Measurement of electrons from semileptonic heavy-flavour hadron decays at midrapidity in pp and Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

ALICE Collaboration

Abstract

The differential invariant cross section as a function of transverse momentum ($p_T$) of electrons from semileptonic heavy-flavour hadron decays was measured at midrapidity in proton–proton (pp) collisions at $\sqrt{s} = 5.02$ TeV in the $p_T$ interval 0.5–10 GeV/c, as well as the invariant yield in central (0–10%), semi-central (30–50%) and peripheral (60–80%) lead–lead (Pb–Pb) collisions at $\sqrt{s_{NN}} = 5.02$ TeV in the $p_T$ intervals 0.5–26 GeV/c (0–10% and 30–50%) and 0.5–10 GeV/c (60–80%). The modification of the electron yield with respect to what is expected for an incoherent superposition of nucleon–nucleon collisions is evaluated by measuring the nuclear modification factor $R_{AA}$. The measurement of the $R_{AA}$ in different centrality classes allows in-medium energy loss of charm and beauty quarks to be investigated. Moreover, the measured $R_{AA}$ is sensitive to the modification of the parton distribution functions (PDF) in nuclei, like nuclear shadowing, which causes a suppression of the heavy-quark production at low $p_T$ in heavy-ion collisions at LHC.
1 Introduction

The main goal of ALICE is the study of the Quark-Gluon Plasma (QGP), a state of matter which is expected to be created in ultra-relativistic heavy-ion collisions where high temperatures and high energy densities are reached at the LHC [1]. Due to their large masses \( m_c \approx 1.5 \text{ GeV}/c^2 \), \( m_b \approx 4.8 \text{ GeV}/c^2 \), charm and beauty quarks (heavy-flavour) are mostly produced via partonic scattering processes with high momentum transfer, which have typical time scales smaller than the QGP thermalisation time (1 fm/c [2]). Furthermore, additional thermal production, as well as annihilation rates, of charm and beauty quarks in the strongly-interacting matter are expected to be small in Pb–Pb collisions even at LHC energies [3, 4]. Consequently, charm and beauty quarks experience the full evolution of the hot and dense medium produced in high-energy heavy-ion collisions, therefore they are ideal probes to investigate the properties of the QGP.

Quarks and gluons interact strongly with the medium and they are expected to lose energy through elastic collisions [5, 6] and radiative processes [7, 8]. Quarks have a smaller colour coupling factor with respect to gluons, hence the energy loss for quarks is expected to be smaller than that for gluons. In addition, the dead-cone effect is expected to reduce small-angle gluon radiation for heavy quarks with moderate energy to mass ratio [9], thus further attenuating the effect of the medium. The combination of all these effects results in the observed hierarchical mass dependent energy loss [8, 10–18].

In order to quantify medium effects on heavy-flavour observables measured in heavy-ion collisions, they are compared with measurements in proton–proton (pp) collisions, where these effects are expected to be absent.

In pp collisions, heavy-quark production can be described by perturbative Quantum Chromodynamics (pQCD) calculations for all transverse momenta, whereas pQCD is not applicable for the calculation of light quark and gluon production at low transverse momenta [3]. Moreover, measurements of heavy-flavour production cross sections in pp collisions provide the necessary experimental reference for heavy-ion collisions.

The medium effects on heavy quarks are quantified through the measurement of the nuclear modification factor, defined as the ratio between the yield of particles produced in ion–ion collisions \( (d^2N_{AA}/dp_Tdy) \) and the cross section measured in proton-proton collisions at the same energy \( (d^2\sigma_{pp}/dp_Tdy) \), normalised by the average nuclear overlap function \( \langle T_{AA} \rangle \):

\[
R_{AA}(p_T,y) = \frac{1}{\langle T_{AA} \rangle} \frac{d^2N_{AA}/dp_Tdy}{d^2\sigma_{pp}/dp_Tdy}.
\]

The \( \langle T_{AA} \rangle \) is defined as the average number of nucleon–nucleon collisions \( \langle N_{\text{coll}} \rangle \), which can be estimated via Glauber model calculations [19, 20], divided by the inelastic nucleon-nucleon cross section. In-medium energy loss shifts the transverse momenta towards lower values, therefore at intermediate and high \( p_T (p_T \gtrsim 2 \text{ GeV}/c) \) a suppression of the production is expected (\( R_{AA} < 1 \)). Assuming the total cross section evaluated using \( \langle N_{\text{coll}} \rangle \) scaling is not modified, the nuclear modification factor is expected to increase towards lower \( p_T \), compensating the depletion at higher momenta. Such a rise was measured by the PHENIX and STAR experiments at RHIC in Au–Au and Cu–Cu collisions at \( \sqrt{s_{NN}} = 200 \text{ GeV} \) for electrons from heavy-flavour hadron decays [21, 22]. The nuclear modification factor for electrons from semileptonic heavy-flavour hadron decays was also measured by the ALICE collaboration in Pb–Pb collisions at \( \sqrt{s_{NN}} = 2.76 \text{ TeV} \) [23, 24], where the mentioned trend of \( R_{AA} \) was also observed. At low \( p_T \), the nuclear modification factor reaches a maximum around 1 GeV/c and tends to decrease at lower \( p_T \). This trend can be explained by initial and final state effects, like the collective expansion of the hot and dense system [25–27], the interplay between hadronisation via fragmentation and coalescence [28, 30] and the modification of the parton distribution functions (PDF) inside bound nucleons [31].

Initial-state effects at the LHC are explored with proton–nucleus collisions, where an extended QGP
phase is not expected to be formed. The nuclear modification factor of electrons from semileptonic heavy-flavour hadron decays and beauty decays in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV was found to be consistent with unity within uncertainties [14, 32, 33]. From this, one can conclude that the strong suppression observed in Pb–Pb collisions is due to substantial final-state interactions of heavy quarks with the QGP formed in these collisions. However, it is important to note that recently the measurement of the elliptic flow of electrons from semileptonic heavy-flavour hadron decays has been published [34, 35], showing intriguing and not yet fully understood collective effects in high-multiplicity p–Pb collisions in the heavy-flavour sector.

This paper reports the measurement of the production cross section in pp collisions, the invariant yields and the nuclear modification factor, $R_{AA}$, in Pb–Pb collisions as a function of $p_T$ of electrons from semileptonic heavy-flavour hadron decays at mid-rapidity at the centre-of-mass energy per nucleon pair $\sqrt{s_{NN}} = 5.02$ TeV.

2 Experimental apparatus and data sample

The ALICE detector is described in detail in Refs. [1, 36]. The experiment mainly consists of a central barrel at midrapidity ($|\eta| < 0.9$), embedded in a cylindrical solenoid which provides a magnetic field of 0.5 T parallel to the beam direction, and a muon spectrometer at forward rapidity ($-4 < \eta < -2.5$).

Charged particles produced in the collisions and originating from particle decays are tracked by the Inner Tracking System (ITS) [37] and the Time Projection Chamber (TPC) [38]. The ITS detector, composed of the Silicon Pixel Detector (SPD), Silicon Drift Detector (SDD), and Silicon Strip Detector (SSD), consists of six cylindrical silicon layers surrounding the beam vacuum pipe. These provide measurements of particle momenta and energy loss ($dE/dx$) used for charged-particle identification (PID), together with the TPC. The particle identification is complemented by a Time-Of-Flight (TOF) [39] detector, which measures the time-of-flight of charged particles. The TOF detector distinguishes electrons from kaons, protons, and pions up to $p_T \simeq 2.5$ GeV/c, $p_T \simeq 4$ GeV/c and $p_T \simeq 1$ GeV/c, respectively. The ElectroMagnetic Calorimeter (EMCal) [40] covers a pseudorapidity region of $|\eta| < 0.7$ and it is used to measure electrons, photons, and jets in an azimuthal region of $\sim 10^7\pi$. The electron identification in the EMCal is based on the measurement of the $E/p$ ratio, where $E$ is the energy of the EMCal cluster matched to the prolongation of the track with momentum $p$ reconstructed with the TPC and ITS detectors. The V0 detectors [41] consist of two arrays of 32 scintillator tiles covering the pseudorapidity ranges $2.8 < \eta < 5.1$ (V0A) and $-3.7 < \eta < -1.7$ (V0C), respectively, and are used for event characterisation.

The results presented in this paper are based on data samples of Pb–Pb collisions recorded in 2015 and of pp collisions at the same energy recorded in 2017. The analysed events were collected with a minimum bias (MB) trigger of a logic AND between the V0A and V0C detectors. Pb–Pb collisions were also recorded using the EMCal trigger, which requires an EMCal cluster energy summed over a group of $4 \times 4$ calorimeter cells larger than an energy threshold of 10 GeV. The EMCal triggered events were used for electron measurements for $p_T > 12$ GeV/c. The centrality classes were defined in terms of percentiles of the hadronic Pb–Pb cross section, defined by selections on the sum of the V0 signal amplitudes [42].

For both collision systems, only events with at least two tracks and a reconstructed primary vertex located between $\pm 10$ cm with respect to the nominal interaction point along the $z$-axis are considered. Events affected by pile-up from different bunch crossings were rejected [23]. The number of events analysed in the two collision systems with the different trigger configurations is summarised in Table [1] together with the average nuclear overlap function $\langle T_{AA} \rangle$ [42, 43].
Table 1: Number of events and $\langle T_{AA} \rangle$ [42, 43] used in the analysis, split by collisions system, trigger configuration, and centrality class.

| Centrality     | MB       | EMCal trigger | $\langle T_{AA} \rangle$ (mb$^{-1}$) |
|----------------|----------|---------------|--------------------------------------|
| pp 0–10%       | 6 $\times$ 10$^6$ | 1.2 $\times$ 10$^6$ | 23.26 $\pm$ 0.17                     |
| 30–50% Pb–Pb   | 12 $\times$ 10$^6$ | 0.3 $\times$ 10$^6$ | 3.917 $\pm$ 0.065                    |
| 60–80% Pb–Pb   | 12 $\times$ 10$^6$ | –              | 0.4188 $\pm$ 0.0106                  |

3 Data analysis

The $p_T$-differential yield of electrons from semileptonic heavy-flavour hadron decays is computed by measuring the inclusive electron yield and subtracting the contribution of electrons that do not originate from semileptonic heavy-flavour hadron decays. In the following, the inclusive electron identification strategy and the subtraction of electrons originating from background sources are described.

3.1 Track selection and electron identification

The selection criteria are similar to the ones described in Refs. [23, 24]. They are summarised together with the kinematic cuts applied in the analyses in Table 2.

It is important to note that only tracks that have hits on both SPD layers are accepted so that electrons from late photon conversions in the detector material are significantly reduced. In the Pb–Pb analysis for $p_T > 3$ GeV/$c$, also tracks with a single hit in the SPD are considered, since the amount of photonic background starts to become negligible. In the analysis in which the EMCal detector is used, specific track-cluster matching criteria are adopted.

Table 2: Track selection criteria used in the analyses. “DCA” is an abbreviation for “distance of closest approach” of a track to the primary vertex.

| Parameter                          | pp ($p_T < 3$ GeV/$c$) | Pb–Pb ($p_T > 3$ GeV/$c$) |
|------------------------------------|-------------------------|---------------------------|
| $|y|$                                | < 0.8                   | < 0.6                     |
| Number of clusters in TPC          | ≥ 100                   | ≥ 120                     |
| TPC clusters in $dE/dx$ calculation| ≥ 80                    | ≥ 80                      |
| Number of clusters in ITS          | ≥ 3                     | ≥ 4                       |
| Minimum number of clusters in SPD  | 2                       | 2                         |
| $|DCA_{xy}|$                         | < 1 cm                  | < 1 cm                    |
| $|DCA_z|$                           | < 2 cm                  | < 2 cm                    |
| Found / findable clusters in TPC   | > 0.6                   | > 0.6                     |
| $\chi^2$/clusters in TPC          | < 4                     | < 4                       |
| track-cluster matching in EMCal    | –                       | –                         |

As in the procedure followed in Refs. [23, 24], electron candidates are identified according to the criteria listed in Table 3. These requirements depend on the data sample and on the transverse momentum interval in which the analyses are performed.

The electron identification in pp collisions is performed by evaluating the signal from the TPC and TOF detectors. The discriminant variable in the former detector is the deviation of $dE/dx$ from the parameterised electron Bethe-Bloch [44] expectation value, expressed in units of the $dE/dx$ resolution, $\sigma_{TPC}$, while in the latter one the analogous variable $n_{\sigma_{TOF}}$, referring to the particle time-of-flight, is considered. The criterion $|n_{\sigma_{TOF}}| < 3$, used for electron identification up to $p_T = 3$ GeV/$c$, is required to reduce back-
ground from kaons and protons. A momentum dependent criterion on \( n^{TPC}_{\sigma, e} \) is adopted to guarantee a constant electron identification efficiency of 70% for \( p_T < 3 \text{ GeV/c} \) and of 50% for higher transverse momenta by reducing the selection window in \( n^{TPC}_{\sigma, e} \), in order to keep the hadron contamination sufficiently low. In the Pb–Pb analysis for \( p_T < 3 \text{ GeV/c} \), the electron identification is performed by applying the same requirement on TOF and due to the large densities of tracks, a selection between \(-4 < n^{ITS}_{\sigma, e} < 2\) on the energy deposited in the SDD and SSD detectors is applied in all centrality classes. Finally, the selection on \( n^{TPC}_{\sigma, e} \) ensures a constant electron identification efficiency of 50% for all centrality classes. The fraction of hadron contamination fraction after the PID is estimated by fitting the \( n^{TPC}_{\sigma, e} \) distribution for each particle species with an analytical function in different momentum intervals \([23, 24]\). The inclusive electron sample is then selected by applying a further criterion on \( n^{TPC}_{\sigma, e} \), which is chosen in order to have a constant efficiency as a function of the momentum, as well as to have the hadron contamination under control. This criterion is loosened for \( p_T > 3 \text{ GeV/c} \), due to the lower amount of selected hadrons when the EMCal detector is employed.

In the Pb–Pb analysis for \( p_T > 3 \text{ GeV/c} \), the electron candidates are first selected by the measurement of the TPC \( dE/dx \) with the criterion \(-1 < n^{TPC}_{\sigma, e} < 3\). Then, the selection \( 0.8 < E/p < 1.3\) on the energy over momentum ratio is applied. Unlike for hadrons, the ratio \( E/p \) is close to 1 for electrons because they deposit most of their energy in the EMCal. Furthermore, the electromagnetic showers of electrons are more circular than the ones produced by hadrons. Generally, the shower shape produced in the calorimeter has an elliptical shape which can be characterised by its two axes: \( \sigma_2 \) for the long, and \( \sigma_1 \) for the short axis. A rather lose selection of \( 0.01 < \sigma_2 < 0.35 \) is chosen, since it reduces the hadron contamination while at the same time it does not affect significantly the electron signal \([24]\). The residual hadron background in the electron sample is evaluated using the \( E/p \) distribution for hadron-dominated tracks selected with \( n^{TPC}_{\sigma, e} < -3.5 \). The \( E/p \) distribution of the hadrons is then normalised to match the distribution of the electron candidates in \( 0.4 < E/p < 0.7 \) (away from the true electron peak), so that the fraction of contaminating hadrons under the electron peak can be estimated.

In pp events, the hadron contamination is below 1% at low \( p_T \), while it reaches about 40% at \( p_T = 10 \text{ GeV/c} \). In Pb–Pb, the largest hadron contamination is measured in the most central collisions, where a contamination of about 7% and 10% due to kaon and proton crossing the electron band at \( p_T = 0.5 \text{ GeV/c} \) and \( p_T = 1 \text{ GeV/c} \), respectively, is present and it amounts to 5% at \( p_T = 3 \text{ GeV/c} \). The hadron contamination contribution tends to decrease towards more peripheral collisions. In the EMCal analysis a maximum residual contamination of about 10% is subtracted at the highest transverse momenta in the 0–10% centrality class. In both collision systems, the hadron contamination is subtracted statistically from the inclusive electron candidate yield.

In Pb–Pb collisions, the rapidity ranges used in the ITS-TPC-TOF \( (p_T < 3 \text{ GeV/c}) \) and TPC-EMCal \( (p_T > 3 \text{ GeV/c}) \) analyses are restricted to \(|y| < 0.8\) and \(|y| < 0.6\), respectively, to avoid the edges of the detectors, where the systematic uncertainties related to particle identification increase.

### 3.2 Subtraction of electrons from non heavy-flavour sources

The selected inclusive electron sample does not only contain electrons from open heavy-flavour hadron decays, but also different sources of background:

1. electrons from Dalitz decays of light neutral mesons, mainly \( \pi^0 \) and \( \eta \), and from photon conversions in the detector material as well as from thermal and hard scattering processes, called photonic in the following;

2. electrons from weak decays of kaons: \( \text{K}^{0/\pm} \rightarrow \text{e}^\pm \pi^{\mp}/\nu_e (K_{e3}) \);  

3. di-electron decays of quarkonia: \( J/\psi, \Upsilon \rightarrow \text{e}^+\text{e}^- \);
well as “high $p_T$” label is used in place of “$p_T > 3 \text{ GeV/c}$”, as well as “$p_T$” in place of “$p_T < 3 \text{ GeV/c}$”.

| Centrality | $n_{TPC}^{\text{TPC}}$ | $n_{TOF}^{\text{TOF}}$ | $n_{ITS}^{\text{ITS}}$ | $E/p$ | Shower shape |
|------------|-------------------------|-------------------------|-------------------------|-------|--------------|
| pp (low $p_T$) | – | $[-0.5 + f(p), 3]$ | $[-3, 3]$ | – | – |
| pp (high $p_T$) | – | $[0 + g(p), 3]$ | – | – | – |
| Pb–Pb (low $p_T$) | 0–10% | $[-0.16, 3]$ | $[-3, 3]$ | $[-4, 2]$ | – | – |
| Pb–Pb (high $p_T$) | 0–10% | $[0, 3]$ | $[0, 2, 3]$ | – | – |
| Pb–Pb (high $p_T$) | 30–50% | $[-1, 3]$ | – | – | [0.8, 1.3] | 0.01 < $\sigma_s^2$ < 0.35 |

4. di-electron decays of light vector mesons: $\omega, \phi, \rho_0 \rightarrow e^+e^−$;
5. electrons from W and Z/\gamma’.

The photonic tagging method \cite{23, 24, 32, 45, 46} is the technique adopted in the present analyses to estimate the contribution from photonic electrons. With a contribution of 80% to the inclusive electron sample, photonic electrons constitute the main background at $p_T = 0.5 \text{ GeV/c}$ \cite{23}. Their contribution decreases with $p_T$ reaching 25% at about 3 GeV/c. The contribution from di-electron decays of light vector mesons ($\rho, \omega$ and $\phi$) is negligible compared to the contributions from the photonic sources \cite{47}.

Photonic electrons are reconstructed statistically by pairing electron (positron) tracks with opposite charge tracks identified as positrons (electrons), called associated electrons in the following, forming the so-called unlike-sign pairs. The combinatorial background is subtracted using the like-sign invariant mass distribution in the same interval. Associated electrons are selected with the criteria listed in Table 4, which are intentionally looser than the ones applied for the inclusive electron selection, shown in Table 2, in order to maximise the probability to find the photonic partners.

Due to the limited acceptance of the detector and the rejection of some associated electrons by applying

| Associated electron | pp ($p_T < 3 \text{ GeV/c}$) | Pb–Pb ($p_T < 3 \text{ GeV/c}$) | Pb–Pb ($p_T > 3 \text{ GeV/c}$) |
|---------------------|-----------------------------|--------------------------------|--------------------------------|
| $p_T^{\text{min}} \text{(GeV/c)}$ | 0.1 | 0.1 | 0.2 |
| $|y|$ | < 0.8 | < 0.8 | < 0.9 |
| Number of clusters in TPC | ≥ 60 | ≥ 60 | ≥ 70 |
| TPC clusters in $dE/dx$ calculation | ≥ 60 | ≥ 60 | – |
| Number of clusters in ITS | ≥ 2 | ≥ 2 | ≥ 2 |
| $|\text{DCA}_{xy}|$ | < 1 cm | < 1 cm | < 2.4 cm |
| $|\text{DCA}_z|$ | < 2 cm | < 2 cm | < 3.2 cm |
| Found / findable clusters in TPC | > 0.6 | > 0.6 | – |
| $\chi^2/d.o.f$ TPC | < 4 | < 4 | < 4 |
| $n_{TPC}^{\text{TPC}}$ | $[-3, 3]$ | $[-3, 3]$ | $[-3, 3]$ |
| $m_{e^+e^-} \text{(MeV/c^2)}$ | < 140 | < 140 | < 100 |
the mentioned criteria, a certain fraction of photon pairs is not reconstructed. Therefore, the raw yield of tagged photon pairs is corrected for efficiency to find the associated electron (positron), the so-called “tagging efficiency ($\varepsilon_{\text{tag}}$). This is evaluated using Monte Carlo (MC) simulations; pp and Pb–Pb collisions are simulated by the PYTHIA 6 [48] and HIJING [49] event generators, respectively. Primary particle generation is followed by particle transport with GEANT3 [50] and a detailed detector response simulation and reconstruction. The tagging efficiency is defined as the ratio of the number of true reconstructed unlike-sign pair electrons and the number of those generated in the simulations. The simulated $p_T$ distributions of $\pi^0$ or $\eta$ mesons are weighted in MC to match the measured spectra. In both pp and Pb–Pb collisions, the weighting factor for $\pi^0$ is provided by using the measured distributions of charged pions [51]. The weighting factor for $\eta$ mesons is computed using an $m_T$-scaling approach [52, 53]. The total tagging efficiency has a monotonic trend. In pp collisions, it starts at 0.4 for $p_T = 0.5$ GeV/$c$ and rises until $p_T = 3$ GeV/$c$, where it flattens at 0.7. In Pb–Pb collisions, it follows the same trend, increasing from 0.3 to 0.7 in the same $p_T$ range.

It was observed in the previous analysis [23] that the contribution from $J/\psi$ decays reaches a maximum of around 5% in the region $2 < p_T < 3$ GeV/$c$ in central Pb–Pb collisions, decreasing to a few percent in more peripheral events. At lower and higher momenta, this contribution quickly decreases and becomes negligible, hence it is not subtracted in the present analyses. The associated systematic uncertainty is taken from similar works [23, 24]. Due to the requirement of hits in both pixel layers, it was also observed from similar studies in previous measurements [23] that the relative contribution from $K_{c\bar{s}}$ decays to the electron background is negligible, hence this contribution is not subtracted in the present analyses. Additional sources of background, such as electrons from $W$ and $Z/\gamma'$ decays, are subtracted from the fully corrected and normalised electron yield in Pb–Pb collisions at high $p_T$. These contributions are obtained from calculations using the POWHEG event generator [54] for pp collisions and scaling it by $\langle N_{\text{coll}} \rangle$, assuming $R_{AA} = 1$. The contribution from $W$ decays increases from 1% at $p_T = 10$ GeV/$c$ to about 20% at $p_T = 25$ GeV/$c$ in the 0–10% centrality class, while the $Z$ contribution reaches about 10% at the same transverse momentum.

### 3.3 Efficiency correction and normalisation

After the statistical subtraction of the hadron contamination and the background from photon pairs, the raw yield of electrons and positrons in bins of $p_T$ is divided by the number of analysed events ($N_{\text{ev}}$), by the transverse momentum value at the bin centre $p_T^{\text{geo}}$ and the bin width $\Delta p_T$, by the width $\Delta y$ of the covered rapidity interval, by the geometrical acceptance ($\varepsilon_{\text{geo}}$) times the reconstruction ($\varepsilon_{\text{reco}}$) and PID efficiencies ($\varepsilon_{\text{ID}}$), and by a factor of two to obtain the charge averaged invariant differential yield, since in the analyses the distinction between positive and negative charges is not done:

$$\frac{1}{2p_T \Delta p_T \Delta y} \frac{d^2N_{\text{ev}}^{\varepsilon}}{d^2y} = \frac{1}{2p_T^{\text{geo}}N_{\text{MB}}^{\varepsilon_{\text{reco}}}} \frac{1}{\Delta y} \frac{1}{\Delta p_T} \frac{N_{\text{ev}}^{\varepsilon_{\text{reco}}}(p_T)}{\varepsilon_{\text{geo}} \times \varepsilon_{\text{reco}} \times \varepsilon_{\text{ID}}}.$$  

(2)

The production cross section in pp collisions is calculated by multiplying the invariant yield of Eq. (2) by the minimum bias trigger cross section at $\sqrt{s} = 5.02$ TeV, that is 50.9 ± 0.9 nb [55]. The per-event yield of electrons from the EMCal triggered sample was scaled to the minimum bias yield by normalisation factors determined with a data-driven method, as described in Ref. [24]. The normalisation is $64.5 \pm 0.5$ in 0–10% and $246 \pm 2.6$ in 30–50% centrality intervals, respectively.

The efficiencies are determined using specific MC simulations, where every collision event is produced with at least either a $c\bar{c}$ or $b\bar{b}$ pair and heavy-flavour hadrons are forced to decay semileptonically to electrons [23, 24]. The underlying Pb–Pb events were simulated using the HIJING generator [49] and heavy-flavour signals were added using the PYTHIA 6 generator [48]. The efficiency of reconstructing electrons from semileptonic heavy-flavour hadron decays is about 20% at $p_T = 0.5$ GeV/$c$, then it increases with $p_T$ up to 58% in pp collisions. In Pb–Pb collisions, it follows the same trend, increasing from 5% to 10% in the same $p_T$ range.
3.4 Systematic uncertainties

The overall systematic uncertainties on the $p_T$ spectra are calculated summing in quadrature the different uncorrelated contributions, which are summarised in Table 5 and discussed in the following.

The systematic uncertainties on the total reconstruction efficiency arising from the comparison between MC and data are estimated by varying the track selection and PID requirements around the default values chosen in the analyses. The analysis is repeated with tighter and looser conditions with respect to the default selection criteria and the systematic uncertainty is calculated as the root mean square (RMS) of the distribution of the resulting corrected yields (or cross sections in pp) in each centrality and $p_T$ interval. The systematic uncertainty estimated in pp collisions is less than 2%, while in Pb–Pb collisions it reaches a maximum value of 4% in 0–10% centrality class for $p_T < 0.9$ GeV/c.

Similarly, the systematic uncertainty arising from the photonic-electron subtraction technique is estimated as the RMS of the distribution of yields obtained by varying the selection criteria listed in Table 4. In pp collisions this contribution has a maximum of 4% for $0.5 < p_T < 0.7$ GeV/c and then it gradually decreases with increasing $p_T$, while in the 0–10% Pb–Pb centrality class it is the dominant source of systematic uncertainty, being 13% in the first $p_T$ interval. This systematic uncertainty mainly arises when the invariant mass criterion on the photonic pairs is varied and it reflects the large contribution of photonic electrons in the low-$p_T$ region.

In order to further test the robustness of the photonic electron tagging, the requirement on the number of clusters for electron candidates in the SPD is relaxed in order to increase the fraction of electrons coming from photon conversions in the detector material. A variation of 3% is observed for the measured pp cross section in the full $p_T$ range, while in central Pb–Pb collisions the observed deviation amounts to 10% for $0.5 < p_T < 0.7$ GeV/c, decreasing with increasing $p_T$. This systematic uncertainty is less relevant in semi-central collisions, and it is compatible with the variation determined in pp measurements for $1.5 < p_T < 3$ GeV/c.

In addition, the systematic uncertainty related to the subtraction of the background electrons from W and Z/$\gamma^*$ is estimated by propagating 15% of uncertainty, which quantifies the difference between the measurements and the theoretical calculations [56, 57]. The uncertainty from the subtraction on the final result is less than 4% for electrons from semileptonic heavy-flavour hadron decays in central (0–10%) Pb–Pb collisions, and less than 1% in other centrality classes for $24 < p_T < 26$ GeV/c. In the pp analysis, a 5% systematic uncertainty is found while varying the selection criterion in the TPC for $p_T > 8$ GeV/c due to the increasing relative amount of hadrons. An additional systematic uncertainty of 5% is assigned in $8 < p_T < 10$ GeV/c, related to the precision that can be achieved in estimating the hadron contamination in this momentum region (about 40% at $p_T = 10$ GeV/c) with a proper analytical function. In Pb–Pb collisions, a 10% systematic uncertainty is assigned for $p_T > 12$ GeV/c due to the variation of electron identification in the TPC, while this contribution does not rise above 5% at lower $p_T$. Moreover, an additional 6% is assigned due to the $E/p$ selection criterion. Finally, for $p_T < 3$ GeV/c, different functional forms are used for the parametrisation of the pion contribution in the fitting procedure adopted to evaluate the hadron contamination. A systematic uncertainty of about 6% is assigned for $p_T < 3$ GeV/c in the 0–10% centrality class, while the contribution of hadron contamination tends to decrease for more peripheral collisions.

In the pp (Pb–Pb) analysis, a systematic uncertainty of about 2% (3%) is assigned due to the incomplete knowledge of the efficiency in matching tracks reconstructed in the ITS and TPC and another 2% (5%) for the track matching between TPC and TOF.

The effects due to the presence of non-uniformity in the correction for the space-charge distortion in the TPC drift volume or irregularities in the detector coverage are then evaluated by repeating the analysis in different geometrical regions. In pp collisions, a maximum systematic uncertainty of 5% is assigned...
when varying the pseudorapidity range used for the cross section measurement. The same value is assigned in the 30–50% and 60–80% Pb–Pb centrality intervals, while a 10% systematic uncertainty is assigned for 0.5 < \( p_T \) < 0.7 GeV/c in the 0–10% centrality interval. An additional uncertainty of 10% for \( p_T < 1 \) GeV/c and of 5% up to \( p_T = 3 \) GeV/c is assigned to the final measurement in central Pb–Pb collisions when varying the azimuthal region. Furthermore, the analysis of Pb–Pb collisions is repeated using different interaction rate regimes. A 5% deviation is observed at low \( p_T \) in central Pb–Pb collisions when selecting only high (> 5 kHz) or low (< 5 kHz) interaction rate events.

The uncertainty from the EMCal trigger normalisation in Pb–Pb collisions at \( p_T > 12 \) GeV/c is estimated as the RMS of the rejection factor values computed at different transverse momenta [24]. The RMS is 4% and assigned as the systematic uncertainty.

The uncertainties on the \( R_{\text{AA}} \) normalisation are the quadratic sum of the uncertainties on the average nuclear overlap functions in Table 1, the normalisation uncertainty due to the luminosity and the uncertainty related to the determination of the centrality intervals, which reflects the uncertainty on the fraction of the hadronic cross section used in the Glauber fit to determine the centrality [16, 58].

Table 5: Contributions to the systematic uncertainties on the cross section (yield) of electrons from heavy-flavour hadron decays in pp (Pb–Pb) collisions, quoted for the transverse momentum intervals 0.5 < \( p_T < 0.7 \) GeV/c and 8 < \( p_T < 10 \) GeV/c. These \( p_T \) intervals are listed because the detectors used for particle identification in the two cases are different. In addition, they also represent the first and the last \( p_T \) intervals in the centrality classes in Pb–Pb collisions, as well as for the pp cross section. The uncertainties quoted with * are not summed in quadrature together with those from the other sources listed in the table.

4 Results

4.1 \( p_T \)-differential cross section in pp collisions and invariant yield in Pb–Pb collisions

The \( p_T \)-differential production cross section of electrons from semileptonic heavy-flavour hadron decays in pp collisions at \( \sqrt{s} = 5.02 \) TeV is shown in Fig. 1. The data in the region 0.5 < \( p_T < 10 \) GeV/c is compared with the Fixed-Order-Next-to-Leading-Log (FONLL) [59] pQCD calculation. The uncertainties of
the FONLL calculations (dashed area) reflect different choices for the charm and beauty quark masses, the factorisation and renormalisation scales as well as the uncertainty on the set of parton distribution functions (PDF) used in the pQCD calculation (CTEQ6.6 [60]). The measured cross section is close to the upper edge of the theoretical prediction up to $p_T \sim 5 \text{ GeV}/c$, as observed in pp collisions at $\sqrt{s} = 2.76$ and 7 TeV [23, 45, 47, 61]. While at higher $p_T$, where electrons from semileptonic beauty hadron decays are expected to dominate, the measurement is close to the mean value of the FONLL prediction.

The $p_T$-differential invariant yield of electrons from semileptonic heavy-flavour hadron decays measured in central (0–10%), semi-central (30–50%), and peripheral (60–80%) Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02 \text{ TeV}$ is shown in Fig. 2. The measurements are performed in the $p_T$ interval 0.5–20 GeV/c in the 0–10% and in the 30–50% centrality intervals, and only up to $p_T = 10 \text{ GeV}/c$ in the 60–80% centrality class due to limited statistics in Pb–Pb data recorded in 2015.

![Figure 1: $p_T$-differential invariant production cross section of electrons from semileptonic heavy-flavour hadron decays in pp collisions at $\sqrt{s} = 5.02 \text{ TeV}$. The measurement is compared with the FONLL calculation [59]. In the bottom panel, the ratios with respect to the central values of the FONLL calculation are shown. An additional 2.1% normalisation uncertainty, due to the measurement of the minimum bias triggered cross section [42], is not shown in the results.](image)

4.2 Nuclear modification factor

The nuclear modification factor of electrons from semileptonic heavy-flavour hadron decays measured in central (0–10%), semi-central (30–50%), and peripheral (60–80%) Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02 \text{ TeV}$ is shown in Fig. 3. The measured cross section in pp collisions at $\sqrt{s} = 5.02 \text{ TeV}$ (Fig. 1) is used as a reference up to $p_T = 10 \text{ GeV}/c$. For $p_T > 10 \text{ GeV}/c$, the reference is obtained by a $p_T$-dependent scaling of the measurement at $\sqrt{s} = 7 \text{ TeV}$ by the ATLAS collaboration [62] with the ratio of the cross section at the two collision energies computed with the FONLL calculation [63]. The calculation at $\sqrt{s} = 7 \text{ TeV}$ is performed by considering the different rapidity coverage of the ATLAS measurement. The systematic
Measurement of electrons from semileptonic heavy-flavour hadron decays

ALICE Collaboration

Figure 2: $p_T$-differential invariant yield in central (0–10%), semi-central (30–50%), and peripheral (60–80%) Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV.

uncertainties of the cross section at $\sqrt{s} = 5.02$ TeV are computed as the propagation of the uncertainties associated with FONLL calculations at $\sqrt{s} = 5.02$ TeV and $\sqrt{s} = 7$ TeV and the systematic uncertainties of the ATLAS measurement. The statistical uncertainties are from the ATLAS measurement.

Statistical and systematic uncertainties of the $p_T$-differential yields and cross sections in Pb–Pb and pp collisions, respectively, are propagated as uncorrelated uncertainties. The uncertainties on the $R_{AA}$ normalisation are reported in Fig. 3 as boxes at unity. The measured $R_{AA}$ shows a clear dependence on the collision centrality, since in most central events it reaches a minimum of about 0.3 around $p_T = 7$ GeV/c, while moving to more peripheral Pb–Pb collisions the $R_{AA}$ gets closer to unity at $p_T > 3$ GeV/c. Such a suppression is not observed in proton-lead collisions at the same energy where the QGP is not expected to be formed and the nuclear modification factor is consistent with unity [14, 32, 33]. Thus the suppression of electron production is due to final-state effects, such as partonic energy loss in the medium. Since electrons from semileptonic beauty decays are expected to dominate the spectrum at high $p_T$ while charm production dominates at low $p_T$ [14], the measurements show that charm and beauty quarks lose energy in the medium. The centrality dependence of the $R_{AA}$ is compatible with the hypothesis of a partonic energy loss dependence on medium density, being larger in a hotter and denser QGP, like the one created in the most central collisions. In addition, it reflects a path-length dependence of energy loss. Moreover, it has been shown in Refs. [64, 65] that a centrality selection bias is present in peripheral Pb–Pb collisions which reduces the $R_{AA}$ below unity even in the absence of any nuclear modification effects. This effect may be responsible for a significant part of the apparent suppression seen in the $R_{AA}$ of electrons from semileptonic heavy-flavour hadron decays in the 60-80% centrality class.

For $p_T < 7$ GeV/c, the $R_{AA}$ of electrons from semileptonic heavy-flavour hadron decays increases with decreasing $p_T$ as a consequence of the scaling of the total heavy-flavour yield with the number of binary collisions among nucleons in Pb–Pb collisions. On the other hand, the nuclear modification factor at low $p_T$ does not rise above unity. This kinematic region is sensitive to the effects of nuclear shadowing: the depletion of parton densities in nuclei at low Bjorken $x$ values can reduce the heavy-quark production cross section per binary collision in Pb–Pb with respect to the pp case [23]. This initial-state effect is studied in p–Pb collisions, however, the present uncertainties on the $R_{pPb}$ measurement do not allow quantitative conclusions on the modification of the PDF in nuclei in the low $p_T$ region to be made [32]. Furthermore, the amount of electrons from semileptonic heavy-flavour hadron decays is reduced due to the presence of hadrochemistry effects. For example, $\Lambda^+_c$ baryons decay into electrons with a branching...
ratio of 5%, while for the D mesons the branching ratio is less than 10%. Since in Pb–Pb collisions more charm quarks might hadronize into baryons [66], this effect reduces the total amount of electrons from semileptonic heavy-flavour hadron decays. Additional effects, such as collective motion induced by the medium, also have an influence on the measured $R_{AA}$. Also, it has been observed that the radial flow can provoke an additional yield enhancement at intermediate $p_T$ [67]. In this case, the radial flow pushes up slow particles to higher momenta, causing a small increase in the nuclear modification factor around $p_T = 1 \text{ GeV}/c$.

![Figure 3](image.png)

**Figure 3:** Nuclear modification factor of electrons from semileptonic heavy-flavour hadron decays measured in the three centrality intervals in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02 \text{ TeV}$.

It should be noted that the $R_{AA}$ measurements in the most central collisions at $\sqrt{s_{NN}} = 2.76 \text{ TeV}$ [23] and 5.02 TeV are compatible within uncertainties. This effect was predicted by the Djordjevic model [68], and it results from the combination of a higher medium temperature at 5.02 TeV, which would decrease the $R_{AA}$ by about 10%, with a harder $p_T$ distribution of heavy quarks at 5.02 TeV, which would increase the $R_{AA}$ by about 5% if the medium temperature were the same as at 2.76 TeV. An analogous behaviour between the measured $R_{AA}$ at the two energies is also observed for the D mesons [16].

### 4.3 Comparison with model predictions

In Fig. 4 the measured $R_{AA}$ in the 0–10% (left panel) and 30–50% (right panel) centrality intervals are compared with model calculations [68–75]. The model calculations take into account different hypotheses about mass dependence of energy loss processes, transport dynamics, charm and beauty quark interactions with the QGP constituents, hadronisation mechanisms of heavy quarks in the plasma, and heavy-quark production cross section in nucleus–nucleus collisions.

Most of the models provide a fair description of the data in the region $p_T < 5 \text{ GeV}/c$ in both centrality classes, except for BAMPS [70]. The predictions from the MC@shHQ+EPOS2 [75], PHSD [71], TAMU [72], and POWLANG [74] models also include nuclear modification of the parton distribution functions, which is necessary to predict the observed suppression of the $R_{AA}$ at low $p_T$. The following observations about the comparison with model calculations are fully in agreement with what is observed in the $R_{AA}$ measurements of D mesons [16].

The nuclear modification factor for central Pb–Pb collisions is well described by the TAMU [72] prediction at $p_T < 3 \text{ GeV}/c$ within the uncertainties related to the shadowing effect on charm quarks. However, this model tends to overestimate the $R_{AA}$ for $p_T > 3 \text{ GeV}/c$, probably due to the missing implementation of the radiative energy loss in the model, which becomes the dominant energy loss mechanism at high $p_T$. 

12
The agreement with TAMU [72] at low $p_T$, on the other hand, confirms the dominance of elastic collisions at low momenta, together with the importance of the inclusion of shadowing effects in the model calculations [31], which reduce the total heavy-flavour production in Pb–Pb collisions with respect to an expectation from the binary scaling.

In semi-central Pb–Pb collisions the TAMU [72] and POWLANG [74] predictions are close to the lower edge of the uncertainties of the measured $R_{AA}$ for $p_T < 3$ GeV/c. The latter calculation describes the data better up to $p_T \approx 8$ GeV/c, while the former provides a good description even at higher transverse momenta. The CUJET3.0 [69] and Djordjevic [68, 73] models provide a good description of the $R_{AA}$ within the uncertainties in both centrality intervals for $p_T > 5$ GeV/c, suggesting that the dependence of radiative energy loss on the path length in the hot and dense medium is well understood.

[Figure 4: Nuclear modification factor of electrons semileptonic from heavy-flavour hadron decays measured in 0–10% and 30–50% centrality in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV compared with model predictions [68–75].]

5 Conclusions

The invariant yield of electrons from semileptonic heavy-flavour hadron decays was measured in central (0–10%), semi-central (30–50%), and peripheral (60–80%) Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV. The measurement of the nuclear modification factor in all the centrality classes is provided using as reference the cross section measured in pp collisions at the same centre-of-mass energy. The systematic uncertainties of this measurement are reduced by a factor of about 2 compared to the published reference in pp collisions at $\sqrt{s} = 2.76$ TeV [24] and the measured cross section is close to the upper edge of the FONLL uncertainty band. As in the Pb–Pb analysis at $\sqrt{s_{NN}} = 2.76$ TeV [23, 24], the main source of background electrons, constituted by photonic electrons, is removed via the photonic tagging method. In addition, compared with the measurements performed in pp and Pb–Pb collisions at 2.76 TeV, the $p_T$ range is extended, and an additional centrality class is added.

The measured $R_{AA}$ confirms the evidence of a strong suppression with respect to what is expected from a simple binary scaling for large $p_T$. This is a clear signature of the medium induced energy loss on heavy quarks traversing the QGP produced in heavy-ion collisions.

The measurement of electrons from semileptonic heavy-flavour hadron decays in different centrality classes exhibits the dependence of energy loss on the path length and energy density in the hot and dense medium. The $R_{AA}$ at high $p_T$ (above 5 GeV/c) is fairly described in the 0–10% and 30–50% centrality
intervals by model calculations that include both radiative and collisional energy loss. This indicates that the centrality dependence of radiative energy loss is theoretically understood. Further investigations and measurement of electrons from semileptonic decays of beauty hadrons will give more information about the mass dependence of the energy loss in the heavy-flavour sector.

With the good precision of the results presented here, the Pb–Pb data exhibit their sensitivity to the modification of the PDF in nuclei, like nuclear shadowing, which causes a suppression of the heavy-quark production at low \( p_T \) in heavy-ion collisions. The implementation of the nuclear modification of the PDF in theoretical calculations is a necessary ingredient in order for the model predictions to correctly describe the measured \( R_{AA} \) [23].

Measurement of electrons from semileptonic heavy-flavour hadron decays

ALICE Collaboration

5 California Polytechnic State University, San Luis Obispo, California, United States
6 Central China Normal University, Wuhan, China
7 Centre de Calcul de l’IN2P3, Villeurbanne, Lyon, France
8 Centro de Aplicaciones Tecnológicas y Desarrollo Nuclear (CEADEN), Havana, Cuba
9 Centro de Investigación y de Estudios Avanzados (CINVESTAV), Mexico City and Mérida, Mexico
10 Centro Fermi - Museo Storico della Fisica e Centro Studi e Ricerche “Enrico Fermi’, Rome, Italy
11 Chicago State University, Chicago, Illinois, United States
12 China Institute of Atomic Energy, Beijing, China
13 Chonbuk National University, Jeonju, Republic of Korea
14 Comenius University Bratislava, Faculty of Mathematics, Physics and Informatics, Bratislava, Slovakia
15 COMSATS University Islamabad, Islamabad, Pakistan
16 Creighton University, Omaha, Nebraska, United States
17 Department of Physics, Aligarh Muslim University, Aligarh, India
18 Department of Physics, Pusan National University, Pusan, Republic of Korea
19 Department of Physics, Sejong University, Seoul, Republic of Korea
20 Department of Physics, University of California, Berkeley, California, United States
21 Department of Physics, University of Oslo, Oslo, Norway
22 Department of Physics and Technology, University of Bergen, Bergen, Norway
23 Dipartimento di Fisica dell’Università ‘La Sapienza’ and Sezione INFN, Rome, Italy
24 Dipartimento di Fisica dell’Università and Sezione INFN, Cagliari, Italy
25 Dipartimento di Fisica dell’Università and Sezione INFN, Trieste, Italy
26 Dipartimento di Fisica dell’Università and Sezione INFN, Turin, Italy
27 Dipartimento di Fisica e Astronomia dell’Università and Sezione INFN, Bologna, Italy
28 Dipartimento di Fisica e Astronomia dell’Università and Sezione INFN, Catania, Italy
29 Dipartimento di Fisica e Astronomia dell’Università and Sezione INFN, Padova, Italy
30 Dipartimento di Fisica ‘E.R. Caianiello’ dell’Università and Gruppo Collegato INFN, Salerno, Italy
31 Dipartimento DISAT del Politecnico and Sezione INFN, Turin, Italy
32 Dipartimento di Scienze e Innovazione Tecnologica dell’Università del Piemonte Orientale and INFN Sezione di Torino, Alessandria, Italy
33 Dipartimento Interateneo di Fisica ‘M. Merlin’ and Sezione INFN, Bari, Italy
34 European Organization for Nuclear Research (CERN), Geneva, Switzerland
35 Faculty of Electrical Engineering, Mechanical Engineering and Naval Architecture, University of Split, Split, Croatia
36 Faculty of Engineering and Science, Western Norway University of Applied Sciences, Bergen, Norway
37 Faculty of Nuclear Sciences and Physical Engineering, Czech Technical University in Prague, Prague, Czech Republic
38 Faculty of Science, P.J. Šafárik University, Košice, Slovakia
39 Frankfurt Institute for Advanced Studies, Johann Wolfgang Goethe-Universität Frankfurt, Frankfurt, Germany
40 Gangneung-Wonju National University, Gangneung, Republic of Korea
