Abstract: Hexokinase (HXK) is the first key enzyme in the glycolytic pathway and plays an extremely important role in energy metabolism. By searching the microsporidian database, we found a sequence (NBO_27g0008) of *Nosema bombycis* Nägali, 1857 with high similarity to hexokinase-2, and named it as NbHXK2. The NbHXK2 gene has 894 bp and encodes 297 amino acids with 34.241 kDa molecular weight and 5.26 isoelectric point. NbHXK2 contains 31 phosphorylation sites and 4 potential N-glycosylation sites with signal peptides and no transmembrane domain. Multiple sequence alignment showed that NbHXK2 shares more than 40% amino acid identity with that of other microsporidia, and the homology with hexokinase-2 of *Nosema tyriae* Canning, Curry, Cheney, Lafranchi-Tristem, Kawakami, Hatakeyama, Iwano et Ishihara, 1999, *Nosema pyrausta* (Paillot, 1927) and *Nosema ceranae* Fries, Feng, da Silva, Slemenda et Pieniazek, 1996 was 89.17%, 87.82% and 69.86%, respectively. Phylogenetic analysis based on the amino acid sequence of hexokinase showed that all microsporidia cluster together in the same clade, and are far away from animals, plants and fungi, and that *N. bombycis* is closely related to *N. tyriae; N. pyrausta; N. ceranae* and *Nosema apis* Zander, 1909. Immunolocalisation with the prepared polyclonal antibody showed that NbHXK2 was mainly distributed in the cytoplasm and plasmalemma in proliferative, sporulation stage and mature spore of *N. bombycis*. qRT-PCR assay showed that the NbHXK2 expressed at higher level during spore germination and at early stage of proliferation. These results indicate that *N. bombycis* may use its own glycolytic pathways to supply energy for infection and development, especially germination and in the early stage of proliferation, and acquire energy from the host through certain ways as well.

Keywords: microsporidia, silkworm, glucose metabolism, NbHXK2

Microsporidia are obligate intracellular parasites that have broad host range including invertebrates and vertebrates. About 1,500 species of microsporidia have been found in 187 genera (Franzen 2005, Vávra and Lukeš 2013). The first microsporidium, to *Nosema bombycis* Nägali, 1857 was discovered in the silkworm by Nägeli in 1857 (Wittner and Weiss 1999). *Pebrine disease* is one of the most devastating diseases in sericulture production. The outbreak of the disease has caused huge economic losses to the sericulture industry. Therefore, pebrine disease is listed as the only quarantine object for sericulture in China. The hexokinase (HXK) catalyses the phosphorylation of glucose to form 6-phosphate-glucose (G-6-P) and plays a vital role in energy metabolism (Wilson 1995, Cardenas et al. 1998). Hexokinases have been identified in a variety of species that range from bacteria, yeast and plants to vertebrates including humans. Multicellular organisms such as plants and animals often have more than one hexokinase isoform. For example, four hexokinase isozymes have been identified in mammalian species according to their electrophoretic mobility.

The hexokinases I, II, III isozymes are 100 kDa molecules thought to have evolved by duplication and fusion of a gene encoding an ancestral 50 kDa hexokinase. Thus, these isozymes display internal sequence repetition, and the N- and C-terminal halves have extensive sequence similarity both to each other and to other members of the hexokinase family.

Hexokinases IV isozyme, commonly known as glucokinase, is about 50 kDa in size (Wilson 2003, Li et al. 2014). Moreover, recent studies have found that HXK is involved...
in the interaction between pathogens and hosts. In macrophages, HXK is an innate immune receptor for the detection of bacterial peptidoglycans (Wolf et al. 2016).

Although microsporidia display extreme degree of genetic reduction resulting in incomplete metabolism that is particularly evident in ATP-generating pathways (Wiredu Boakye et al. 2017), the microsporidial genomes can expand through several common molecular mechanisms such as gene duplication, horizontal gene transfer and transposable element expansion (Pan et al. 2013).

Data from two microsporidia species of Nematocida Troemel, Félix, Whiteman, Barrière et Ausubel, 2008 revealed that the use of a large number of rapidly evolving species-specific proteins represents a common strategy for microsporidia to interact with their hosts (Reinke et al. 2017). Microsporidia can acquire transporters that import nucleosides to fuel rapid growth. In addition, microsporidian hexokinases may be targeted into the host cell to program it toward biosynthesis (Cuomo et al. 2012).

Research on hexokinases from microsporidia N. bombycis and Nosema ceranae Fries, Feng, da Silva, Slemenda et Pieniazek, 1996 demonstrated the capability of microsporidia-secreted HKs to phosphorylate glucose in infected cells, suggesting that they actively mediate the effects of the parasite on host metabolism (Dolgikh et al. 2019). Nosema bombycis has two hexokinase isoforms. In this study, we identified one hexokinase isoform (EOB14451.1) of N. bombycis from which we infer that this hexokinase may supply energy for infection and early development by both its own glycolytic pathways and the host.

**MATERIALS AND METHODS**

**Materials**

*Nosema bombycis* strain was preserved in the Laboratory of Silkworm Physiology and Pathology, Sericulture Research Institute of the Chinese Academy of Agricultural Sciences, Zhenjiang, China. The BmN cell line was maintained at 27°C in TC-100 insect medium supplemented with 10% (v/v) fetal bovine serum.

**Bioinformatic analysis**

By searching the microsporidian database (http://microsporidiaDB.org/), we found a sequence in the microsporidian *N. bombycis*, namely NbHXK2 (NBO_27g0008, Accession No. EOB14451.1), with high similarity to hexokinase-2. The isoelectric point and molecular weight of NbHXK2 were predicted using ExPaSy proteomic tools (http://web.expasy.org/compute_pi/).

The signal peptide and the transmembrane domain were predicted according to the manufacturer’s instructions.

The signal peptide and the transmembrane domain were predicted using ANTHEPRO 6.3.6 software and TMHMM Server v.2.0 (http://www.cbs.dtu.dk/services/TMHMM/). Subcellular localisation was predicted using Cell-PLoc 2.0 (http://www.ncbi.nlm.nih.gov/biocin/Cell-PLoc-2/). The N-terminal region of NbHXK2 was used to blast homologous sequences in NCBI (https://www.ncbi.nlm.nih.gov/). The homologous sequences were compared using DNAMAN. The phylogenetic tree was constructed by the NJ method using MEGA6.

**Gene cloning, recombinant protein expression and purification**

In this study, NbHXK2 genomic DNA was extracted from *N. bombycis* as previously described (Fredricks et al. 2005). The NbHXK2 was amplified by PCR amplification reaction: 96°C for 6 min; 95°C for 20 s, 44°C for 15 s, and 72°C for 1 min, 35 cycles; and 72°C for 10 min using the forward primer 5'- CCGGATCCATGATTGATTACGTATT-3' containing an BamH I restriction site, and the reverse primer 5'-GGCTGACTTATATAATATCGATG-3' containing a Sal I restriction site. The PCR products were separated on a 1% agarose gel, purified with the AXY Prep DNA fragment purification kit (Corning, Shanghai, China) and cloned into the pMD19-T vector (TaKaRa, Dalian, China).

Then, the vector was transformed into *Escherichia coli* strain Top10 competent cells. Positive clones were confirmed by blue-white selection and the isolated plasmids were sequenced by Sangon BioTech (Shanghai, China).

Then, the pMD19-T-NbHXK2 recombinant plasmid and the pET28a expression vector were digested with BamH I and Sal I, ligated and transformed into Top10 cells. Positive recombinant plasmids were confirmed by enzyme digestion and transformed into *E. coli* BL21 (DE3) cells. These bacterial cells were induced for 6 h at 37°C with 0.6 mM IPTG.

After induction, bacterial cells were lysed in pre-cooled PBS buffer (pH 7.4) using supersonic waves, ultrasonic supernatant and precipitation were collected respectively by centrifugation at 12000 rpm for 10 min. Ultrasonic precipitation was dissolved overnight in a binding buffer (containing 8M urea), and ultrasonic supernatant and precipitation were boiled for 10 min in SDS extraction buffer. The recombinant protein pET-28a-NbHXK2 was identified by SDS-PAGE and mass spectrometry (Sangon BioTech). The expressed recombinant proteins were purified with the His-Bind purification kit (GE Healthcare, Uppsala, Sweden).

**Preparation of polyclonal antibodies and immunoblotting**

Preparation of polyclonal antibodies and immunoblotting protocols to detect the HXK-1 protein of *N. bombycis* were performed as previously described (Wu et al. 2008, Li et al. 2009). Briefly, each rabbit (New Zealand) was subcutaneously injected every 14 days with the NbHXK2 recombinant protein mixed with Freund’s adjuvant (Sigma) for four times. Rabbts in the negative control group were injected with PBS. Ten days after the last injection, serum was collected from rabbit blood and purified.

**Subcellular localisation of NbHXK2 protein in Nosema bombycis**

BmN cells were inoculated with and grown on coverlips for 24 h. Proliferating *N. bombycis* in the host cells were collected by disruption of the infected BmN cells followed by filtration through glass wool, then fixed on glass slides (Taupin et al. 2006, Tsouaissis et al. 2008). Proliferative cells obtained, as described above, mature spores, germinated spores of *N. bombycis*, and healthy Bm cells were fixed with 4% paraformaldehyde and permeabilised with 1% Triton X-100 for 1 h at room temperature, respectively, then blocked with a blocking regent comprising of 0.5% (w/v) BSA and 10% (w/v) goat serum for 1 h, and incubated with 1:200 dilutions of anti-NbHXK2 serum at 37°C for 1 h. After washing with PBS three times (10 min each time), Alexa Fluor 488-conjugated goat anti-rabbit IgG (Sangon Bio-Tech) was used to detect the binding of primary antibodies at room temperature. The nuclei were stained with 4', 6-diamidino-2-phenylindole (DAPI) and observed by an upright epifluorescent microscope.
nylindole (DAPI) (Sangon BioTech, Shanghai, China) for 40 min. Samples were observed and imaged with Olympus TH4-200 fluorescence microscope and Olympus DP80 camera.

Analysis of transcriptional activity of NbHXK2 of *Nosema bombycis*

The fifth instars of silkworm were fed on mulberry leaves which had been already smeared with \(2 \times 10^{4}\) ml\(^{-1}\) of *N. bombycis* suspension. The silkworms were dissected to obtain the mid-gut which was washed with PBS at 10 different post-infected time (2, 6, 12, 24, 48, 72, 96, 120, 144 and 168 hours), and preserved at -80°C. Then, the total RNA of the silkworm mid-gut was extracted according to the TaKaRa MiniBEST Universal RNA Extraction Kit instructions, and stored at -80°C. The reverse transcription reaction solution was prepared according to the instructions of the PrimeScriptTM RT Master Mix (Perfect Real Time), and the reaction mixture was mixed and incubated at 37°C for 30 min, then 85°C for 5 s. After reaction, cDNA was stored at -20°C. The qPCR assay was performed on an Applied Biosystems 7300 Fast Real Time PCR System according to the qPCR kit SYBR\(^{®}\) Premix Ex TaqTM II (Tli RNaseH Plus) instructions (TaKaRa). The specific primers NbHXK2-qF: 5’-TTATAGCCGCT-TAACATTGG-3’, NbHXK2-qR: 5’-TTGGGTATCAATC-CAGATCC-3’ were used for qPCR reaction. The β- tubulin gene of *N. bombycis* served as the reference gene. The relative gene expression was calculated using delta-delta Ct.

RESULTS

Cloning and characterisation of NbHXK2 gene

Sequencing results showed that the NbHXK2 gene contains a complete ORF of 894 bp in length and encodes 297 amino acids. It is predicted that the NbHXK2 is 34.241 kD with an isoelectric point of 5.26, and contains 31 phosphorylation sites and 4 potential N-glycosylation sites without intrinsic glycosylation sites. The NbHXK2 gene as reference gene. The relative gene expression was calculated using delta-delta Ct.

Phylogenetic analysis showed that all the microsporidia clustered together in the same clade, which was far away from *Homo sapiens*, *Solanium tuberosum*, *Drosophila melanogaster*, *Bombyx mori* and fungi such as Basidionymycota, Ascomycota, Chytridomyycota, Glomeromyycota, Zygomycota, suggesting that the microsporidia share the close evolutionary relationship (Fig. 2).

NbHXK2 recombinant protein expression and specificity of polyclonal antibody

The NbHXK2 recombinant protein was expressed as inclusion bodies in *Escherichia coli* BL21 (DE3). Mass spectrometry result showed that the sequence similarity of the NbHXK2 recombinant protein is consistent with that of HXK2 in the *Nosema bombycis*. The NbHXK2 recombinant protein was purified by nickel column affinity chromatography, and the purified NbHXK2 recombinant protein was obtained by imidazole elution with different concentration gradients (see Fig. S1 in the Supplementary material). The concentration of NbHXK2 recombinant protein was 0.7 mg/mL by BCA method.

The specificity of the polyclonal antibody was tested by Western blotting. A protein of approximately 35 kDa was detected in the total protein extracted from *N. bombycis* and NbHXK2 recombinant protein while the NbHXK2 protein polyclonal antibody served as a primary antibody and HRP-labeled goat anti-rabbit antibody as a secondary antibody (Fig. 3), whereas no band was detected when the pre-immune serum was used as control. The size is consistent with the predicted molecular weight of the NbHXK2 protein.

Subcellular localisation of NbHXK2

The distribution of NbHXK2 in *N. bombycis* at different developmental stages was observed by immunofluorescence microscopy. In all experiments, pre-immune serum of rabbit was used as negative control, and no green fluorescence signal was observed in *N. bombycis* (Fig. 4). In the mature spores, the green fluorescence was mainly distributed in the cytoplasm of spore and plasma membrane (Fig. 4A, Fig. S2A), and no fluorescence was observed on the nucleus.

After the spores germination, strong green fluorescent signal is clearly visible inside the polar tube which were extruded to outside of the spore, and there is weak green fluorescence at the periphery underlying the spore wall (Fig. 4B, Fig. S2B), indicating that most of the NbHXK2 protein is ejected outside the spore together with the sporoplasm and a little of protein was residual on the site where the plasma membrane originally located. During proliferative stage, the green fluorescent signal mainly appears in the interior and near the plasma membrane of the replicating cells. No fluorescence was observed in the cytoplasm of the BmN cells, indicating that NbHXK2 was not secreted into the host cells during proliferation of *N. bombycis* (Fig. 4C, Fig. S2C).

When *N. bombycis* developed to the sporulation stage, the green fluorescence was mainly concentrated around the plasma membrane (Fig. 4D, Fig. S2D). As *N. bombycis* progressed to maturation, many pear-shaped immature spores and oval mature spores have been released from...
Fig. 1. Amino acid alignment of hexokinases from *Nosema bombycis* Nägali, 1857 and other microsporidian species (*p* <0.05).
the dissociated BmN cells, strong green fluorescence appeared throughout the spores (Fig. 4E), especially the plasma membrane (Fig. S2E). The above results indicate that NbHXK2 protein was expressed through all life stages and is mainly distributed in the cytoplasm and plasma membrane of *N. bombycis*.

**Transcriptional profile of NbHXK2 in *Nosema bombycis* infected midgut of silkworm**

The transcription level of the NbHXK2 gene at different post-infection time was detected by qPCR with β-tubulin of *N. bombycis* as the reference gene. The relative expression level was higher in the early stage of infection (2–12 h), and decreased significantly from 24 h to 72 h. It is slightly increased at 96 h and then decreased rapidly at 120 h, and kept the lowest at 144 h (Fig. 5). The results suggest that NbHXK2 is related to the development of *N. bombycis*, especially involved in the energy metabolism of infection, early proliferation and sporulation phase of *N. bombycis*.

**DISCUSSION**

Hexokinase is widely present in many species and is the rate-limiting enzyme in the glycolytic pathway. We searched for the hexokinase protein in the databases, and found that the hexokinases existed commonly in the fungal kingdom, such as Basidiomycota, Ascomycota, Glomeromycota, Chytridiomycota, and Zygomycota. In the two basal fungi Chytridiomycota and Zygomycota, we found that the proteins annotated as hexokinase are present in many species of the Zygomycota, such as *Mucor ambiguous*, *Syncephalis pseudoplumigaleata*, *Rhizopus microsporus*, etc., and only one species, *Neocallimastix frontalis*, in the Chytridiomycota.

The relative expression level of NbHXK2 at different post-infection time. Error bars represent the standard deviations of three independent replicates.

Among the microsporidia, we found that the hexokinase existed in the genus *Nosema* (*N. bombycis, N. tyriae; N. pyrausta; N. ceranae and N. apis*) and *Encephalitozoon* (*E. intestinalis; E. cuniculi and E. hellem*), as well as *Spraguea lophii* Vávra et Sprague, 1976; *Trachipleistophora hominis*; *Pseudoloma neurophilia* Matthews, Brown, Larison, Bishop-Stewart, Rogers et Kent, 2001; etc. The amino acid sequence alignment showed that *N. bombycis* has higher homology with *N. tyriae; N. pyrausta* and *N. ceranae*, and lower homology with other genera in microsporidia.

Phylogenetic analysis showed that all the microsporidia clustered together in the same clade, especially species of *Nosema*, and far away from animals (*Homo sapiens; Drosophila melanogaster; Bombyx mori*), plant (*Solanium tuberosum*) and fungi such as *Rhizoctonia solani* Kühn, 1858; *Puccinia sorgei* Schweinitz, 1834; *Venturia inaequalis* (Cooke, 1866); *Penicillium digitatum*; *Rhizophagus irregularis*; *Neoccadiimastix frontalis* (Braune, 1913); *Muco ambigous; Syncephalis pseudoplumigaleata* pseudoplumigaleata Benny et Ho, 2017 and *Rhizopus microsporus*, which indicated that the genetic relationship between microsporidia is closer.

Obligate intracellular parasites can steal energy from host cells in a variety of ways. Rickettsia and chlamydia acquire energy molecules such as ATP directly from host cells via ATP/ADP transporters (Krause et al. 1985, Trentmann et al. 2007). *Encephalitozoon cuniculi* contains four copies of the ATP/ADP transporter of which three are located in the cell membrane of *E. cuniculi*, and are involved in the transport of the host cell cytoplasmic ATP. The other is located in the mitosome of *E. cuniculi* and provide ATP for the metabolism of mitosome (Tsaousis et al. 2008).

An infiltrative cell coat, termed plaque matrix (PQM), which lies at the interface between the microsporidian *T. hominis* and the mammalian host cytoplasm, has been identified. The presence of two secreted HK isoforms implicates that the PQM theft from the host cell in orchestrating metabolic energy (Ferguson and Lucocq 2018). In addition, a series of nucleotide transporters (NTTs) has been found in microsporidia and steal energy molecules such as ATP from host cells (Heinz et al. 2014, Dean et al. 2016).

Bioinformatic analysis predicted that the NbHXK2 has signal peptide, which implies that NbHXK2 may be a secreted protein. However, our study found that this protein is mainly distributed in the cytoplasm and the plasma membrane of *N. bombycis*, and was not secreted into the host cell during infection and intracellular parasitism. Actually, the hexokinase in *N. bombycis* has two isoforms; the other isoform (Accession No. EOB11276.1) can be secreted into the host cell as a secreted protein (Huang et al. 2018) and phosphorylate glucose in infected cells (Dolgikh et al. 2019), indicating that *N. bombycis* can acquire energy from the host.

In this study, we found that NbHXK2 was expressed relatively at high level at the infection and early proliferative stage (2–12 hpi) of *N. bombycis*, which is consistent with the transcriptional profile of the *Nematocida hexokinase*, which was highly expressed at 8 hpi (Cuomo et al. 2012). The NbHXK2 was distributed in the cytoplasm of dormant spore. When the spore was undergoing germination, most of the NbHXK2 released through the reverted polar tube (Fig. 4A,B), indicating that accompanying by germination of the dormant spore the NbHXK2 was probably entered into the host cell together with sporoplasm, which will accomplish proliferation in the host cell.

During the early proliferative stage, at which the cell of *N. bombycis* is fusiform in shape and contains multi-nuclei, the NbHXK2 was mainly distributed in inner periphery, especially the two ends, of the meront (Fig. 4C). In the sporogenic phase, the NbHXK2 protein was further concentrated in the plasma membrane of sporoblast. Moreover, this phenomenon appeared more significantly in immature spores whose nuclei become more dense and smaller (Fig. 4D). As the functional active site of hexokinase, Lys176, Asp211, Thr234, Ser 419, Glu269 and Glu302 play important roles in ATP binding, glucose binding and catalytic bases in *S. cerevisiae* (HXK1, HXK2) and *T. hominis* (HK2, HK3) (Wiredu Boakye et al. 2017). However, NbHXK2 only contains two conserved functional active sites, Lys176 and Ser419 (ATP binding), which may imply that the NbHXK2 has lost some functions but retains the ability to bind ATP.

*Trachipleistophora hominis* forms sporophorous vacuole at the late developmental stage (Ferguson and Lucocq 2018), whereas *N. bombycis* interacts extensively with the host cell throughout the parasite life cycle until mature spores formed. Although we have not found distinct evidence that the NbHXK2 has been secreted into the host cell, this protein was clearly gathering to the plasma membrane during proliferative phase and sporulation phase. These results suggest that *N. bombycis* may provide energy by its own glycolytic pathway, especially during the infection and early proliferative stage at which *N. bombycis* has not established close relationship with the host cell, and that *N. bombycis* may acquire ATP from host through infiltrating its hexokinase into the host cell as well.

Microsporidia possess genes involved in metabolic processes such as nitrogen metabolism, transport, stress, biosynthesis, cellular metabolic processes, and biological regulation to complete basic metabolism. Otherwise, as
an obligate intracellular parasitic single-cell eukaryotes, microsporidia display a variable reduction in glycolytic pathways, which is combined with significant loss of mitochondrial functions including oxidative phosphorylation. They are obliged to acquire nutrition from the host for its rapid replication and differentiation within the host cells, which may be the best evidence for long-term co-evolution of parasite and host.
