Deadenylation of maternal mRNAs during *Xenopus* oocyte maturation does not require specific cis-sequences: a default mechanism for translational control

The meiotic maturation of *Xenopus* oocytes initiates significant changes in the translation of a number of maternal mRNAs that coincide with alterations in their polyadenylation states. A considerable number of maternal mRNAs are deadenylated in mature oocytes, thereby reducing their translational efficiencies. In this report we demonstrate that deadenylation does not require specific cis-acting sequences. Polyadenylated RNAs derived from either ribosomal protein or β-globin mRNAs, or that contain non-mRNA-derived sequences, are deadenylated in mature oocytes. Translation of a substrate RNA is not required for its deadenylation. G10 mRNA is representative of a class of mRNAs that is translationally activated at maturation and contains the cytoplasmic polyadenylation element (U)P AU. A deletion mutant G10 transcript that lacks the (U)P AU element is not polyadenylated in mature oocytes but is deadenylated instead. Insertion of the (U)P AU element into the 3'-untranslated region of the ribosomal protein L1 mRNA is sufficient to prevent both its deadenylation and polysomal release in mature oocytes. These results indicate that the deadenylation and translational inactivation of maternal mRNAs during *Xenopus* oocyte maturation occur by a default pathway in which transcripts lacking a cytoplasmic polyadenylation element undergo poly(A) removal.

Received August 22, 1990; revised version accepted October 11, 1990.

A large pool of maternal mRNAs is synthesized and sequestered during *Xenopus* oogenesis. The stage-specific post-transcriptional and -translational regulation of these stored mRNAs determines all protein synthesis between the meiotic maturation of fully grown oocytes and development of the 4000-cell blastula embryo when zygotic transcription is initiated (for review, see Davidson 1986). The induction of oocyte maturation in several organisms initiates significant changes in the translational utilization of a number of maternal mRNAs that coincide with alterations in their polyadenylation states (for reviews, see Jackson and Standart 1990; Wickens 1990).

In *Xenopus*, a considerable number of maternal mRNAs are deadenylated in mature oocytes, thereby reducing the total poly(A) content by ~40% (Sagata et al. 1980). In general, this deadenylation correlates with markedly reduced translational efficiencies, as observed for the mRNAs encoding cytoskeletal actin (Sturgess et al. 1980), ribosomal proteins (Hyman and Wormington 1988), and translation elongation factor 1α (Wormington 1989). The core histone mRNAs are an exception to this correlation because their translation increases significantly after maturation despite their deadenylation (Ruderman et al. 1979). Conversely, the translational activation of maternal mRNAs such as D7, G10, and c-mos in mature oocytes correlates with their cytoplasmic polyadenylation (Dworkin and Dworkin-Rastl 1985; Dworkin et al. 1985; Sagata et al. 1988; Fox et al. 1989; McGrew et al. 1989). The translational activity of a third class of maternal mRNAs that includes histone H1 (Woodland et al. 1979), fibronectin (Lee et al. 1984), lamin (Stick and Hansen 1985), and c-myc (Taylor et al. 1986) is not altered during maturation.

The cis-acting sequence requirements for maturation-specific changes in the polyadenylation and translation of maternal mRNAs have been investigated by the microinjection of synthetic RNAs into *Xenopus* oocytes. The cytoplasmic polyadenylation and translational activation of synthetic D7 and G10 mRNAs during oocyte maturation require two discrete cis-acting elements, a U-rich sequence referred to hereafter as the cytoplasmic polyadenylation element. Insertion of this element into the 3'-untranslated region of a substrate mRNA is sufficient to cause its deadenylation and translation inactivation in mature oocytes. These results indicate that the deadenylation and translational inactivation of maternal mRNAs during *Xenopus* oocyte maturation occur by a default pathway in which transcripts lacking a cytoplasmic polyadenylation element undergo poly(A) removal.

polyadenylation element (CPE), and the ubiquitous nuclear polyadenylation signal [AAUAAA], which are present in the 3'-untranslated regions of these mRNAs (Fox et al. 1989; McGrew et al. 1989; McGrew and Richter 1990). These sequences are sufficient to confer maturation-specific polyadenylation and increased translation when fused to a Xenopus β-globin mRNA that is otherwise not subject to this regulation (McGrew et al. 1989). In the case of G10 mRNA, it appears that the actual process of polyadenylation and not the presence of a poly(A) tail per se is required for its translational activation (McGrew et al. 1989). U-rich sequences that closely resemble the CPEs found in G10 and D7 mRNAs are also present in the 3'-untranslated regions of additional transcripts that are polyadenylated during oocyte maturation in Xenopus as well as in other organisms (Fox et al. 1989; McGrew et al. 1989; McGrew and Richter 1990; Paris and Richter 1990).

Initial studies from our laboratory showed that a synthetic ribosomal protein (r-protein) L1 mRNA, when microinjected into stage VI oocytes, is deadenylated and released from polysomes simultaneously with the translational inactivation of endogenous r-protein mRNAs upon maturation (Hyman and Wormington 1988). These studies also indicated that sequences located within 387 nucleotides of the 3' end of the L1 mRNA direct maturation-specific deadenylation and polysomal release when fused to Xenopus β-globin mRNA. In this report we have extended these studies to address the sequence specificity of deadenylation. We demonstrate that deadenylation does not require specific cis-acting sequences. Polyadenylated RNAs that are derived from either r-protein or β-globin mRNAs or that contain a homopolymer sequence are deadenylated in mature oocytes. A deletion mutant G10 mRNA that lacks the CPE, [U]aAU, is neither polyadenylated nor associated with polysomes in mature oocytes but is deadenylated. Insertion of the [U]aAU element into the 3'-untranslated region of the r-protein L1 mRNA is sufficient to prevent both its deadenylation and polysomal release in mature oocytes. These results indicate that the deadenylation and translational inactivation of maternal mRNAs during Xenopus oocyte maturation occur by a default pathway in which transcripts lacking a CPE undergo poly(A) removal.

Results

Deadenylation and polysomal release of a synthetic r-protein S22 mRNA in mature oocytes

Our initial studies showed that an SP6-derived L1 mRNA was deadenylated and released from polysomes after the maturation of microinjected oocytes, thereby mimicking the translational inactivation of endogenous r-protein mRNAs (Hyman and Wormington 1988). To extend these analyses, the regulation of an SP6-derived r-protein S22 mRNA was also characterized in microinjected oocytes (Fig. 1A). The polyadenylation state and translation of the SP6-derived S22 mRNA were determined before and after progesterone-induced maturation in vitro. Figure 1B shows that the microinjected SP6-derived S22 transcript was reduced in length after oocyte maturation. To confirm that this transcript was deadenylated, total RNA was extracted from microinjected stage VI and mature oocytes, hybridized to oligo(dT), and incubated with RNase H (+RNase H lanes). RNAs were electrophoresed on a 4% polyacrylamide–urea gel. Treatment of the stage VI oocyte cytoplasmic extract with EDTA prior to centrifugation through the 20% sucrose cushion resulted in the complete release of S22 mRNA from the polysomal pellet (P) into the nonpolysomal (NP) supernatant.

Figure 1. Deadenylation and polysome release of S22 mRNA.

(A) Schematic of pS22 that contains a full-length S22 cDNA. Radiolabeled SP6-derived S22 mRNA with a poly(A) tail was synthesized from a template linearized with SacI and 3'-protruding ends removed by T4 DNA polymerase. SP6 RNA was microinjected into the cytoplasm of stage VI oocytes that were incubated in either the presence or absence of 1 μg/ml of progesterone. (B) Total RNA was isolated from stage VI (VI lanes) and mature oocytes (Mat lanes). In some cases, total RNA was hybridized to oligo(dT) and incubated with RNase H (+RNase H lanes). RNAs were electrophoresed on a 4% polyacrylamide–urea gel. (C) Polyosomal (P) and nonpolyosomal (NP) RNA was isolated from stage VI and mature oocytes and electrophoresed on a 1.3% agarose–formaldehyde gel. Treatment of the stage VI oocyte cytoplasmic extract with EDTA prior to centrifugation through the 20% sucrose cushion resulted in the complete release of S22 mRNA from the polysomal pellet (P) into the nonpolyosomal (NP) supernatant.

RNA was prepared from polyosomal (P) and nonpolyosomal (NP) fractions isolated from microinjected oocytes. Figure 1C shows that while the polyadenylated SP6-derived S22 mRNA was translated in stage VI oocytes, the deadenylated transcript in mature oocytes was not associated with polysomes. Thus, the SP6 S22 mRNA is deadenylated and translationally inactivated in mature oocytes, as observed previously for other r-protein mRNAs (Baum and Wormington 1985; Hyman and Wormington 1988).

GENES & DEVELOPMENT
Xenopus β-globin mRNA is deadenylated and released from polysomes in mature oocytes

Our initial analyses of the translational inactivation of the SP6 L1 mRNA in mature oocytes also utilized the plasmid pSP64-Xβm to synthesize Xenopus β-globin mRNA [Hyman and Wormington 1988]. This transcript was chosen as a control because previous studies had indicated that the translational efficiency of rabbit globin mRNA in microinjected oocytes increased in parallel with the twofold stimulation in overall protein synthesis after the induction of maturation [Richter et al. 1982]. Our results were consistent with this observation and showed that the pSP64-Xβm-derived mRNA was not deadenylated and remained polysomal in mature oocytes [Hyman and Wormington 1988]. However, the pSP64-Xβm transcript contains only a 3' poly(A)23 tract followed by a poly(C)190 tract [Krieg and Melton 1984]. Thus, the failure of this transcript to be deadenylated could be due to either its short poly(A) tract or the presence of the extraneous poly(C) tail as opposed to the absence of specific cis-acting sequences required for poly(A) removal. To address these possibilities, we determined the minimal poly(A) tail length required for deadenylation and have examined the regulation of a β-globin mRNA that contains a 3' poly(A)50–100 tail and lacks the extraneous poly(C) sequences encoded by the pSP64-Xβm template.

To ascertain the minimal poly(A) tail length requirement for deadenylation, we synthesized SP6 L1 mRNAs that contained 3' poly(A) tails of either 20 or 42 adenylate residues in length (Fig. 2A). Figure 2B shows that while the poly(A)20 tail was not removed from L1-20 RNA in mature oocytes, the L1-42 RNA with a poly(A)42 tail, was deadenylated. Both transcripts were substrates for deadenylation in vitro by RNase H after hybridization to oligo(dT). Therefore, a poly(A)50–100 tail is insufficient for deadenylation in mature oocytes.

These results suggest that the poly(A)20 tract on the pSP64-Xβm transcript is probably insufficient in length to be removed in mature oocytes. Therefore, we removed both the poly(A) and poly(C) homopolymer tracts from this SP6 RNA by hybridization to oligo(dT) and digestion with RNase H [Fig. 3A]. A 3' poly(A)50–100 tail was then added with Escherichia coli poly(A) polymerase. This modified transcript, which more closely resembles native Xenopus β-globin mRNA, was deadenylated and released from polysomes in mature oocytes (Fig. 3B,C). We have not resolved the apparent discrepancy between this result and the elevated translation of rabbit globin mRNA in mature oocytes reported initially by Richter et al. [1982]. We note, however, that Richter et al. [1982] microinjected 20–40 ng of partially purified rabbit globin mRNA, whereas we have used 1 ng of synthetic Xenopus β-globin mRNA. We conclude, therefore, that Xenopus β-globin mRNA does not require sequences derived from the r-protein L1 mRNA to specify its deadenylation and translational inactivation in mature oocytes as proposed originally [Hyman and Wormington 1988].

Deadenylation does not require specific cis-acting sequences

The deadenylation of Xenopus β-globin mRNA raised the possibility that the removal of poly(A) from endogenous oocyte mRNAs may also not require specific cis-acting sequences. To address this issue, transcripts derived from the 3'-untranslated region (UTR) of the S22 mRNA were constructed and analyzed for maturation-specific deadenylation in microinjected oocytes [Fig. 4A]. The wild-type S22 3' UTR RNA was deadenylated in mature oocytes [Fig. 4B]. Two mutant templates were constructed that altered a total of 34 of the 45 nucleotides present in the S22 3' UTR [Fig. 4A]. In S22-mut2 RNA, 14 nucleotides were altered, including the canonical poly(A) addition site, AAUAAA, and the sequence, UUUCUGUUU, that is conserved among Xenopus r-protein mRNAs [Mariottini et al. 1988]. In S22-mut3 RNA, the 3'-terminal 20 nucleotides, including a second sequence, GUGGAUG, which is also conserved among Xenopus r-protein mRNAs [Mariottini et al. 1988], were altered. Figure 4B shows that both mutant RNAs were deadenylated in mature oocytes. A smaller proportion of S22-mut2 RNA was deadenylated relative to the wild-type transcript, suggesting that specific sequences may influence the efficiency of poly(A) removal. Both mutant S22 RNAs were deadenylated more extensively in mature oocytes than by treatment with RNase H after hybridization to oligo(dT). Thus, neither the poly(A) addition site nor the two elements conserved in Xenopus r-protein mRNAs are required for maturation-specific
Poly(A) removal during Xenopus oocyte maturation

Globin mRNA is deadenylated and released from polysomes in mature oocytes. [A] Diagram of the pSP64-Xβm transcription plasmid. Radiolabeled SP6 Xβm RNA was synthesized from a template linearized with Psrl, and 3' protruding ends were removed by T4 DNA polymerase. The RNA was hybridized to oligo(dT) and digested with RNase H, and a poly(Ado)~tail was added with poly(A) polymerase. SP6 RNA was microinjected into stage VI oocytes that were incubated in either the presence or absence of progesterone. (B) Total RNA was extracted from stage VI and mature oocytes. (C) RNA extracted from nonpolysomal (NP) and polysomal (P) fractions of stage VI and mature oocytes. RNAs were electrophoresed on a 1.3% agarose-formaldehyde gel.

deadenylation.

As an additional test for the absence of sequence specificity for deadenylation, we constructed a transcription template in which a homopolymer [(dC)·(dG)]24 oligonucleotide, flanked by initiation and termination codons, was inserted adjacent to the [(dA)·(dT)]100 tract in pSP65AT (Fig. 5A). Figure 5B shows that the HP1 RNA was deadenylated in mature oocytes, providing additional evidence that maturation-specific deadenylation does not require specific cis-acting sequences.

Deadenylation does not require translation of a substrate RNA

To determine whether a substrate RNA must be associated with polysomes for its deadenylation, we synthesized a polyadenylated RNA fragment, G52, that contains the terminal 52 nucleotides from the 3’-untranslated region of Xenopus β-globin mRNA (Fig. 5C). The G52 transcript lacks a consensus translation initiation sequence and contains no internal AUGs. This RNA was not associated with polysomes in stage VI oocytes (Fig. 5D). The exclusion of G52 RNA from the polysomal pellet was not due to its short length because the similarly sized wild-type S22 3’ UTR RNA, which contains a consensus translation initiation sequence, can be efficiently recovered in the polysomal pellet (S.M. Varnum, unpubl.). Figure 5D shows that the nontranslatable G52 RNA was deadenylated following maturation. This result is consistent with our initial observation that the nonpolysomal fraction of endogenous r-protein mRNAs is deadenylated in mature oocytes [Hyman and Wormald 1988].

The cytoplasmic polyadenylation element (U)_AU prevents deadenylation

A class of maternal transcripts that includes the G10 and D7 mRNAs escapes deadenylation in mature oocytes [Fox et al. 1989; McGrew et al. 1989; Paris and Richter 1990]. The cytoplasmic polyadenylation of these transcripts may prevent their deadenylation. In contrast...
to deadenylation, cytoplasmic polyadenylation requires a CPE and the nuclear polyadenylation signal AAUAAA (Fox et al. 1989; McGrew et al. 1989). The AAUAAA element is insufficient to confer resistance to poly(A) removal because this sequence is also present in mRNAs that are deadenylated in mature oocytes. To determine whether the CPE, [U]6AU, prevents deadenylation, we analyzed the regulation of β-globin–G10 fusion RNAs whose substrate activities for polyadenylation have been characterized previously (Fig. 6A; McGrew et al. 1989). Extraneous vector sequences that prevent cytoplasmic polyadenylation [McGrew et al. 1989] were removed from the SP6 RNAs by hybridization to oligo(dT) and digestion with RNase H. Figure 6B shows that the fusion transcript XBG10Δ763-797/dT underwent maturation-specific polyadenylation in microinjected oocytes. In contrast, the XBG10Δ741-748/dT transcript lacking the [U]6AU CPE was not polyadenylated in mature oocytes (Fig. 6C). To determine whether this mutant transcript was deadenylated, a 3′ poly(A) tail was added posttranscriptionally with E. coli poly(A) polymerase. As shown in Figure 6D, the poly(A) tail on the XBG10A741-748/dT/A100 RNA was not elongated in mature oocytes, but was deadenylated instead.

These results suggest that the deadenylation of maternal mRNAs could occur by default in the absence of CPE-dependent cytoplasmic polyadenylation. To address this potential mechanism further, we determined whether insertion of the [U]6AU CPE into the 3′ untranslated region of the r-protein L1 mRNA was sufficient to prevent its deadenylation and translational inactivation. The [U]6AU sequence was inserted into the L1 mRNA at the same position relative to the poly(A) addition site as it is found in the G10 mRNA (Fig. 7A). Extraneous vector sequences were removed from the resultant L1-1095 RNA, and a poly(A) tail was added with E. coli poly(A) polymerase. Figure 7B shows that the poly(A)100 tail on the L1 mRNA was removed in mature oocytes. In contrast, the presence of the [U]6AU element in L1-1095 RNA resulted in the maturation-specific extension of its poly(A) tail (Fig. 7B). Additional experiments indicated that a nonadenylated L1-1095 RNA injected into oocytes was also polyadenylated at maturation analogous to the behavior of the XBG10Δ763-797/dT transcript (Fig. 7B; data not shown). The translational efficiency of the L1 mRNA in mature oocytes was determined by the fate of its poly(A) tail. The wild-type L1 mRNA was released from polysomes concomitant with its deadenylation in mature oocytes (Fig. 7B). However, the L1-1095 transcript not only retained a poly(A) tail after maturation but also remained associated with polysomes. Thus, the CPE-dependent persistence of a poly(A) tail is sufficient to prevent the translational inactivation of a r-protein mRNA in mature oocytes.

Discussion

A default pathway for the deadenylation and translational inactivation of maternal mRNAs during oocyte maturation

A translational control mechanism is established during Xenopus oocyte maturation that discriminates between two classes of maternal mRNAs. One class of mRNAs undergoes a sequence-dependent cytoplasmic polyade-
Poly(A) removal during Xenopus oocyte maturation

Deadenylation does require a minimal poly(A) tract length. Although a poly(A)_{42} tail can be removed at maturation, a transcript containing only a poly(A)_{30} tract is not deadenylated. This probably explains why a β-globin mRNA with a poly(A)_{42} tail was not deadenylated in our previous studies [Hyman and Worthington 1988]. It is also possible that the presence of an extraneous poly(C)_{30} tail inhibited the deadenylation of this transcript. However, deadenylation does not require that the poly(A) tail must actually terminate with an adenylate residue. The 3' ends of several SP6-derived RNAs used in previous studies [Hyman and Worthington 1988] and in this report are terminated by 3 to 5 nonadenylate residues of poly(A). Nonetheless, these RNAs are deadenylated.

The nontranslatable G52 RNA was deadenylated at maturation, demonstrating that mRNAs do not need to be associated with polysomes to undergo poly(A) removal. This indicates that nontranslating mRNAs are not required to cycle through polysomes for their deadenylation at maturation. This absence of a translation requirement differs from the regulation of tubulin and histone mRNA turnover in mammalian cells in which only polysomal transcripts are targeted for degradation [for reviews, see Cleveland 1988; Marzluff and Pandey 1988]. The deadenylation of nonpolysomal mRNAs in mature oocytes suggests that this activity may differ from those found in mature mammalian cells.

We proposed previously that cis-acting sequences are involved in specifying deadenylation [Hyman and Worthington 1988]. This proposal was based on the observation that sequences located near the 3' end of the r-protein LI mRNA directed maturation-specific deadenylation when fused to a Xenopus β-globin mRNA that was otherwise not subject to this regulation. In this report we have shown that a Xenopus β-globin mRNA, with an appropriate 3' terminus, is indeed deadenylated. In addition, extensively mutated transcripts derived from the 3'-untranslated region of the r-protein S22 mRNA were all deadenylated in mature oocytes. The reduced amount of deadenylated S22-mu27 RNA suggests, however, that specific sequences may influence the efficiency of poly(A) removal. Nonetheless, the deadenylation of a homopolymer RNA provides the strongest evidence that this RNA processing event does not require specific sequences.

Deadenylation does require a minimal poly(A) tract length. Although a poly(A)_{42} tail can be removed at maturation, a transcript containing only a poly(A)_{30} tract is not deadenylated. This probably explains why a β-globin mRNA with a poly(A)_{42} tail was not deadenylated in our previous studies [Hyman and Worthington 1988]. It is also possible that the presence of an extraneous poly(C)_{30} tail inhibited the deadenylation of this transcript. However, deadenylation does not require that the poly(A) tail must actually terminate with an adenylate residue. The 3' ends of several SP6-derived RNAs used in previous studies [Hyman and Worthington 1988] and in this report are terminated by 3 to 5 nonadenylate residues of poly(A). Nonetheless, these RNAs are deadenylated.

The nontranslatable G52 RNA was deadenylated at maturation, demonstrating that mRNAs do not need to be associated with polysomes to undergo poly(A) removal. This indicates that nontranslating mRNAs are not required to cycle through polysomes for their deadenylation at maturation. This absence of a translation requirement differs from the regulation of tubulin and histone mRNA turnover in mammalian cells in which only polysomal transcripts are targeted for degradation [for reviews, see Cleveland 1988; Marzluff and Pandey 1988]. The deadenylation of nonpolysomal mRNAs in mature oocytes suggests that this activity may differ from those found in mature mammalian cells.

We proposed previously that cis-acting sequences are involved in specifying deadenylation [Hyman and Worthington 1988]. This proposal was based on the observation that sequences located near the 3' end of the r-protein LI mRNA directed maturation-specific deadenylation when fused to a Xenopus β-globin mRNA that was otherwise not subject to this regulation. In this report we have shown that a Xenopus β-globin mRNA, with an appropriate 3' terminus, is indeed deadenylated. In addition, extensively mutated transcripts derived from the 3'-untranslated region of the r-protein S22 mRNA were all deadenylated in mature oocytes. The reduced amount of deadenylated S22-mu27 RNA suggests, however, that specific sequences may influence the efficiency of poly(A) removal. Nonetheless, the deadenylation of a homopolymer RNA provides the strongest evidence that this RNA processing event does not require specific sequences.

Deadenylation does require a minimal poly(A) tract length. Although a poly(A)_{42} tail can be removed at maturation, a transcript containing only a poly(A)_{30} tract is not deadenylated. This probably explains why a β-globin mRNA with a poly(A)_{42} tail was not deadenylated in our previous studies [Hyman and Worthington 1988]. It is also possible that the presence of an extraneous poly(C)_{30} tail inhibited the deadenylation of this transcript. However, deadenylation does not require that the poly(A) tail must actually terminate with an adenylate residue. The 3' ends of several SP6-derived RNAs used in previous studies [Hyman and Worthington 1988] and in this report are terminated by 3 to 5 nonadenylate residues of poly(A). Nonetheless, these RNAs are deadenylated.

The nontranslatable G52 RNA was deadenylated at maturation, demonstrating that mRNAs do not need to be associated with polysomes to undergo poly(A) removal. This indicates that nontranslating mRNAs are not required to cycle through polysomes for their deadenylation at maturation. This absence of a translation requirement differs from the regulation of tubulin and histone mRNA turnover in mammalian cells in which only polysomal transcripts are targeted for degradation [for reviews, see Cleveland 1988; Marzluff and Pandey 1988]. The deadenylation of nonpolysomal mRNAs in mature oocytes suggests that this activity may differ from those found in mature mammalian cells.

We proposed previously that cis-acting sequences are involved in specifying deadenylation [Hyman and Worthington 1988]. This proposal was based on the observation that sequences located near the 3' end of the r-protein LI mRNA directed maturation-specific deadenylation when fused to a Xenopus β-globin mRNA that was otherwise not subject to this regulation. In this report we have shown that a Xenopus β-globin mRNA, with an appropriate 3' terminus, is indeed deadenylated. In addition, extensively mutated transcripts derived from the 3'-untranslated region of the r-protein S22 mRNA were all deadenylated in mature oocytes. The reduced amount of deadenylated S22-mu27 RNA suggests, however, that specific sequences may influence the efficiency of poly(A) removal. Nonetheless, the deadenylation of a homopolymer RNA provides the strongest evidence that this RNA processing event does not require specific sequences.
from a poly(A) removal activity that is bound to polysomes in mammalian cells [Brewer and Ross 1988].

The contribution of the poly(A) tail to translational efficiency has been documented extensively for many eukaryotic mRNAs (for review, see Jackson and Standart 1990). The behavior of maternal mRNAs during *Xenopus* oocyte maturation indicates that the poly(A) tail is a primary determinant of translational efficiency at this developmental stage. A wide variety of mRNAs that are translated efficiently in stage VI oocytes are released from polysomes upon their deadenylation at maturation [Sturgess et al. 1980; Dworkin and Dworkin-Rastl 1985; Dworkin et al. 1985; Hyman and Wormington 1988; Wormington 1989]. The core histone mRNAs are notable exceptions [Ruderman et al. 1979]. There is increasing evidence that the poly(A) tail enhances translation initiation [Galili et al. 1988; Munroe and Jacobson 1990]. Recent studies suggest that this enhancement is mediated through the poly(A)-binding protein [Sachs and Davis 1989, 1990]. Thus, polyadenylated RNAs would be preferentially translated relative to deadenylated transcripts in mature oocytes.

Our results indicate that deadenylation results in the translational inactivation of r-protein mRNAs in mature oocytes. We have shown that insertion of the CPE, [U]_6AU, into the 3' UTR of the r-protein L1 mRNA results in the retention of its poly(A) tail and its continued translation. We have not determined whether translation of the CPE-containing L1-1095 mRNA is due to the presence of a poly(A) tail or whether it requires the actual process of polyadenylation as does G10 mRNA [McGrew et al. 1989]. The regulation of the two mRNAs may not be directly comparable. Although both the L1 and G10 mRNAs are polyadenylated to similar extents in stage VI oocytes, only the L1 mRNA is translated efficiently before maturation. Thus, the mechanism that maintains translation of the polyadenylated L1-1095 mRNA in mature oocytes may differ from the initial recruitment of G10 mRNA onto polysomes. It is important to note that the [U]_6AU CPE alone cannot prevent the deadenylation and permit the translation of L1-1095 RNA. If extraneous sequences located distal to the poly(A) tract are not removed from the L1-1095 RNA prior to microinjection, its poly(A) tail is not retained and it is not associated with polysomes despite the presence of the CPE (S.M. Varnum, unpubl.). Similarly, McGrew et al [1989] showed that extraneous vector sequences prevented the [U]_6AU-dependent polyadenylation and polysomal recruitment of G10 mRNA. These results do not rule out the possibility that the CPE functions as a translational enhancer in mature oocytes, but only in the context of polyadenylation.

The poly(A) tail is not a determinant of mRNA stability during maturation. Deadenylated maternal mRNAs are not degraded immediately in mature oocytes but are stably maintained as nonpolysomal transcripts [Dworkin and Dworkin-Rastl 1985; Dworkin et al. 1985; Hyman and Wormington 1988]. It is likely, however, that deadenylation facilitates the eventual degradation of these maternal mRNAs after fertilization [Baum and Wormington 1985; Duval et al. 1990].

The mechanism by which CPE-containing RNAs escape deadenylation remains to be defined. It is a formal possibility that all maternal mRNAs undergo poly(A) removal during maturation. Only mRNAs that contain a CPE would be substrates for a subsequent polyadenylation reaction. However, deadenylated intermediates of D7 or G10 mRNAs have not been detected during maturation [Fox et al. 1989; McGrew et al. 1989]. Additional studies indicate that cytoplasmic polyadenylation precedes deadenylation. Cytoplasmic polyadenylation is an early event that precedes germinal vesicle breakdown [McGrew and Richter 1990]. In contrast, deadenylation occurs after germinal vesicle breakdown and requires several hours for its completion (S.M. Varnum, unpubl.). It is possible that CPE-containing mRNAs may bind to factors that prevent deadenylation. An 82-kD CPE-binding protein that is present in egg but not oocyte extracts is one candidate for such a factor [McGrew and Richter 1990]. Wickens [1990] has suggested that the actual process or end product of polyadenylation may prevent deadenylation. For example, the poly(A) tracts added to CPE-containing RNAs could contain modified adenylate residues that are resistant to deadenylation. Bass and Weintraub [1988] have identified an RNA helicase activity that also converts adenosine residues to inosine in *Xenopus* eggs, although its modification of 3' poly(A) tracts has not been addressed. Alternatively, the newly added poly(A) tracts could bind to a different form of poly(A)-binding protein that prevents deadenylation.

A default mechanism of translational control is particularly applicable to oocyte maturation, given the enormous complexity of the maternal mRNA population (for review, see Davidson 1986). The absence of a specific sequence requirement for deadenylation provides a simple mechanism for the translational inactivation of unrelated mRNAs that are utilized during oogenesis but that otherwise share no common regulation. The deadenylation activity we have described is itself subject to regulation during maturation because poly(A) removal does not occur until after germinal vesicle breakdown. It will also be of interest to determine how deadenylation activity is eliminated during embryogenesis, as the majority of new transcription commencing at the midblastula transition is due to the re-expression of sequences present previously as maternal mRNAs [Dworkin and Dawid 1980; Colot and Rosbash 1982; Baum and Wormington 1985; Krieg et al. 1989]. The development of an in vitro deadenylation system and purification of this RNA processing activity will address these aspects of its regulation and define its mechanism of poly(A) removal.

**Materials and methods**

**Plasmid constructions and preparation of transcription templates**

The plasmid pS22, isolated from a *Xenopus* stage 17 embryo cDNA library [Kintner and Melton 1987], contains a 531-bp S22 cDNA insert with a residual 3' [A]_120 tail cloned downstream of the SP6 promoter in a derivative of pSP6S [Keiper and Wormington 1990]. pS22 DNA was linearized with *SacI*, and 3'-pro-
truding ends were removed with T4 DNA polymerase for use as a transcription template.

To construct the plasmid pS22-3'UTR, a fragment containing the S22 3' UTR was isolated by digestion of pS22 with NsiI and EcoRI. The fragment was cloned into the PstI and EcoRI sites of pSP65AT (Baum et al. 1988). pS22-3'UTR DNA was linearized with EcoRI for use as a transcription template.

To construct plasmids encoding mutant S22-3'UTR RNAs or the G52 RNA derived from the 3' UTR of β-globin mRNA, oligonucleotides specific for each sequence were synthesized. Complementary oligonucleotides containing a 5' BglII site and a 3' SacI site were phosphorylated, annealed by heating to 75°C, and cooled slowly to room temperature. The annealed oligonucleotides were ligated into the BglII and SacI sites of pSP65-L1A* (Baum et al. 1988). The oligonucleotide inserts containing a [dA]·[dT]100 tract were subsequently isolated by digestion with BglII and BamHI and ligated into the BamHI site of pSP65. The plasmid pS22-mut2 contained the oligonucleotide sequence 5'-GATCTCTAATCGTATCTGCTCCTA-3', while the complementary sequence 5'-TTTTTTAT was inserted by site-directed mutagenesis (G Olsen and E. E. Eckenroth 1990) 25 bp upstream of the poly(A) addition site AATAAACCTGCAGCCAACATCAGGCAGAGCT and inserted into the SacI site of pSP65AT. pHPI1 DNA was linearized with BamHI for use as a transcription template.

To construct pHPI, the oligonucleotide sequence 5'-CTTCATCGATCTCTGTT-3' was annealed with its complement and phosphorylated and annealed as above and inserted into the SacI site of pSP65AT. pHPI1 DNA was linearized with BamHI for use as a transcription template.

Total RNA was extracted from microinjected oocytes as described (Wormington 1986). In some cases, total RNA preparations were hybridized to oligo(dT)12-18 and denatured in vitro with RNase H, as described by Hyman and Wormington (1988), except that reactions were incubated for 1 hr. Polysomal and nonpolysomal RNAs were isolated from cytoplasmic extracts centrifuged through 20% sucrose cushions as described in detail (Baum et al. 1988). RNAs were resolved by electrophoresis in either 1% or 1.3% agarose-2.2 M formaldehyde gels or in 4% or 6% polyacrylamide—7 M urea gels (Maniatis et al. 1982). Each lane contained the RNA equivalent of one to two oocytes. Gels were dried, and the radiolabeled RNAs were detected by autoradiography. Differences in the intensities of RNA bands between lanes are due to variability in the stability of the injected RNAs in stage VI or mature oocytes.

Acknowledgments

We are grateful to Joel Richter and Lynn McGrew for generously providing G10 plasmids and we thank Mary Wickens for communicating results prior to publication. We also thank Linda Hyman, Brett Keiper, Lynn McGrew, Joel Richter, Michael Rosbash, and Ranjan Sen for many stimulating discussions. This work was supported by National Institutes of Health grant HD17691 to W.M.W.

The publication costs of this article were defrayed in part by payment of page charges. This article must therefore be hereby marked "advertisement" in accordance with 18 USC section 1734 solely to indicate this fact.
