Recent lattice QCD calculations indicate the position of the tri-critical point of strongly interacting matter at a temperature $T=(160 \pm 3.5)$ MeV and a baryo-chemical potential of $\mu_b=(725 \pm 35)$ MeV [16]. Thus, the primordial conditions in a RHIC collision are close to the critical temperature, but the baryo-chemical potential has a difference of a few hundred MeV to the tri-critical point. As one consequence, large scale event-by-event fluctuations in the number of charged hadrons (as one might expect close to the tri-critical point) are not expected at RHIC. However, it should be noted, that in the 2-dimensional QCD phase diagram ($T$ vs. $\mu_B$) the primordial conditions of a RHIC collision are very close to those of the primordial universe.

2.1. The Temperature

One distinguishes between the chemical freeze-out temperature $T_{chem}$ and the kinetic freeze-out temperature $T_{kin}$, which correspond to different times in the system evolution. $t(T_{chem})$ denotes the end of the inelastic collisions inside the particle wave front, i.e. relative particle abundances become fixed. $t(T_{kin})$ denotes the end of the elastic collisions and is $\approx 100$ MeV cooler than $T_{chem}$. The temperature $T_{chem} = 181$ MeV corresponds to $2.1 \cdot 10^{12}$ K, which can be compared to the temperature in other systems (Tab. 3). The temperature resembles one of the highest temperatures in the universe.

Also an interesting fact from the comparison of the temperatures at $\sqrt{s} = 130$ GeV and $\sqrt{s} = 200$ GeV shall be noted: although the collision energy increases by $\Delta E = 70$ GeV, the temperature only increases by $\Delta T = 7$ MeV, which corresponds to a small fraction of $\leq 10^{-6} A \cdot \Delta E$.

Note that the new GSI accelerator facility FAIR (see Ch. 6) will test a ($\mu_B, T$) region in the vicinity of the predicted tri-critical point, where event-by-event fluctuations might occur.
2.2. The Matter Density

The spatial matter density, i.e. the number of partons per volume $\rho=N_{\text{partons}}/V$ can be estimated by a Bjorken ansatz [17]. If assuming that initial and final entropy are equal, the number of partons at $t<1$ fm/c is equal to the measured number of final state hadrons $N_{\text{hadron}}$. The volume can be calculated by inserting the fireball radius ($R_{\text{out}}$ and $R_{\text{long}}$ in Tab. 2) into a cylindrical volume (due to Lorentz boost in the beam direction), i.e. $\rho\approx dN_{\text{parton}}/dy(1/(\pi R^2 t))$ using the rapidity $y$. For a time early in the system evolution $t=0.2$ fm/c the matter density is $\rho\approx 20$/fm$^3$, which corresponds to $\approx 15\times \rho_0$, $\rho_0$ denoting the density of cold gold nuclei. At this high density, hadrons are definitely non-existent. In Tab. 4, the density is compared to other systems.

### Table 4

Comparison of the density in various systems.

| Density (kg/cm$^3$) | Collision/Process |
|---------------------|-------------------|
| $3\times 10^{-17}$   | $Au+Au$ collision |
| $2\times 10^{17}$   | $Au$ nuclear density |
| $20,000$            | $Au$ atomic density (solid) |
| $1000$              | metalic hydrogen |
| $1.1\times 10^{-26}$| universe critical density |

2.3. The Energy Density

About 90% of all emerging particle are $\pi$ mesons, thus one may assume (as an educated guess) the $\pi$ meson mass in the particle energy $E^2=m^2+p^2$. By $(a)$ counting the number of charged particles, $(b)$ measuring the average particle momentum $p$ and $(c)$ using the volume according to Ch. 2.2, one can estimate the total energy density as $\varepsilon \approx 5$ GeV/fm$^3$, corresponding to a factor $\approx 30$ higher energy density than in cold $Au$ nuclei. For comparison, the estimate for the AGS is $\varepsilon = 1.2$ GeV/fm$^3$, for the SPS $\varepsilon = 2.4$ GeV/fm$^3$ [18]. A better estimate based upon perturbative QCD can be found elsewhere [1], leading to an even higher energy density of $\varepsilon \approx 18$ GeV/fm$^3$.

3. From $p+p$ to $Au+Au$

As RHIC experiments measure both $Au+Au$ and $p+p$ collisions in the same detector, corresponding data of both collision types can be directly compared with identical systematic errors. Fig. 4 shows transverse momentum distributions for $\pi^-$, $K^-$ and $\bar{p}$ for $\sqrt{s}=200$ GeV $p+p$ (top) and $Au+Au$ (bottom) as a compilation of all four RHIC experiments. One can immediately see that a $Au+Au$ collision is not a simple superposition of many $p+p$ collisions. In fact, the average mean transverse momentum $<p_T>$ is $\approx 390$ MeV/c for $p+p$ and $\approx 508$ MeV/c for central $Au+Au$. The increase by $\approx 30\%$ indicates the presence of collective effects. For further details see [19, 20].

4. Qualitative comparison to the primordial universe

A RHIC $Au+Au$ collision is sometimes being referred to as the “little bang”, in reference to the “big bang” of the primordial universe. However, a few important differences shall be noted:

- The primordial universe underwent a matter-dominated and a radiation-dominated period. At RHIC, matter dominates exclusively.
- At the time when the universe reached RHIC temperatures of $T=100$ MeV, it already had developed a macroscopical horizon distance of $L=10$ km, and thus had a size which was roughly larger than the size of a RHIC collision by a factor $10^{18}$.
- The expansion velocity of $v=0.56c$ at RHIC indicates an almost explosive character. In case of the primordial universe (after inflation) it was much slower by a factor $1/M_{\text{Planck}}=10^{19}$.

---

4The rapidity $y$ of a particle is defined as $y=1/2\ln((E+p_z)/(E-p_z))$ with the total particle energy $E$ and the momentum component in beam direction $p_z$. The yield $dN/dy$ is Lorentz invariant.
5. Anti-Helium

Currently one of the most interesting questions of cosmology is: where is the primordial anti-matter? Several experiments (e.g. the balloon bound BESS experiment \(^{22}\) at a height of \(H=27 \text{ km}\) and the space-shuttle bound AMS experiment \(^{23}\) at an orbit of \(H=320-390 \text{ km}\)) search for direct evidence of anti-matter in cosmic rays. It should be noted that incident particle energies at the AMS orbit location (i.e. quasi-“beam” energies) range from \(10^1\text{-}10^6 \text{ MeV per nucleon, comparable to RHIC beam energies at } 10^2 \text{ MeV per nucleon.} A \text{ particularly suited probe for anti-matter search is } \text{anti-He beam energies at } 10^2 \text{ MeV per nucleon. A particularly suited probe for anti-matter search is } \text{anti-He, as the signature of charge } Z=-2 \text{ is clean}^5. A Z=-1 \text{ signature of } \pi^- \text{ is contaminated by } K^- \text{ and } \pi^- \text{ mesons. The STAR level-3 trigger system was used to identify } Z=-2 \text{ candidate events in realtime. Primordial Helium is not rare, but in fact represents } \approx 24\% \text{ of all primordially created matter (created at time scales } t\sim 1 \text{ s and at temperatures } T\sim 0.1 \text{ MeV). Under the assumption of an a priori symmetric primordial production of } \text{anti-He, one may conclude that anti-He might be detectable, too. In a RHIC Au+Au collision, there is trivially no anti-matter in the initial state, as nuclei are completely made of matter. However, even anti-nuclei are created in a detectable quantity. The dominant anti-nuclei production mechanism is a two-step process, namely (1) pair production of } p\bar{p}, n\bar{n}, \text{ followed by (2) coalescence, i.e. the antinucleon wave functions overlap inside a homogeneity volume. For the systematic study of the } \text{A dependence of anti-nuclei production yields, it is useful to define an } \text{invariant yield}

\[ E \frac{d^3N_A}{d^2p} = B_A \left( E \frac{d^3N_A}{d^2p} \right)^A \]

with anti-nuclei yield } N_A, \text{ the anti-nucleon yield } N_N, \text{ the anti-nucleon momentum } p, \text{ and } p=p/A. \text{ The coalescence coefficient } B_A \text{ denotes the probability that } A \text{ anti-nucleons form a bound state. It might be regarded as a “penalty factor” for the step from } n \text{ to } n+1 \text{ anti-nucleons in the system. Typical orders of magnitude are } B_2=10^{-3} \text{ and } B_3=10^{-6}. \text{ For high } \sqrt{s} \text{ and a large system size, the coalescence coefficient is related to the inverse of the effective volume containing the anti-nuclei (i.e. the fireball volume) by } B_A=1/V_{eff}^{A-1}. \text{ So far, STAR has been able to collect a raw yield of 193 anti-He in a total of } 4\cdot10^6 \text{ Au+Au events at } \sqrt{s}=200 \text{ GeV. In the same data set, 6416 anti-deuterons were also identified and used for a de-}

5\text{Except anti-He and hypothetical pentaquark states there are no other stable } Z=-2 \text{ particles predicted in nature.}
termination of $B_2$. Further details are given elsewhere [24]. Fig. 5 shows the measured ionization $dE/dx$ vs. momentum for the anti-$He$ candidates in the STAR Time Projection Chamber.

The coalescence coefficient is also an important input to calculations of anti-$He$ yield from nucleus-nucleus collisions in the stellar medium [20], which is the dominant background for the primordial anti-$He$ search by AMS.

The STAR 2004 data set is currently being analyzed. The data are expected to contain $2.7 \pm 0.3$ anti-$^4He$, which would be a first experimental observation.

6. Forward Physics

For high energy $pA$ collisions in the earth’s upper atmosphere, a proper knowledge of the particle shower in the forward rapidity region is very important, as the forward particles are the visible center of the showers as seen on the detector systems at sea level. Ideally $pAu$ collisions would be preferable, but due to technical accelerator issues $dAu$ collisions were chosen at RHIC. As shown in Tab. 1, several million $dAu$ collisions were recorded at RHIC in 2003. Fig. 7 shows the rapidity distribution of particles from a $dAu$ collision at $\sqrt{s}=200$ GeV with data from BRAHMS [27], in comparison to a perturbative QCD calculation [28]. The $\eta$ asymmetry ratio of forward (Au side) to backward (d side) is a characteristic of the collision system. STAR measured the ratio for these collisions as a function of $p_T$ (Fig. 8) [29]. As a surprising result, for $0 \leq |\eta| \leq 0.5$ the ratio is flat, but for $0.5 \leq |\eta| \leq 1.0$ the ratio shows a rising behaviour up to $p_T \approx 2-3$ GeV/c, followed by a descending slope for higher $p_T$. Fig. 8 also shows the comparison to model calculations, including (a) shadowing [7] and (b) saturation at high gluon densities. The data seem to support a saturation ansatz, which, in a geometrical picture, assumes that the probability that two gluons collide is one. $pA$ collisions will also be an important part of the future GSI accelerator facility FAIR at Darmstadt, Germany (Fig. 9), which will provide $p$ beams for fixed target experiments up to $6$ One the one hand, the $d$ beam has a charge/mass ratio close to the $Au$ beam. On the other hand the beam-beam interaction, which shortens the lifetime of a RHIC store, is in the case of $pAu$ a factor of $\approx 2$ higher than in the case of $dAu$.

$^7$ Shadowing is the depletion of parton distributions at small $x$ inside a nucleus.
90 GeV.

Figure 7. Pseudorapidity distribution for charged particles from $d+Au$ collisions at $\sqrt{s}=200$ GeV in BRAHMS \cite{27} for two different centralities, corresponding to two different impact parameter ranges.

Figure 8. Forward/backward pseudorapidity ratio vs. $p_T$ $d+Au$ collision at $\sqrt{s}=200$ GeV in STAR \cite{29}. For details see Ch. 6.

Another important class of forward reactions are ultra-peripheral $Au+Au$ collisions, in which the $Au$ nuclei interact by a very strong electromagnetic field ($10^{20}$ V/cm at the surface of the nuclei). Photons produced in these strong fields are peaked forward, and may create vector mesons by scattering off the $Au$ nuclei. Fig. 10 shows the differential cross section $d\sigma(\gamma Au\rightarrow\rho^0Au)/dt$ vs. the momentum transfer $t$. The very small $t$ values indicate the forward scattering. From an exponential fit (shown as line in Fig. 10) a forward cross section was determined to be

$$d\sigma/\sigma(t=0)=965\pm140\pm230 \text{ mb/GeV}^2.$$ Details are given elsewhere \cite{30}.

7. Charm cross sections

For high energy cosmic nuclear collisions in the galactic medium or the earth’s atmosphere, the knowledge of heavy quark production cross sections is very important. Both STAR \cite{31} and PHENIX \cite{32} have measured the charm cross section. Fig. 11 shows the total $c\bar{c}$ cross section per nucleon-nucleon collision vs. $\sqrt{s}$. There is a preliminary indication that the measured cross section is higher than the expected cross section extrapolation obtained from (a) PYTHIA Monte-Carlo simulation (based upon Lund fragmentation) \cite{33} and (b) a NLO QCD calculation \cite{34}.

Figure 10. Forward differential cross section $d\sigma(\gamma Au\rightarrow\rho^0Au)/dt$ vs. $t$ \cite{30}.

$\sigma|_{t=0}=965\pm140\pm230 \text{ mb/GeV}^2$. Details are given elsewhere \cite{30}.
Figure 11. Total $\pi^0$ cross section per nucleon-nucleon collision vs. $\sqrt{s}$. For details see [31].

8. Summary

In 4 years of operation, RHIC has collected a data set of millions of $p+p$, $d+Au$ and $Au+Au$ collisions. From the analysis we may conclude that a RHIC $Au+Au$ collision is a very hot and very dense hadronic system, which expands explosively with $v=0.56c$. During the short freeze-out the system undergoes a graceful QCD self-organisation, which could be successfully described by models based upon perturbative QCD. One of the most basic but also most important observations is that a $Au+Au$ collisions is not a simple superposition of $p+p$ collisions, but in fact the mean transverse momentum increases by $\approx 30\%$, indicating collective effects.
