Nonlinear Opinion Dynamics with Tunable Sensitivity

Anastasia Bizyaeva, Alessio Franci, and Naomi Ehrich Leonard

Abstract—We propose a continuous-time multi-option nonlinear generalization of classical linear weighted-average opinion dynamics. Nonlinearity is introduced by saturating opinion exchange, and this is enough to enable a significantly greater range of opinion-forming behaviors with our model as compared to existing linear and nonlinear models. For a group of agents that communicate opinions over a network, these behaviors include multistable agreement and disagreement, tunable sensitivity to input, robustness to disturbance, flexible transition between patterns of opinions, and opinion cascades. We derive network-dependent tuning rules to robustly control the system behavior and we design state-feedback dynamics for the model parameters to make the behavior adaptive to changing external conditions. The model provides new means for systematic study of dynamics on natural and engineered networks, from information spread and political polarization to collective decision making and dynamic task allocation.

I. INTRODUCTION.

Opinion dynamics of networked agents are the subject of long-standing interdisciplinary interest, and there is a large and growing literature on agent-based models created to study mechanisms that drive the formation of consensus and opinion clustering in groups. These models appear, for example, in studies of collective animal behavior and voting patterns in human social networks. In engineering, they are fundamental to designing distributed coordination of autonomous agents and dynamic allocation of tasks across a network.

Agent-based models are typically used to investigate parameter regimes and network structures for which opinions in a group converge over time to a desired configuration. However, natural groups exhibit much more flexibility than captured with existing models. Remarkably, groups in nature can rapidly switch between different opinion configurations in response to changes in their environment, and they can break deadlock, i.e., choose among options with little, if any, evidence that one option is better than another. Understanding the mechanisms that explain the temporal dynamics of opinion formation in groups and the ultra-sensitivity and robustness needed for groups to pick out meaningful information and to break deadlock in uncertain and changing environments is important in its own right. It is also pivotal to developing the means to design provably adaptable yet robust control laws for robotic teams and other networked multi-agent systems.

Motivated by these observations, we explore the following questions in this paper. How can a network of decision makers come rapidly and reliably to coherent configurations of opinions, including both agreement and disagreement, on multiple options in response to, or in the absence of, internal biases or external inputs? How can a network reliably transition from one configuration of opinions to another in response to change? How can the sensitivity of the opinion formation process be tuned so that meaningful signals are distinguished from spurious signals? To investigate these questions, we present an agent-based dynamic model of the opinion formation process that generalizes linear and existing nonlinear models. The model is rich in the behaviors it exhibits yet tractable to analysis by virtue of the small number of parameters needed to generate the full range of behaviors.

We emphasize that our modeling approach is distinct from existing models in the literature in the following way. Models of opinion formation are typically built on the fundamental assumption that individuals update their opinions through a linear averaging process [1]–[5]. Additional feedback dynamics are then often imposed on the coupling weights between agents, for example in bounded confidence models [6]–[9], biased assimilation models [10], [11], and models of evolution of social power [12], [13]. Nonlinearity thereby arises through the superposition of linear opinion dynamics and nonlinear coupling-weight dynamics. When persistent disagreement is observed, it is necessarily the consequence of the dynamic updating of the coupling weights. However, state-dependent interactions are not the only way for a network to achieve structurally stable disagreement. We are instead proposing that the opinion update process itself is fundamentally nonlinear due to saturation of information. We introduce a new multi-option nonlinear model of opinion formation with saturated interactions in Section III and in Section IV we prove that this modeling assumption supports persistent disagreement with a completely static interaction network.

As is done for linear models, dynamic feedback can also be introduced to the nonlinear model parameters. We explore the effects of several dynamic parameter update laws in detail in Section V. The feedback laws we consider are simple, yet they make our model adaptive to changing external conditions with tunable sensitivity and they allow robust and tunable transitions between distinctly different patterns of opinions.

Our model generalizes recent literature on opinion formation with input saturation [14]–[20]. Closely related to these
are nonlinear models that leverage coupled oscillator dynamics [21]–[23], biologically inspired mean-field models [24], and the Ising model [25], [26].

Our major contributions are as follows. 1) We introduce a new nonlinear model for the study of multi-agent, multi-option opinion dynamics. The model has a social term weighted by an attention parameter, which can also represent social effort or susceptibility to social influence, and an input term, which can represent, e.g., external stimuli, bias, or persistent opinions.

2) We show that the model exhibits a rich variety of opinion-formation behaviors governed by bifurcations. This includes rapid and reliable opinion formation and multistable agreement and disagreement, with flexible transitions between them. It also includes ultra-sensitivity to inputs near the opinion forming bifurcation, and robustness to disturbances and uncertainties, away from the bifurcation. Moreover, the behaviors are governed by a small number of key parameters, rendering the model analytically tractable. We prove the central role of the spectral properties of the network graph adjacency matrix in informing the model behavior.

3) We show how the model recovers a range of models in the literature for suitable parameter combinations and/or when linearized, and how the reliance on structurally unstable network conditions in linear models breaks down in the nonlinear setting. The central role of the network graph adjacency matrix in our nonlinear model generalizes the central role of the network graph Laplacian in opinion dynamics in the literature. We show that the right and left adjacency matrix eigenstructures determine patterns of opinion and sensitivity to inputs, respectively.

4) We introduce distributed adaptive feedback dynamics to the agent parameters. We show how design parameters in the attention feedback allow tunable sensitivity of opinion formation to inputs and robustness to changes in inputs, as well as tunable opinion cascades even in response to a single agent receiving an input.

5) We examine tunable transitions between consensus and dissensus using feedback dynamics also on network weights.

We define notation in Section [II] We present the new nonlinear opinion dynamics model in Section [III] In Section [IV] we prove results on agreement and disagreement opinion formation for the new model. We introduce attention dynamics and prove results on tunability of opinion formation in Section [V] in the special case of two options. In Section [VI] we illustrate feedback controlled transitions between agreement and disagreement. We conclude in Section [VII]

II. Notation

Given \( y \in \mathbb{R}^n \), the norm \( \|y\| \) is the standard Euclidean 2-norm and \( \text{diag}\{y\} \in \mathbb{R}^{n \times n} \) is a diagonal matrix with \( y_i \) in row \( i \), column \( i \). Let \( I_N \in \mathbb{R}^{N \times N} \) be the identity matrix, \( 1_N \in \mathbb{R}^N \) the vector of ones, and \( P_0 = (I_N - \frac{1}{N} 1_N 1_N^T) \) the projection onto \( 1_N \). Let \( \{v_1, \ldots, v_k\} \) be the span of vectors \( v_1, \ldots, v_k \in \mathbb{R}^n \). We define \( v_i \in \mathbb{R}^n \) component-wise as \( (v_{i1}, \ldots, v_{in}) \). Let \( U, V \) and \( W \) be vector spaces. \( U \) is the direct sum of \( V \) and \( W \), i.e., \( U = V \oplus W \), if and only if \( V = U + W \) and \( U \cap W = \{0\} \). Given matrices \( B = (b_{ij}) \in \mathbb{R}^{m \times n} \) and \( C = (c_{ij}) \in \mathbb{R}^{p \times q} \), the Kronecker product \( B \otimes C \in \mathbb{R}^{mp \times nq} \) has entries \( (B \otimes C)_{pr+u,qr+w} = b_{ru}c_{vw} \).

Let the set of vertices \( V = \{1, \ldots, N\} \) index a group of \( N_a \) agents, and let edges \( E \subseteq V \times V \) represent interactions between agents. If edge \( e_{ik} \in E \), then agent \( k \) is a neighbor of agent \( i \). The communication topology between agents is captured by the directed graph \( G = (V, E) \) and its associated adjacency matrix \( A \in \mathbb{R}^{N_a \times N_a} \). A is made up of elements \( a_{ik} \) and \( a_{ik} \neq 0 \) if and only if agent \( k \) is a neighbor of agent \( i \). When \( A \) is symmetric (i.e., communication between agents is bidirectional), the graph is undirected.

III. Nonlinear Multi-Option Opinion Dynamics

In this section we present our nonlinear model of opinion dynamics for a network of interacting agents that form opinions about an arbitrary number of options. In Section [III-A] we recall the classical consensus model of DeGroot [1] and several of the extensions that have been proposed and studied in the literature. All of the cited models (with one exception noted) use an opinion update rule that depends on a linear weighted-average of exchanged opinions. In our model, as discussed in Section [III-B] and formalized in Section [III-C] we apply a saturation function to opinion exchanges, which makes the update rule fundamentally nonlinear, even before introducing extensions. The fundamentally nonlinear update rule makes all the difference with respect to generality and flexibility of the model as we show here and in the rest of the paper.

A. Linear Averaging Models: Drawbacks and Extensions

Opinion formation is classically modeled as a weighted-averaging process, as originally introduced by DeGroot [1]. In this framework an agent’s opinion \( x_i \in \mathbb{R} \) reflects how strongly the agent supports an issue or topic of interest. The real-valued opinion is updated in discrete time as a weighted average of the agent’s own and other agents’ opinions, i.e.,

\[
x_i(T + 1) = a_{i1} x_1(T) + \cdots + a_{iN_a} x_{N_a}(T)
\]  

(1)

where \( a_{i1} + \cdots + a_{iN_a} = 1 \) and \( a_{ik} \geq 0 \). The weights \( a_{ik} \) describe the influence of the opinion of agent \( k \) on the opinion of agent \( i \) and the matrix \( A \in \mathbb{R}^{N_a \times N_a} \) with entries \( a_{ik} \) represents the structure of the influence network.

A key drawback of linear weighted-average models is that consensus among the agents is the only possible outcome. As observed in [27], this necessarily happens because the attraction strength of agent \( i \)’s opinion toward agent \( k \)’s opinion increases linearly with the difference of opinions between the two agents. In other words, the more divergent the two agents’ opinions are, the more strongly they are attracted to each other, which is paradoxical from an opinion formation perspective.

To overcome these limitations, a number of prominent variations on averaging models have been proposed. For example in “bounded confidence” models, agents average network opinions but delete communication links to any neighbors whose opinions are sufficiently divergent from their own [6]–[9]. In a similar spirit, “biased assimilation” models instead incorporate a self-feedback into the interaction weights of an averaging model [10], [11]. This self-feedback accounts...
for an individual’s bias towards evidence that conforms with its existing beliefs. The linear model and its variations have also been extended to the case of signed networks, where the linear weights \( a_{ij} \) can be negative \([5, 23, 29]\). Meanwhile, in \([27]\) the authors do away with averaging altogether and instead propose that opinions form through a weighted-median mechanism.

In the present paper we propose an alternative perspective to this literature: driven by the above motivation and the model-independent theory developed in \([30]\), we introduce a parsimonious nonlinear extension of linear weighted-average opinion dynamics that leverages the saturation function.

The linear weighted-average discrete-time opinion dynamics \([1]\) can equivalently be written as

\[
x_i(T+1) = x_i(T) + \left( -x_i(T) + a_{11}x_1(T) + \cdots + a_{iN}x_N(T) \right).
\]

This discrete-time update rule is the unit time-step Euler discretization of the continuous time linear dynamics

\[
\dot{x}_i = -x_i + a_{1i}x_1 + \cdots + a_{Ni}x_N.
\]

Observe that \([1]\) and \([2]\) have exactly the same steady states with the same (neutral) stability.

The linear consensus dynamics \([2]\) are determined by two terms: a weighted-average opinion-exchange term, modeling the pull felt by agent \( i \) toward the weighted group opinion, and a linear damping term, which can be interpreted as the agent’s resistance to changing its opinion.

B. Nonlinear Multi-option Extension of Weighted-average Models: Defining Properties

Our goal is to derive a novel nonlinear extension of \([2]\) satisfying the following defining properties.

1. **Opinion exchanges are saturated.** Saturated nonlinearities appear in virtually every natural and artificial signaling network due to bounds on action and sensing. For example dynamics that evolve according to saturating interactions appear in spatially localized and extended neuronal population models of thalamo-cortical dynamics \([31, 32]\), in Hopfield neural network models \([33–35]\), in models of perceptual decision making \([36, 37]\), and in control systems with sensor and actuator saturations \([38, 39]\). Saturated interactions between decision-makers also effectively bound the attraction between opinions, thus overcoming the linear weighted-average model paradox mentioned above.

2. **Multi-option opinion formation.** Allowing for an arbitrary number of options makes the model relevant to a wide range of applications, for example, in task allocation problems where options represent tasks or in strategic settings where options represent strategies. We extend the model to multiple options by suitably generalizing the agent’s opinion state space, analogous to existing multi-option extensions of averaging models such as \([40–46]\).

To construct this extension formally, observe that in the scalar opinion setting, \( x_i > 0 \) \((x_i < 0)\) is usually interpreted as favoring (disfavoring) an option A and disfavoring (favoring) an option B. The strength of favoring or disfavoring is represented by the magnitude \( |x_i| \) and \( x_i = 0 \) is interpreted as being neutral. This formalism is equivalent to one in which each agent is characterized by two scalar variables \( z_{iA} \) (modeling the preference of agent \( i \) for option A) and \( z_{iB} \) (modeling the preference of agent \( i \) for option B) that are “mutually-exclusive”, i.e., that satisfy \( z_{iA} + z_{iB} = 0 \). The scalar opinion is then obtained simply by defining \( z_i = z_{iA} \). This observation leads to the following multi-option generalization of the state space of model \([2]\). Given \( N_o \) options, we model each agent’s opinion state space as the subspace \( 1_{N_o} N_o \subset \mathbb{R}^{N_o} \). Thus, in our model, the opinion state of agent \( i, i = 1, \ldots, N_o \), is described by the state variable \( Z_i \in 1_{N_o} N_o \), with components \( z_{ij}, j = 1, \ldots, N_o \). When \( Z_i = 0 \), we say that agent \( i \) is neutral or unopinionated. When \( Z_i \neq 0 \) we say that the agent is opinionated. The full model state space is \( V = \underset{N_o \text{ times}}{\underbrace{1_{N_o} \times \cdots \times 1_{N_o}}} \), and \( Z = (Z_1, \ldots, Z_{N_o}) \in V \) is the system state. The origin \( Z = 0 \) is the neutral point. Another way of interpreting our choice of \( 1_{N_o} N_o \) as an agent’s state space comes from observing that \( 1_{N_o} N_o \) is the tangent space to the \((N_o-1)\)-dimensional simplex in \( \mathbb{R}^{N_o} \). Because \( 1_{N_o} N_o \) and the simplex are isomorphic, our modeling approach naturally applies to multi-option decision-making problems in which an agent’s state space is the \((N_o-1)\)-dimensional simplex. This is useful when the agents’ opinions are interpreted as probabilities of choosing options, for example, in the case of mixed strategies in games where an option refers to a strategy \([47]\).

For more details on the connection to simplex dynamics see Appendix B.

3. **Agents have allocable attention.** Because an agent’s attention or susceptibility to exchanged opinions may be variable, we introduce, for each agent \( i \), two parameters, \( d_i > 0 \) and \( u_i \geq 0 \), that weight the relative influence of the linear resistance term and the opinion-exchange term, respectively.

When the resistance parameter \( d_i \) dominates the attention parameter \( u_i \), the agent is weakly attentive to other agents’ opinions. When \( u_i \) dominates \( d_i \), the agent is strongly attentive to other agents’ opinions. A shift from a weakly attentive to a strongly attentive state can be induced, for instance, by a time-urgency (election day approaching) or a spatial-urgency (target getting closer) to form an informed collective opinion. The attention parameter \( u_i \) can also be used to model social effort, excitability, or susceptibility of agent \( i \) to social influence.

4. **Agents have exogenous inputs.** For each agent, we introduce an input parameter \( b_{ij} \), which represents an input signal from the environment or a bias or predisposition that directly affects agent \( i \)’s opinion of option \( j \). For example, the input \( b_{ij} \) can be used to model the exogenous influence of agent \( i \)’s initial opinions, as in \([2]\), where agents hold on to their initial opinions (sometimes called “stubborn” agents as in \([48]\)).

If the attention and/or bias parameters are hard or impossible to measure or control, which may be the case in sociopolitical applications, we can use standard homogeneity assumptions, e.g., \( d_i = 1 \), \( u_i = u \), \( b_{ij} = 0 \) for all agents, and include random perturbations to capture modeling uncertainties. In technological applications (e.g. robotic swarms), however, tunable parameters of the model provide novel, analytically tractable means to design complex collective behaviors - see for example \([49]\).
C. A General Nonlinear Opinion Dynamics Model

In the multi-option setting, there are four possible types of coupling in the resulting opinion network (see Figure 1):
1) Intra-agent, same-option coupling, with gain \( \alpha_i \);
2) Intra-agent, inter-option coupling, with gain \( \beta_i \);
3) Inter-agent, same-option coupling, with gains \( \gamma_{ik}, i \neq k \);
4) Inter-agent, inter-option coupling, with gains \( \delta_{ik}, i \neq k \).

Parameters \( \alpha_i, \beta_i, \gamma_{ik}, \delta_{ik} \) determine qualitative properties of opinion interactions. Parameter \( \alpha_i \) determines sign and magnitude of opinion self-interaction for agent \( i \). To avoid redundancy with resistance \( d_i \), we assume \( \alpha_i \geq 0 \), i.e., either no self-coupling (\( \alpha_i = 0 \)) or self-reinforcing coupling (\( \alpha_i > 0 \)). Parameter \( \beta_i \) determines how different intra-agent opinions interact. Parameters \( \gamma_{ik} \) and \( \delta_{ik} \) determine whether agents \( i \) and \( k \) cooperate (\( \gamma_{ik} - \delta_{ik} > 0 \)) or compete (\( \gamma_{ik} - \delta_{ik} < 0 \)).

When different option dimensions have no interdependence, we can set \( \beta_i = \delta_{ik} = 0 \) for all \( i, k = 1, \ldots, N_o \). The proposed general nonlinear opinion dynamics are

\[
\begin{align*}
\dot{Z}_i &= P_0 F_i(Z) \\
F_{ij}(Z) &= -d_i z_{ij} + b_{ij} + u_i \left( S_1 \left( \alpha_i z_{ij} + \sum_{k \neq i} N_o \gamma_{ik} z_{kj} \right) \right) \\
&\quad + \sum_{k \neq i} N_o S_2 \left( \beta_i z_{il} + \sum_{k \neq i, k \neq l} \delta_{ik} z_{kl} \right) .
\end{align*}
\]

(3a) (3b)

\( S_q : \mathbb{R} \to [-k_{q1}, k_{q2}] \) with \( k_{q1}, k_{q2} \in \mathbb{R}^{>0} \) for \( q \in \{1, 2\} \) is a generic sigmoidal saturating function satisfying constraints \( S_q(0) = 0, S_q'(0) = 1, S_q''(0) \neq 0, S_q''(0) \neq 0 \). \( S_1 \) saturates same-option interactions, and \( S_2 \) saturates inter-option interactions. \( S_1 \) and \( S_2 \) could be the same but are distinguished in [3] for a more general statement of the model. We provide an even more general formulation of the model in Appendix A that makes use of an adjacency tensor and allows for the possibility of heterogeneous interactions between options. In the following we let

\[
\Gamma = [\gamma_{ik}] \in \mathbb{R}^{N_o \times N_o}, \quad \Delta = [\delta_{ik}] \in \mathbb{R}^{N_o \times N_o} .
\]

(4)

We note that in [3] the sum over the agents could be brought outside of the two sigmoids without altering the qualitative behavior of the model. Our choice in [3] corresponds to an opinion network with saturated inputs. Bringing the sum over the agents outside the sigmoids corresponds to an opinion network with saturated outputs. Either choice could be useful depending on the application. On the other hand, the sum over the options cannot be brought inside \( S_2 \) as the mutual exclusivity condition \( Z_i \in 1_{N_o} \) would lead to spurious term cancellations for some parameter choices. Intuitively, this means that opinions about different options are processed through different input channels. Dynamics [3] are well defined on the system state space \( V \), as we rigorously prove in Appendix [3].

Let \( b_i = \frac{1}{N_o} \sum_{l=1}^{N_o} b_{il} \) be the average input to agent \( i \) and let \( b_{ij} = b_{ij} - b_i \) be the relative input to agent \( i \) for option \( j \).

**Lemma III.1.** The dynamics (3) are independent of the average input \( b_i \) in the sense that \( \frac{\partial z_{ij}}{\partial b_i} = 0 \).

**Proof.** Recall that \( P_0 \) is the projection onto \( 1_{N_o} \) as defined in Section [II]. Then \( P_0 b_i = b_i^+ \), and the conclusion follows trivially from the form of (3).

**Lemma III.1** implies that only relative inputs affect the location of the equilibria of the opinion dynamics [3].

**Assumption 1.** In light of Lemma [III.1] for the remainder of the paper we assume without loss of generality that the average input \( b_i = 0 \) for all \( i = 1, \ldots, N_o \). Thus, \( b_{ij} = b_{ij}^+ \).

Without relative inputs, the system (3) always has the neutral point as an equilibrium.

**Lemma III.2.** \( Z = 0 \) is an equilibrium for (3) if and only if there are no relative inputs, i.e., \( b_{ij} = 0 \) for all \( i \) and all \( j \).

When relative inputs are small, i.e., they do not dominate the dynamics, the formation of opinions in the general model (3) is governed by the balance between the resistance term, which inhibits opinion formation, and the social term, which promotes opinion formation. For illustrative purposes, consider the case in which \( u_i = u \geq 0 \) for all \( i \). Then for \( u \) small, resistance dominates and the system behaves linearly. The opinions \( z_{ij} \) remain small and their relative magnitude is determined by the small inputs \( b_{ij} \). For \( u \) large, the social term dominates and the system behaves nonlinearly.

Importantly, in the nonlinear regime, opinions \( z_{ij} \) form that are much larger than, and potentially unrelated to, inputs \( b_{ij} \), even for very small initial conditions. Opinion exchanges govern opinion formation through bifurcation mechanisms as discussed in the next section and formalized and investigated in the remainder of the paper.

**D. Generality and Connection to Existing Models**

The model [3] is general in the sense that it recovers a number of published opinion-formation, decision-making, and consensus models for specific sets of parameters and/or when linearized. In order to illustrate this we consider the model specialized to \( N_o = 2 \), as most of the models in the literature consider two-option scenarios. The opinion state of agent \( i \) is one-dimensional: following the notation introduced in Section III-B we define \( x_i = z_{i1} = -z_{i2} \) as agent \( i \)'s opinion. Then, opinion dynamics (3) reduce to

\[
\dot{x}_i = -d_i x_i + u_i \left( S_1 \left( \alpha_i x_i + \sum_{k \neq i} N_o \gamma_{ik} x_k \right) \right) \\
&\quad - S_2 \left( \beta_i x_i + \sum_{k \neq i} N_o \delta_{ik} x_k \right) + b_i ,
\]

(5)
where \( \hat{S}_i(y) = \frac{1}{2}(S_i(y) - S_i(-y)) \) are odd saturating functions for \( i = 1, 2 \), \( b_i := b_{i1} = -b_{i2} \), and \( d_i = \frac{1}{2}(d_{i1} + d_{i2}) \). Let the network opinion state be \( x = (x_1, \ldots, x_N) \in \mathbb{R}^N \) and vector of inputs be \( b = (b_1, \ldots, b_N) \in \mathbb{R}^N \). When interactions between option dimensions are disregarded, i.e. with \( \beta_k = \delta_{ik} = 0 \) for all \( i, k = 1, \ldots, N \), the two-option model \( \hat{S}_i \) further reduces to

\[
\dot{x}_i = -d_i x_i + u_i \hat{S}_i \left( \alpha_i x_i + \sum_{k \neq i}^{N} \gamma_{ik} x_k \right) + b_i
\]

which, with appropriate restrictions on the model coefficients, recovers a number of nonlinear consensus models studied in recent literature. We illustrate this in the following example.

**Example III.1** (Specialization to nonlinear consensus protocols). A. When \( \alpha_i = 0 \), \( \gamma_{ik} \in \{0, 1\} \) (or more generally, \( \gamma_{ik} \geq 0 \), \( u_i := u \geq 0 \), and the resistance parameter \( d_i \) is defined as \( d_i := \sum_{k=1}^{N} \gamma_{ik} \) with \( k \neq i \) (the network in-degree for node \( i ))\), reduces to the nonlinear consensus dynamics of [74]–[77].

B. When \( \alpha_i = 0 \), \( \gamma_{ik} \in \{0, 1, -1\} \) (or more generally, \( \gamma_{ik} \in \mathbb{R} \), \( u_i := u \geq 0 \), and the resistance parameter \( d_i \) is defined as \( d_i := \sum_{k=1}^{N} \gamma_{ik} \) with \( k \neq i \), reduces to the nonlinear consensus dynamics with antagonistic interactions studied in [78], [50].

In the nonlinear consensus models of Example III.1 the formation of consensus opinions on the network is a bifurcation phenomenon. Namely when \( b_i = 0 \) for all \( i = 1, \ldots, N \) and \( 0 \leq u < u^* \leq 1 \), the neutral point \( x = 0 \) is an asymptotically stable equilibrium. At a critical value \( u = u^* > 0 \) a pitchfork bifurcation is observed in both models, at which point \( x = 0 \) loses stability and two non-zero asymptotically stable equilibria appear [16] Theorem 1]. [50] Theorem 1]. For nonzero inputs, the pitchfork unfolds.

Importantly, the linearization of these models about the origin \( x = 0 \) at \( u = 1 \) yields \( \dot{x} = -(D - \Gamma)x \), where \( D = \text{diag}(d_i) \in \mathbb{R}^{N_r \times N} \) is the degree matrix for the network. For the positive weights of Example III.1A this corresponds to the standard Laplacian consensus protocol [4], a continuous-time analogue of the weighted-average models discussed in Section II-A. For the signed weights of Example III.1B this linearization is exactly the model of linear consensus with antagonistic, i.e., signed, interconnections [5]. [28]. [29], which is sometimes referred to as the “Altafini” model.

In linear models, nonzero agreement (e.g., bipartite consensus and its generalizations) equilibria are never exponentially asymptotically stable because the model Jacobian has a zero eigenvalue. The eigenspace of the zero eigenvalue is \( \mathbb{R}\{1\} \) in the case of agreement, whereas it is spanned by a mixed-sign vector determined by the coupling topology in the case of disagreement [5], [45], [41], [52]. In other words, linear agreement and disagreement models are not structurally stable and arbitrary small unmodelled (nonlinear) dynamics will in general destroy the predicted behavior. Adding saturated opinion exchanges has a two-fold advantage: i) it makes the model generically structurally stable and, therefore, the agreement and disagreement equilibria hyperbolic (i.e., with no eigenvalues on the imaginary axis); ii) it weakens the necessary conditions for the existence of stable disagreement states. In linear models, the existence of neutrally stable agreement or disagreement states is always linked to restrictive and non-generic assumptions on the coupling topology, for example, balanced coupling for consensus [4] and either strongly connected structurally balanced coupled [5], [45], quasi-strongly connected coupled with an in-isolated structurally balanced subgraph [52], or the existence of a spanning tree on the coupling graph [51] for disagreement. As we rigorously show in the next section, in our model agreement is always possible for generic strongly connected (balanced or unbalanced) graphs, whereas disagreement only requires a weak and provable condition on the spectral properties of the adjacency matrix. It follows that our model recovers the behavior of linear models when one of the above conditions is satisfied (Figure 2) but also highlights the conservativeness of linear model predictions under more general coupling topologies (Figure 3).

### E. Clustering and Model Reduction

The opinion states \( Z_i \) of the model [5] can either represent individual agents or alternatively the average opinion of a
subgroup. The latter perspective can be advantageous, for example, in designing methodology for robotic swarm activities where subgroups of robots need to make consensus decisions, in studying cognitive control where the behavior of competing subpopulations of neurons determines task switching [53], and in modeling and investigating mechanisms that explain sociopolitical processes such as political polarization [54]. In this section we prove a sufficient condition for cluster synchronization of the opinions on the network with the opinion dynamics (3), in which the network trajectories converge to a lower-dimensional manifold on which agents within each cluster have identical opinions.

The cluster synchronization problem has been extensively studied in dynamical systems with diffusive coupling, as in [55], [56]. More broadly, cluster synchronization has been linked to graph symmetries and graph structure called external equitable partitions [57]–[61]. In the following theorem we show that such a network structure constitutes a sufficient condition for a network of agents to form opinion clusters – see Appendix C for the proof.

**Theorem III.3** (Model Reduction with Opinion Clusters). Consider \( N_c \) clusters with \( N_p \) agents in cluster \( p \) such that \( \sum_{p=1}^{N_c} N_p = N_a \). Let \( I_p \) be the set of indices for agents in cluster \( p \). Assume for every \( p = 1, \ldots, N_c \): 1) \( u_i = \bar{u}_p \), \( d_i = \bar{d}_p \), \( b_{ij} = b_{pj} \) for \( i \in I_p, j \in I_p \); 2) within a cluster \( \alpha_i = \bar{\alpha}_p \), \( \gamma_{ik} = \delta_{ps} \), \( \beta_i = \bar{\beta}_p \), \( \delta_{ik} = \delta_{ps} \) for \( i, k \in I_p \), and \( i \neq k \); 3) between clusters \( \gamma_{ik} = \bar{\gamma}_{ps}, \delta_{ik} = \delta_{ps} \) for \( i \in I_p, k \in I_s \) \( s = 1, \ldots, N_c \) and \( s \neq p \). Define bounded set \( K_q \subset \mathbb{R}_{>0}^q \), \( q = 1, 2 \), as the image of the derivative of the saturating function \( S'_q \) of (5). If the following condition holds:

\[
\sup_{\kappa_1 \in K_1, \kappa_2 \in K_2} \left\{ -d_p + u_p \kappa_1 (\bar{\alpha}_p - \bar{\alpha}_p) + u_p \kappa_2 (\bar{\beta}_p - \bar{\beta}_p) \right\} < 0,
\]

for all \( p = 1, \ldots, N_c \), then every trajectory of (3) converges exponentially to the \( N_c(N_0 - 1) \)-dimensional manifold

\[
\mathcal{E} = \{ Z \in \mathbb{R}^{q} | z_{ij} = z_{kj} \quad \forall i, k \in I_p, p = 1, \ldots, N_c \}.
\]

The dynamics on \( \mathcal{E} \) reduce to (3) with \( N_c \) agents with opinion states \( \tilde{x}_{pj} \), \( p = 1, \ldots, N_c \), and with coupling weights

\[
\begin{align*}
\tilde{\alpha}_p &= \bar{\alpha}_p + (N_p - 1)\bar{\alpha}_p, & \tilde{\gamma}_{ps} &= N_p \tilde{\gamma}_{ps}, \\
\tilde{\beta}_p &= \bar{\beta}_p + (N_p - 1)\bar{\beta}_p, & \tilde{\delta}_{ps} &= N_s \tilde{\delta}_{ps}.
\end{align*}
\]

Whenever conditions of Theorem III.3 are met, the group of \( N_a \) agents will converge to a clustered group opinion state. This can happen for a broad class of interaction networks including an all-to-all network with interaction weights that all have the same sign. The sufficient condition can, for example, inform network design for technological systems where several groups of units must make collaborative decisions. See Figure (3) for an illustration of opinion trajectories with two clusters, membership in which is defined by the network structure.

**F: A Minimal Opinion Network Model**

Several of the results characterizing opinion formation in (3) will be proved in the homogeneous regime defined by

\[
\begin{align*}
\beta_k &= \bar{\beta} \in \mathbb{R}, & \gamma_{ik} &= \gamma \alpha_{ik}, & \delta_{ik} &= \delta_{ik}, & A &= [\alpha_{ik}] \quad (10)
\end{align*}
\]

where \( \alpha, \beta, \gamma, \delta \in \mathbb{R} \) and \( \alpha_{ik} \in \{0, 1\} \), \( \alpha_{ii} = 0 \) for all \( i, k \), \( k = 1, \ldots, N_a \), \( k \neq i \), so that \( A \) is an unweighted adjacency matrix without self-loops.

With this choice of parameters, the nonlinear model is minimal in the following sense. The matrix \( A \) with elements \( \alpha_{ik} \) defines the influence network topology. The set of four interactions gains \( \alpha, \beta, \gamma, \delta \) is minimal because in general there are four distinct types of arrows in a multi-option opinion network. Removing one of these four parameters will in general compromise the existence of possibly crucial opinion-formation behaviors. The (global) attention parameter \( u \) and resistance parameter \( d \) tune an agent’s attention to other agents’ opinions and they jointly determine the occurrence of opinion-formation bifurcations, as we prove in Section IV.

We show that our model, even in the fully homogeneous regime, exhibits extremely rich and analytically provable opinion-formation behaviors. We further build upon the results proved for the homogeneous model to study, either analytically or numerically, the effects of heterogeneity and perturbations.

**IV. AGREEMENT AND DISAGREEMENT OPINION FORMATION**

In this section, we show the following key results on opinion formation for dynamics (3).

1) Opinion formation can be modeled as a bifurcation, an intrinsically nonlinear dynamical phenomenon. Opinions form rapidly through bifurcation-induced instabilities rather than slow linear integration of evidence. Opinions can form even in the absence of input, as long as attention (urgency or susceptibility, etc.) is sufficiently high.

2) The way opinions form at a bifurcation depends on the eigenstructure of the matrix \( \Gamma - \Delta \) defined by (4).

3) In the homogeneous regime defined by (10), cooperative agents \( (\gamma > \delta) \) always form agreement opinions, whereas under suitable assumptions on the eigenstructure of the adjacency matrix \( A \) competitive agents \( (\gamma < \delta) \) always form disagreement opinions.

4) At the bifurcation, there are multiple stable solutions, and opinion formation breaks deadlock, that is, the situation in which all agents remains neutral, and therefore undecided, about all the options.

5) Near the bifurcation, opinion formation is ultra-sensitive to input.

6) Away from the bifurcation, opinion formation is robust to small heterogeneity in parameter values and small inputs.

7) In the absence of inputs, multistable agreement solutions and multistable disagreement solutions emerge generically at opinion-forming bifurcations.

8) In the presence of inputs, the opinion-forming bifurcation unfolds (i.e., multistability is broken) in a such a way
that the opinion states favored by inputs attract most of the initial conditions close to the bifurcation. The network structure governs the relative influence of inputs, which leads to a formal notion of centrality indices for agreement and disagreement.

9) Agreement and disagreement can co-exist, revealing the possibility of easy transition between agreement and disagreement.

10) With sufficient symmetry, agreement specializes to consensus and disagreement to dissensus.

A. Agreement and Disagreement States

In this section we clarify what it means for agents in a group to agree and disagree. We say the agents agree, i.e., are in an agreement state, when \( z_{ij} = z_{kj} \) for all \( i, k = 1, \ldots, N_a \). This means that all agents unanimously favor or disfavor each of the options, although they may differ on the magnitude of their opinions. Agreement specializes to consensus when \( Z_i = Z_k \) for all \( i, k = 1, \ldots, N_a \). We say the agents disagree, i.e., are in a disagreement state, when \( z_{ij} \neq z_{kj} \) for at least one pair of agents \( i, k = 1, \ldots, N_a, i \neq k \), and at least one option \( j \). Disagreement specializes to dissensus when the average opinion of the group is neutral, i.e., \( \sum_{i=1}^{N_a} Z_i = 0 \).

Remark IV.1. In the presence of nonzero inputs \( b_{ij} \), agents will generically have nonzero opinions about options as follows from Lemma III.2. For realistic applications, small opinions formed in a linear response to inputs should be distinguished from large opinions which arise from a nonlinear response. To make this distinction we say agents are opinionated when their opinions are large, and unopinionated when their opinions are close to zero. In this paper we keep this distinction qualitative. A precise bound between opinionated and unopinionated magnitudes depends on the application and can be defined when necessary.

B. Opinions Form through a Bifurcation

In this section we prove how steady-state bifurcations of the opinion dynamics (3) result in nonzero opinions on the network. The following theorem, proved in Appendix D provides sufficient conditions under which opinions form through a bifurcation from the neutral equilibrium \( Z = 0 \) and formulas to compute the kernel along which the bifurcation appears.

Theorem IV.1 (Opinion Formation as a Bifurcation). Consider model (3) with \( b_{ij} = 0, \ d_i = d, \ u_i = u, \ \alpha_i = \alpha, \) and \( \beta_i = \beta, \) for all \( i = 1, \ldots, N_a \). Let \( J \) be the Jacobian of the system evaluated at neutral equilibrium \( Z = 0 \). Define \( \lambda \) to be the eigenvalue of \( \Gamma - \Delta \) with largest real part, with \( \Gamma \) and \( \Delta \) from (4). Assume that \( \lambda \) is real, \( \alpha - \beta + \lambda > 0 \), and that \( \text{Re}[\mu] \neq \lambda \) for any eigenvalue \( \mu \neq \lambda \) of \( \Gamma - \Delta \). Then \( Z = 0 \) is locally exponentially stable for \( 0 < u < u^* \), with

\[
u^* = \frac{d}{\alpha - \beta + \lambda},\]

and unstable for \( u > u^* \). If \( \lambda \) is simple at \( u = u^* \) an opinion-forming steady-state bifurcation happens along \( \ker J = \mathbb{R}\{v^* \} \otimes 1_{N_o} \), where \( v^* \) is the right unit eigenvector associated to \( \lambda \). More precisely, generically, for each bifurcation branch there exists \( v_{ax} \in 1_{N_o} \) such that the branch is tangent to \( Z = 0 \) to the one-dimensional subspace \( \mathbb{R}\{v^* \otimes v_{ax} \} \).

Remark IV.2. The vector \( v_{ax} \) can be computed as the generator of the fixed-point subspace of an axial subgroup \( \mathbb{Z} \) Section 1.4) of the (irreducible) action of \( \mathbb{S}_{N_o} \) on \( \ker J \).

Theorem IV.1 reveals how nonzero opinions can form even without input: opinions form when attention \( u \) is greater than threshold \( u^* \). This means that deadlock can be avoided even when there is little or no evidence to distinguish among options. The value of the threshold is determined from the structure of the communication network. Additionally, from this result we can deduce how agreement and disagreement solutions are informed by the network structure. In particular, the equilibrium opinions of each agent near the bifurcation are directly proportional to the vector \( v_{ax} \), scaled by the entries of \( v^* \). When all of the entries of \( v^* \) have the same sign, the agents will be in an agreement state. If \( v^* \) contains mixed-sign entries, the agents will necessarily be in a disagreement state. This provides a straightforward connection between the spectral properties of the effective inter-agent communication graph \( \Gamma - \Delta \) and the opinion configurations which arise from the opinion dynamics (3). On the other hand, the entries of the vector \( v_{ax} \) determine the relative preference associated to the various options. In the following corollary we show how in the homogeneous regime (10) Theorem IV.1 specializes to simple conditions for agreement and disagreement.

Corollary IV.1.1 (Agreement and Disagreement). Consider model (3) with homogeneous parameters as in (10) on a strongly connected graph. Let \( \lambda_{\max} > 0 \) be the largest real-part eigenvalue of \( A \), i.e. the Perron-Frobenius eigenvalue, with associated positive eigenvector \( v_{ax} \). Let \( \lambda_{\min} < 0 \) be the smallest real-part eigenvalue of \( A \). Assume \( \lambda_{\min} \) is real, simple, and for all eigenvalues \( \xi \neq \lambda_{\min} \) of \( A \), Re[\xi] \neq \lambda_{\min} \). A. Cooperative agents. Suppose that \( \gamma - \delta > 0 \) and that \( \alpha - \beta + \gamma > 0 \). Then the critical value of attention at which the steady-state bifurcation predicted by Theorem IV.1 happens is given by

\[
u^* := u_a = \frac{d}{\alpha - \beta + \gamma},\]

and close to bifurcation all the bifurcation branches are made of agreement solutions.

B. Competitive agents. Suppose \( \gamma - \delta < 0 \) and that \( \alpha - \beta + \gamma > 0 \). Then the critical value of attention at which the steady-state bifurcation predicted by Theorem IV.1 happens is given by

\[
u^* := u_d = \frac{d}{\alpha - \beta + \gamma},\]

This result can be generalized to networks for which \( \lambda \) is not simple, which we leave for future work.
Moreover, whenever \( \mathbf{v}_{\text{min}} \) has mixed-sign entries, close to bifurcation all the bifurcation branches are made of disagreement solutions.

We emphasize that the assumption about eigenvalues \( \lambda \) of Theorem IV.1 and \( \lambda_{\text{min}} \) of Corollary IV.1.1 being simple often holds, and can be easily verified numerically for various graph structures. Furthermore, the eigenvector \( \mathbf{v}_{\text{min}} \) of Corollary IV.1.1 typically has mixed-sign entries, and competition between agents therefore tends to result in network disagreement for example, on undirected networks \( \mathbf{v}_{\text{min}} \) always has mixed-sign entries since \( \mathbf{v}_{\text{max}} \) is the positive Perron-Frobenius eigenvector and \( \langle \mathbf{v}_{\text{max}}, \mathbf{v}_{\text{min}} \rangle = 0 \). For example see Figure 5 for patterns of agreement and disagreement solutions for \( N_o = 2 \) and several representative undirected graphs.

An important feature of the opinion dynamics (5) is the multistability of opinion configurations at the bifurcations described by Theorem IV.1 and Corollary IV.1.1. When agents cooperate and \( \ker \mathbf{J} \) is made of agreement vectors, if agreement in favor of one option is stable then agreement in favor of each other option is stable, and likewise for disagreement solutions. There is a deadlock when \( u < u_c \) \((u < u_d)\) and breaking of deadlock when \( u > u_c \) \((u > u_d)\).

At the bifurcation the linearization is singular, and the model is ultra-sensitive at transition from neutral to opinionated. Even infinitesimal perturbations (e.g., tiny difference in opinion values) are sufficient to destroy multistability at bifurcation by selecting a subset of stable equilibria (e.g., those corresponding to higher-valued options), a phenomenon known as forced-symmetry breaking and widely exploited in nonlinear decision-making model [16], [24], [63].

Generically, stable equilibria that appear at the bifurcation are hyperbolic, and thus they and their basin of attraction are robust to perturbations, a key property that ensures stability of opinion formation despite (sufficiently small) changes in inputs, heterogeneity in parameters, and perturbations in the communication network. Robustness bounds can be derived using methods like those used for Hopfield networks in [64]. Robust multistability of equilibria gives the opinion-forming process hysteresis, and thus memory, between different opinion states: once an opinion is formed in favor of an option, a large change in the inputs is necessary for a switch.

Remark IV.3. Under the clustering conditions of Theorem III.3 we can apply Theorem IV.1 and Corollary IV.1.1 with \( N_c \) agents and coupling parameters defined by (9).

Remark IV.4 (Mode Interaction and Coexistence of Agreement and Disagreement). When \( \gamma = \delta \), there is mode interaction [65], and agreement and disagreement bifurcations appear at the same critical value of \( u \). This regime is especially interesting because it allows for co-existence of stable agreement and disagreement solutions, which can result in agents easily transitioning between the two in response to changing conditions. However, additional primary solution branches not captured by the analysis presented here can appear in this regime, and we leave exploring this parameter regime more thoroughly to future work.

C. Patterns of Opinion Formation for Two Options

In this section we examine the ultra-sensitivity of the network opinion dynamics to inputs or biases of individual agents when operating near its bifurcation point. We consider the two-option opinion dynamics (6) with homogeneous parameters (10), relaxing the assumption of zero inputs:

\[
\dot{x}_i = -d x_i + \hat{S}_i \left( \alpha x_i + \gamma \sum_{k=1}^{N_o} a_{ik} x_k \right) + b_i, \tag{14}
\]

The next corollary follows from Corollary IV.1.1 and [66] Theorems IV.1 and IV.2. It recognizes the opinion-forming bifurcations of (14) as agreement and disagreement pitchfork bifurcations and predicts their unfolding in response to distributed inputs as a function of network structure. In other words, it predicts the location of the two symmetric agreement (or disagreement) solutions and how the input-driven unfolding selects one of the two solutions (see Figure 4).

Corollary IV.1.2. Consider (14) and suppose that adjacency matrix \( A \) is irreducible, i.e., the associated graph is strongly connected. Let \( \lambda_{\text{max}} > 0 \) be the largest real-part eigenvalue of \( A \), i.e., the Perron-Frobenius eigenvalue, with associated unitary right eigenvector \( \mathbf{v}_{\text{max}} \), and unitary positive left eigenvector \( \mathbf{w}_{\text{max}} \). Let \( \lambda_{\text{min}} < 0 \) be the smallest real-part eigenvalue of \( A \). Assume \( \lambda_{\text{min}} \) is real, simple, and for all eigenvalues \( \xi \neq \lambda_{\text{min}} \), Re[\( \xi \)] \( \neq \lambda_{\text{min}} \). Let \( \mathbf{v}_{\text{min}} \) and \( \mathbf{w}_{\text{min}} \) be the right and left unitary eigenvectors associated to \( \lambda_{\text{min}} \) with \( \langle \mathbf{v}_{\text{min}}, \mathbf{w}_{\text{min}} \rangle > 0 \).

A. Cooperative agents. If \( \gamma > 0 \), inputs satisfy \( \langle \mathbf{b}, \mathbf{w}_{\text{max}} \rangle = 0 \), and \( \alpha + \lambda_{\text{max}} \gamma > 0 \), model (14) undergoes a supercritical pitchfork bifurcation for \( u = u^* = d/m(\alpha + \lambda_{\text{max}} \gamma) \), at which opinion-forming bifurcation branches emerge from \( x = 0 \). The associated bifurcation branches are tangent at \( x = 0 \) to \( \mathbb{R} \{ \mathbf{v}_{\text{max}} \} \).

The pitchfork unfolds in the direction given by \( \langle \mathbf{b}, \mathbf{w}_{\text{max}} \rangle \), i.e., if \( \langle \mathbf{b}, \mathbf{w}_{\text{max}} \rangle > 0 \), then the only stable equilibrium \( x^* \) for \( u \) close to \( u^* \) satisfies \( \langle x^*, \mathbf{v}_{\text{max}} \rangle > 0 \).

B. Competitive agents. If \( \gamma < 0 \), inputs satisfy \( \langle \mathbf{b}, \mathbf{w}_{\text{min}} \rangle = 0 \), and \( \alpha + \lambda_{\text{min}} \gamma > 0 \), model (14) undergoes a supercritical pitchfork bifurcation for \( u = u^* = d/m(\alpha + \lambda_{\text{min}} \gamma) \), at which opinion-forming bifurcation branches emerge from \( x = 0 \). The associated bifurcation branches are tangent at \( x = 0 \) to \( \mathbb{R} \{ \mathbf{v}_{\text{min}} \} \).

The pitchfork unfolds in the direction given by \( \langle \mathbf{b}, \mathbf{w}_{\text{min}} \rangle \), i.e., if \( \langle \mathbf{b}, \mathbf{w}_{\text{min}} \rangle > 0 \), then the only stable equilibrium \( x^* \) for \( u \) close to \( u^* \) satisfies \( \langle x^*, \mathbf{v}_{\text{min}} \rangle > 0 \).

Remark IV.5. For (5) with homogeneous parameters (10) an analogous result to Corollary IV.1.2 holds, except with \( u^* = d/m(\alpha - \beta) \).

The symmetric opinion-forming pitchfork bifurcation predicted by Corollary IV.1.2 in the case of trivial or balanced inputs \( \langle \mathbf{b}, \mathbf{w}_{\text{max,min}} \rangle = 0 \) constitutes the simplest instance of multi-stability (bistability in this case) between different possible opinion states (see Figure 4 left for the disagreement case - an identical figure is found for the agreement case [66] Figure 1). For attention \( u \) greater than the critical value \( u^* \) (the bifurcation point), the group of agents can converge to either of the two stable opinion states depending on initial
conditions and (in a real-world setting) unmodelled uncertainties and disturbances.

In the agreement regime solutions on the upper branch correspond to agents agreeing on option 1 and on the lower branch to agents agreeing on option 2. In the disagreement regime solutions on the upper branch correspond to one subgroup favoring option 1 and the second subgroup favoring option 2 and the lower branch to the first subgroup favoring option 2 and the second subgroup favoring option 1. Both the sign and relative magnitudes of the agent opinions are predicted by \( \mathbf{v}_{\text{max}} \) in the agreement regime and \( \mathbf{v}_{\text{min}} \) in the disagreement regime – see Figure 5 for an illustration for four types of graphs. Observe that for the highly symmetric cycle graph, the group splits evenly in the disagreement case, whereas in the star and wheel graphs, the center node disagrees with all of the peripheral nodes. These results are easily predicted using well-known results on the eigenstructure of the adjacency matrix for these graphs. See [68] for details.

The symmetric pitchfork unfolds (Figure 4 right) in such a way that only one solution (that predicted by the sign \( \langle \mathbf{b}, \mathbf{w}_{\text{min}} \rangle \)) is stable close to the symmetric bifurcation point. For larger values of the attention parameter, the other solution also regains stability in a saddle-node bifurcation but the input-driven asymmetry is still reflected in the size of the basin of attraction of the two solutions. The left eigenvectors of the adjacency matrix \( \mathbf{w}_{\text{max/min}} \) define agreement/disagreement centrality indices because the unfolding formula \( \langle \mathbf{b}, \mathbf{w}_{\text{max/min}} \rangle \leq 0 \) implies that the larger \( \mathbf{w}_{\text{max/min}} \), the larger the effect of a nonzero input \( b_i \) on the agreement/disagreement pitchfork unfolding. Agreement and disagreement centrality indices can thus naturally be used to control opinion forming behavior via distributed inputs. By augmenting our opinion dynamics with an attention feedback mechanism, these centrality indices determine distributed thresholds for the triggering of opinion cascade, as illustrate in the next section (see also [49] for numerical illustrations on large random graphs and an application to task allocation in robot swarms). Finally, all the results in this section generalize to the case \( N_a > 2 \). This generalization requires the computation of the vector \( v_{\text{az}} \) appearing in Theorem IV.1 via equivariant bifurcation theory methods (see Remark IV.2), a direction that we leave for future extensions of this work.

D. Consensus and Dissensus Generic for Transitive Symmetry

In Section IV-B we have shown how graph structure can inform what types of opinion configurations arise in the group. In this section we consider, for the homogeneous regime (10), how the presence of symmetry in the communication graph can further constrains opinion configurations. We show how consensus and dissensus emerge for opinion dynamics (3) with two different examples of transitive symmetry. We first introduce a few technical definitions from group theory and equivariant bifurcation theory.

Let \( \mathcal{G} \) be a compact Lie group acting on \( \mathbb{R}^n \). Consider a dynamical system \( \dot{x} = h(x) \) where \( x \in \mathbb{R}^n \) and \( h : \mathbb{R}^n \to \mathbb{R}^n \). Then \( \rho \in \mathcal{G} \) is a symmetry of the system, equivalently \( h \) is \( \rho \)-equivariant, if \( \rho(h(x)) = h(\rho x) \). If \( h \) is \( \rho \)-equivariant for all \( \rho \in \mathcal{G} \), then \( h \) is \( \mathcal{G} \)-equivariant [62]. \( \mathcal{G} \)-equivariance means elements of symmetry group \( \mathcal{G} \) send solutions to solutions.

The compact Lie group associated with permutation symmetries of \( n \) objects is the symmetric group on \( n \) symbols \( S_n \), which is the set of all bijections of \( \Omega_n := \{1, \ldots, n\} \) to itself (i.e., all permutations of ordered sets of \( n \) elements). The opinion dynamics (3) with homogeneous parameters (10) and all-to-all coupling are maximally symmetric, i.e. \( (S_N_x \times S_N_a) \)-equivariant, where elements of \( S_N_a \) permute the \( N_a \)-element set of agents and elements of \( S_N_x \) permute the \( N_a \)-element set of options (10). Maximally symmetric opinion dynamics are unchanged under any permutation of agents or options.

A subgroup \( \mathcal{G}_n \subset S_n \) is transitive if the orbit \( \mathcal{G}_n i = \{\rho i, \rho \in \mathcal{G}_n\} = \Omega_n \) for some (and thus all) \( i \in \Omega_n \). \( (S_N_x \times S_N_a) \)-equivariant opinion dynamics, with transitive \( \mathcal{G}_N_x \), are still highly symmetric since any pair of agents, while not necessarily interchangeable by arbitrary permutations, can be mapped into each other by the symmetry group action. The following are examples of transitive subgroups of \( S_N_a \):

- \( D_{N_a} \), dihedral group of order \( 2N_a \); symmetries correspond to \( N_a \) rotations and \( N_a \) reflections. \( D_{N_a} \)-equivariant opin-
tion dynamics are unchanged if agents are permuted by a rotation or a reflection, e.g., if agents communicate over a network defined by an undirected cycle.

- $3_{N_a}$, cyclic group of order $N_a$; symmetries correspond to $N_a$ rotations (and no reflections). $3_{N_a}$-equivariant opinion dynamics are unchanged if agents are permuted by a rotation, e.g., if agents communicate over a network defined by a directed cycle.

Observe that the system opinion state space decomposes as $V = W_c \oplus W_d$, where $W_c$ is the multi-option consensus space defined as

$$W_c = \{(Z_1, \ldots, Z_{N_a}) | Z_1 = Z \in 1_{N_a}, \forall i\},$$

and $W_d$ is the multi-option dissensus space defined as

$$W_d = \{(Z_1, \ldots, Z_{N_a}) | Z_1 + \cdots + Z_{N_a} = 0\}.$$

On the consensus space $W_c$, agents have identical opinions. On the dissensus space $W_d$, agent opinions are balanced over the options such that the average opinion of the group is neutral.

Model-independent results [30, Theorem 4.6 and Remark 4.7] ensure that, in the presence of transitive symmetry, ker $J = W_c$ or ker $J = W_d$. I.e., if (3) is symmetric with respect to a group $\Gamma_a$ that acts by swapping the agent indices transitively, then generically ker $J = W_c$ or ker $J = W_d$. In the homogeneous regime (10), agent symmetry of (3) is fully determined by $A$ as proved in the following proposition for the maximally symmetric case $\mathcal{G}_a = \mathcal{G}_N$, and the highly symmetric case $\mathcal{G}_a = \mathcal{D}_N$, (see Appendix E for proof). The same result holds, with similar proof, for other transitive agent symmetries, e.g., $\mathcal{G}_a = 3_{N_a}$.

Proposition IV.2. Consider model (3) in the homogeneous regime defined by (10). Then the following hold true:

1) Model (3) is $(\mathcal{G}_N \times \mathcal{S}_{N_a})$-equivariant if and only if $A$ is the adjacency matrix of an all-to-all graph;
2) If $A$ is the adjacency matrix of an undirected cycle graph, then model (3) is $(\mathcal{G}_N \times \mathcal{D}_N)$-equivariant.

Remark IV.6. More generally, the symmetry of the opinion dynamics is determined by the automorphism group of the graph associated to $A$. The proof follows as for Proposition IV.2.

The next corollary follows from Theorem IV.1 and [30, Theorem 4.6 and Remark 4.7]. The two types of opinion-formation behaviors proved in this corollary, i.e., consensus for cooperative agents and dissensus for competitive agents, respectively, constitute an opinion-formation analogue of consensus and balanced (split) states in coupled phase oscillators (see, e.g., [4], [69]–[71]).

Corollary IV.2.1 (Consensus from Cooperation and Dissensus from Competition). Consider model (3) in the homogeneous regime (10). Suppose that the graph associated to adjacency matrix $A$ is either all-to-all or an undirected cycle. Let $u_a$ and $u_d$ be defined by (12) and (13).

A. Cooperative agents and consensus. If agents are cooperative ($\gamma - \delta > 0$), then opinion formation appears as a bifurcation along the consensus space at $u = u_a$ with

$$\lambda = N_a - 1$$

for the all-to-all case and $\lambda = 2$ for the cycle case.

B. Competitive agents and dissensus. If agents are competitive ($\gamma - \delta < 0$), then opinion formation appears as a bifurcation along the dissensus space at $u = u_d$ with $\lambda = -1$ for the all-to-all case, $\lambda = -2$ for the cycle case, when $N_a$ is even, and $\lambda = 2 \cos(\pi (N_a - 1)/N_a)$, when $N_a$ is odd.

Remark IV.7 (Stability of Consensus and Dissensus). Consensus and dissensus solution branches predicted for the symmetric networks in Corollary IV.2.1 are a consequence of the Equivariant Branching Lemma [62, Section 1.4], and are made of hyperbolic equilibria. Their stability can be proved using the tools in [73, Section XIII.4] and [62, Section 2.3].

V. ATTENTION DYNAMICS AND TUNABLE SENSITIVITY

We have established that existence of agreement and disagreement equilibria and multistability of opinion formation outcomes arise from bifurcations of the general opinion dynamics model (3). In this section we explore how ultra-sensitivity to inputs $b_{ij}$, robustness to changes in inputs, and opinion cascade dynamics also arise from bifurcations. With the addition of dynamic state feedback for model parameters in (3), the opinion formation process can reliably amplify arbitrarily small inputs $b_{ij}$, reject small changes in input as unwanted disturbance, and move opinion cascade even if only one agent gets an input, and enable groups to move easily between consensus and dissensus. The choice of feedback design parameters determine implicit thresholds that make all of these behaviors tunable.

The addition of dynamic state feedback for parameters in our model is similar in spirit to the extension of linear weighted-average model with nonlinear state-feedback update rules for the coupling gains, as in bounded confidence models [6]–[8] and biased assimilation models [10], [11]. However, our motivation, rather than to capture a specific sociological
phenomenon, is to make our model adaptable to inputs and flexibly responsive to changing environments. This is achieved by ensuring tunable sensitivity of opinion formation to inputs. We illustrate our ideas and prove our results for the case $N_o = 2$. The multi-option extension is left for future work.

A. Dynamic State Feedback Law for Attention

In the same spirit as [16], [74], we augment the opinion dynamics (3) by introducing feedback dynamics on the attention parameter $u_i$ for each agent $i$, in the form of a leaky integrator with saturated input

$$
\tau_u \dot{u}_i = -u_i + S_u \left( \frac{1}{N_o} \sum_{k=1}^{N_o} \sum_{l=1}^{N_o} (\bar{a}_{ik} z_{lk})^2 \right),
$$

(17)
a simple dynamics universally found, in particular, in decision making models [36], [37], [53]. Here, $\tau_u > 0$ is a time scale, which can be freely chosen. $S_u$ is a smooth saturating function, satisfying $S_u(0) = 0$, $S_u(y) \to \bar{u} > 0$ as $y \to \infty$, $S_u'(y) > 0$ for all $y \in \mathbb{R}$, and $S_u''(y) > 0$ for all $y > 0$. We define $S_u$ as a Hill saturating function

$$
S_u(y) = \frac{y^n}{(y^n + y^\gamma)^{n/\gamma}},
$$

(18)
where threshold $y_{th} > 0$ and $n > 0$. In [18], we constrain $\bar{u}$ and $y$ such that $\bar{u} > u_c \geq u > 0$, with $u_c = u_a(S_a(u_a))$ and $u_a(u_d)$ when $\gamma > 0$ ($< 0$) and $u_a, u_d$ are defined by (12), (13). For the remainder of this section we consider the homogeneous regime (10), except for the $u_i$, which are heterogeneous. The attention coupling matrix $A$ with elements $\bar{a}_{ik}$ can be distinct from the opinion coupling matrix $A$ but here we let $\bar{A} = A + \mathcal{I} N_o$. For $N_o = 2$ the attention feedback dynamics (17) simplify to

$$
\tau_u \dot{u}_i = -u_i + S_u \left( \sum_{k=1}^{N_o} (\bar{a}_{ik} x_{ik})^2 \right),
$$

(19)

B. Tunable Sensitivity and Robustness for a Single Agent

In this section we first consider a single agent with dynamic opinions (5) and dynamic attention (19) with no neighbors, i.e., $a_{ik} = 0$ for all $k = 1, \ldots, N_o$. As shown in Figures 7 and 8, the equilibria of the coupled opinion and attention dynamics can graphically be represented as the intersection of the $x_i$-nullcline $\{ \dot{x}_i = 0 \}$ (black solid) and $u_i$-nullcline $\{ \dot{u}_i = 0 \}$ (red dashed) in the $(u_i, x_i)$ plane. Corollary IV.1.2 defines the shape of the $x_i$-nullcline as a pitchfork bifurcation which unfolds with nonzero input $b_i$, analogous to Figure 4.

For model (5), (19), define agent $i$ to be strongly opinionated when its attention is close to its upper saturation value, i.e., $u_i \approx \bar{u}$, and weakly opinionated when its attention is close to its lower saturation value, i.e., $u_i \approx 0$. What we refer to as tunable sensitivity of opinion formation to input $b_i$ can then be understood by comparing the plots of Figure 7, where the opinion trajectory for agent $i$ is plotted on the left for $b_i = 0.5$ and on the right for $b_i = 1$. For the given parameters and $b_i = 0.5$, the nullclines intersect at three points in the positive half-plane. For unopinionated initial conditions, the opinion state is attracted to the point corresponding to a weakly opinionated equilibrium: agent $i$ rejects the input $b_i = 0.5$ and does not form a strong opinion. For the same parameters and $b_i = 1$, the nullclines intersect at only one point, corresponding to a strongly opinionated equilibrium. Thus, for the same initial conditions, agent $i$ accepts the input $b_i = 1$ and forms a strong opinion. The implicit sensitivity threshold that distinguishes rejected from accepted inputs can be tuned by using parameters $n, y_{th}$ in (18). Changing their value changes the shape of the $u_i$-nullcline and thereby varies how strong of an input $b_i$ is required to reduce the number of nullcline intersections from three to one, as in Figure 7.

Tunable robustness of opinion formation to changes in input $b_i$ can be understood by comparing the sequence of plots in the top and bottom halves of Figure 8. The plots on the left show agent $i$ forming a strong opinion in the direction of the input $b_i = 1$. The plots on the right show what happens to agent $i$’s opinion when the input switches to $b_i = -1$, i.e., an input that is in opposition to the original input. In the top sequence, when $\bar{u} = 1$, agent $i$ accepts the change of input and forms a strong opinion in the direction of the new input. In the bottom sequence, when $\bar{u} = 2.5$, agent $i$ rejects the change of input and retains a strong opinion in the direction of the original input. The implicit robustness threshold that distinguishes rejected from accepted changes in input can be tuned by design parameter $\bar{u}$.

C. Opinion Cascades with Tunable Distributed Sensitivity

The following corollary shows that our feedback attention dynamics create a distributed threshold for the opinion dynamics below which the agents remain weakly opinionated and above which agents converge to a strongly opinionated equilibrium. The transition from a weakly opinionated to a strongly opinionated equilibrium in response to inputs is called an opinion cascade. The threshold is defined in terms of the inner product of the vector of inputs $b$ and suitable eigenvectors of the opinion network adjacency matrix. In other words, the threshold is distributed across the agents and the spectral properties of the adjacency matrix determine highly

![Fig. 7: Sensitivity of opinion formation to input magnitude. ($u_i, x_i$)-phase plane and trajectories of (5), (19); $n = 2, y_{th} = 0.4, \alpha_1 = 2, \beta_1 = -1, \gamma_{ik} = \delta_{ik} = 0, \eta_i = 1, \tau_c = 1, \bar{u} = 0, u = 2$ for $b_i = 0.5$ (left) and $b_i = 1$ (right). Initial state ($u_i(0), x_i(0)$) = (0, 0) is a blue circle, and final state a yellow diamond. Nullclines of (5) are black solid and (19) are red dashed. Gray arrows show flow streamlines. Color scale is time.](image-url)
sensitive and weakly sensitive directions in the input vector space. As in Section V.B for single agents, the threshold can be tuned with parameters of the attention dynamics.

In the following theorem, we let $\lambda_{\max}$, $w_{\max}$ and $w_{\min}$ satisfy the assumptions of Corollary [V.1.2].

**Theorem V.1.** Consider the coupled system (6),(17) with $d_i = d, \alpha_i = \alpha$, and $\gamma_{ik} = \gamma a_{ik}$, where $A = [a_{ik}]$ is a symmetric and irreducible adjacency matrix. Let $u_c = \frac{d}{\alpha + \lambda_{\max} \gamma}$, $w_c = w_{\max}$ if $\gamma > 0$ and $u_c = \frac{\alpha + \lambda_{\min} \gamma}{\alpha + \lambda_{\max} \gamma}$, $w_c = w_{\min}$ if $\gamma < 0$. There exists $\varepsilon > 0$ such that for $0 < u_c - \bar{u}, y_{th} < \varepsilon$ and $n$ sufficiently large, the following generically hold. There exists $p = p(y_{th}) > 0$ satisfying $\frac{dp}{\sigma_{w_{\min}}} > 0$ such that, for $|\langle w_c, b \rangle| < p$, model (5),(17) possesses a weakly opinionated locally exponentially stable equilibrium. This equilibrium loses stability in a saddle-node bifurcation for $|\langle w_c, b \rangle| = p$. No weakly opinionated equilibria exist for $|\langle w_c, b \rangle| > p$ and all trajectories converge to a strongly opinionated agreement (equilibrium) for $\gamma > 0$ ($\gamma < 0$). For $\gamma = 0$, the strongly opinionated equilibrium $\langle x^*, u^* \rangle$ satisfies $\text{sign}(x_i^*) = \text{sign}(b_i)$.

Figure 8 illustrates the predictions of Theorem V.1. It shows that the arrival of a suprathreshold input at $t = 20$ triggers an opinion cascade. Independently of the entries of the input vector $b$, the cascade goes to a strongly opinionated agreement equilibrium for $\gamma > 0$ (Figure 8a) and to a strongly opinionated disagreement equilibrium for $\gamma < 0$ (Figure 8b). Conversely, for $\gamma = 0$, the pattern of opinions at the strongly opinionated equilibrium is determined by the sign of the entries of the input vector. Figure 9 makes these observations more quantitative by showing the cascade threshold predicted by Theorem V.1 as a joint function of the norm of the input vector and of the cosine of the angle between the input vector and the relevant eigenvector of the adjacency matrix. As predicted by the theorem, when the input vector is misaligned with respect to the adjacency matrix eigenvector, large-magnitude inputs are necessary to robustly trigger an opinion cascade. Conversely, as the two vectors align, an opinion cascade can be triggered with much smaller inputs.

**VI. AGREEMENT – DISAGREEMENT TRANSITIONS**

We illustrate how feedback dynamics of social influence weights in the two-option opinion dynamics (5) can be used to facilitate transitions between agreement and disagreement on the network. Suppose agents comprise two clusters of size $N_1$ and $N_2$ with index sets $\mathcal{I}_1$ and $\mathcal{I}_2$. Let $b_i = b_p$ for $i \in \mathcal{I}_p$ and $\hat{x}_p = \frac{1}{N_p} \sum_{i \in \mathcal{I}_p} x_i$, where $p \in \{1, 2\}$. We define intra-cluster coupling as $\gamma_{ik} = \alpha/N_p > 0$ and $\delta_{ik} = \beta/N_p < 0$, $l \neq j$, $p = 1, 2$, $d_i = d$ for all $i, k \in \mathcal{I}_p$, and agent attention dynamics by (19) with $\bar{a}_{ik} = 1$ for all $i, k$.

The influence network between the clusters is dynamic. We define feedback dynamics for the inter-cluster coupling as

$$\tau\gamma_{ij} = -\gamma_{ij} + \sigma S_{\alpha}(\hat{x}_1 \hat{x}_2)$$  \hspace{1cm} (20a)

$$\tau\delta_{ij} = -\delta_{ij} - \sigma S_{\beta}(\hat{x}_1 \hat{x}_2)$$  \hspace{1cm} (20b)
evolve back towards a clustered dissensus state once \( \gamma = 300 \) in informed by the agents’ inputs. However, because \( \sigma_1 \) and the second favoring option 2. Initially, the sign can reliably trigger a transition between agreement where \( \beta \). Parameters \( d_i, \alpha_i, \beta_i, b_i \) have additive perturbations drawn from \( N(0,0.1) \) independently for each agent \( i \). For \( t < 300 \), \( \sigma = 1 \) and for \( t \geq 300 \), \( \sigma = -1 \).

where \( \sigma \in \{1,-1\}, \tau_i, \tau_k > 0 \) are time scales, \( S_i(y) = \gamma f \tanh(g_f y), S_k(y) = \delta f \tanh(g_f y) \), and \( \gamma_f, \delta_f, g_f, g_k > 0 \).

The sign of design parameter \( \sigma \) in (20) determines whether the system tends towards consensus or dissensus, and switching the sign can reliably trigger a transition between agreement and disagreement. Figure 11 illustrates the opinion formation of 7 agents that form two clusters, one with 3 agents and the other with 4 agents. One cluster has input favoring option 1 and the second favoring option 2. Initially, \( \gamma - \delta < 0 \) on average and the clusters evolve to a dissensus state which is informed by the agents’ inputs. However, because \( \sigma = 1 \), the two clusters eventually evolve towards a consensus state once \( \gamma - \delta > 0 \) despite the inputs favoring disagreement. At time \( t = 300 \), \( \sigma \) switches sign to \( \sigma = -1 \) and the two clusters evolve back towards a clustered dissensus state once \( \gamma - \delta < 0 \).

VI. FINAL REMARKS

Our opinion dynamics provide a new modeling framework for studying a variety of phenomena in which opinion formation is the governing behavior. In contrast to previous models, our approach focuses on the intrinsic nonlinear nature of opinion exchanges and thus on bifurcations as the key mechanism for analyzing and controlling opinion formation. Our model exhibits the flexibility, adaptability and robustness of natural opinion-forming systems, including deadlock-breaking and tunable sensitivity to changing inputs. A special instance of our model was motivated by modeling decision making in honeybee communities [16]. The analytical tractability of our model makes it possible to tackle its rich dynamical behavior constructively. This has allowed us to make novel predictions about the role of the opinion network structure in determining the emerging patterns of opinion formations and the sensitivity of the network to exogenous inputs, as well as to design adaptive feedback control laws for the model parameters.

The applicability of our model to real-world problems has recently been confirmed by our recent contributions in sociopolitical problems [54], the design of task-allocation algorithms in robot swarms [49], cognitive control [53], and game theory [47]. Other possible applications include decision making in biological and artificial neural networks, epidemiology and disease spread, and decision making in groups, from humans and robots to bacteria and animals on the move.

ACKNOWLEDGEMENTS

We acknowledge the contributions of Ayanna Matthews and Timothy Sorochkin to Figures 5 and 10.

APPENDIX

A. Extension to Heterogeneous Inter-option Coupling

In future applications of the opinion dynamics model, it may be useful to consider scenarios in which there is a heterogeneous level of influence between different options, i.e., in addition to the inter-agent interaction network there is an inter-option interaction network. In order to capture this, we introduce the adjacency tensor whose entries \( A_{ik}^j \) capture the weight of influence agent \( k \)'s opinion on option \( l \) has on agent \( i \)'s opinion on option \( j \), which leads to the generalized opinion dynamics:

\[
\dot{z}_i = P_0 F_i(Z)
\]

\[
F_{ij}(Z) = -d_i z_{ij} + u_i \sum_{l=1}^{N_o} S_l \left( \sum_{k=1}^{N_o} A_{ik}^j z_{kl} \right) + b_{ij}
\]

The model studied in this paper is recovered when \( S_l = S_1 \) for same-option interactions and \( S_2 \) for inter-option interactions, and \( A_{ij}^j = \alpha_i, A_{ik}^j = \gamma_{ik}, A_{ij}^j = \beta_i, \) and \( A_{ik}^j = \delta_{ik} \) for all \( i,k = 1, \ldots, N_a, j,l = 1, \ldots, N_o, i \neq k,l \neq i \).

B. Well-definedness of Model

We show that the general model is well defined by showing in Lemma A.1 that \( V \) is forward invariant for \( E \) and in Theorem A.2 that solutions are bounded. We define \( D = \text{diag}\{d_1, \ldots, d_{N_o}\} \otimes I_{N_a} \).
Lemma A.1. \( V \) is forward invariant for (3).

Proof. For all \( i = 1, \ldots, N_a, \sum_{j=1}^{N_i} \hat{z}_{ij} = 0 \), so if \( z_{ij}(0) + \cdots + z_{iN_a}(0) = 0, z_{ij}(t) + \cdots + z_{iN_a}(t) = 0 \) for all \( t > 0 \). \( \square \)

Theorem A.2 (Boundedness). Let \( U \) be a compact subset of \( \mathbb{R} \). There exists \( R > 0 \) such that, for all \( u_i, d_i, \alpha_i, \beta_i, \gamma_i, \delta_i, b_i \in U, i, k = 1, \ldots, N_a, j, l = 1, \ldots, N_n, \) the set \( V \cap \{ |z_i| \leq R, i = 1, \ldots, N_a, j = 1, \ldots, N \} \) is forward invariant for (3). This implies that the solutions (Z) of the dynamics (3) are bounded for all time \( t \geq 0 \).

Proof. By boundedness of \( S_p(\cdot) \), there exists \( R > 0 \) such that, for all \( u_i, d_i, \alpha_i, \beta_i, \gamma_i, \delta_i, b_i \in U, \) \( U_j(\cdot) = -d_j z_{ij} + C_{ij}(Z) \), with \( |C_{ij}(Z)| \leq R \). For all \( Z \in V \), it holds that \( \frac{d}{dt} \| Z \|^2 = \sum_{i=1}^{N_a} \sum_{j=1}^{N_n} \left( d_i z_{ij} + C_{ij}(Z) + \frac{1}{N_a} \sum_{l=1}^{N_a} \left( d_i z_{il} - C_i(Z) \right) \right) \) \( = Z^T D Z + \sum_{i=1}^{N_a} \sum_{j=1}^{N_n} \left( C_{ij}(Z) - \frac{1}{N_a} \sum_{l=1}^{N_a} C_{il}(Z) \right) \leq Z^T D Z + N_a N_o \tilde{R} \| Z \| \), where we have used \( \sum_{i=1}^{N_a} \sum_{j=1}^{N_n} = 0 \) for all \( i \). We compute \( Z^T D Z = \sum_{i=1}^{N_a} \sum_{j=1}^{N_n} (-d_i z_{ij}^2) + \frac{1}{N_a} \sum_{l=1}^{N_a} \sum_{j=1}^{N_n} d_i z_{il} \left( \sum_{j=1}^{N_n} z_{ij} \right) = \sum_{i=1}^{N_a} \sum_{j=1}^{N_n} -d_i z_{ij}^2 \leq -\min \{ d_i \} \| Z \|^2 \). Then, for all \( \| Z \| \geq \min \{ d_i \} \), it follows that \( \frac{d}{dt} \| Z \|^2 \leq -\| Z \| \left( \min \{ d_i \} \| Z \| - N_a N_o \tilde{R} \right) \leq 0 \). The result follows by \[ \square \]

These forward invariance and boundedness results lead us to a natural connection of the opinion vector \( Z_i \in 1_{N_o}^* \) to a simplex vector \( y_i = (y_{i1}, \ldots, y_{iN_o}) \), where \( y_{ij} \geq 0 \) for all \( i, j \) and \( \sum_{j=1}^{N_o} y_{ij} = 1, i = 1, \ldots, N_n \). Then, the vector field of (3) can be mapped from the forward invariant region \( V \cap \{ |z_i| \leq R, i = 1, \ldots, N_a, j = 1, \ldots, N \} \) to the simplex product \( \mathcal{V} \) by the affine change of coordinates \( L : V \cap \{ |z_i| \leq R, i = 1, \ldots, N_a, j = 1, \ldots, N \} \rightarrow \mathcal{V} \).

The simplex product space \( \mathcal{V} \) is often associated with models of opinion dynamics, e.g., in [12], [76], [77]. Under the mapping proposed in Corollary A.2.1 or any other bijective mapping to the simplex product space (e.g. using the standard softmax function), the system state \( y = (y_1, \ldots, y_N) \in \mathcal{V} \) can be interpreted as the absolute opinions of agents that have equal voting capacity in the collective decision (30), or as probabilities of choosing a particular option.

C. Proof of Theorem III.3

Opinion dynamics (3) of agent \( i \in I_p \) are defined by

\[
F_{ij}(Z) = -d_p z_{ij} + b_p + \sum_{l=1}^{N_o} S_2(\beta_p z_{il} + \beta_p \sum_{k \in I_p \setminus \{i\}} z_{kl} + \sum_{s \neq p}^{N_o} \sum_{k \in I_p} \sum_{l=1}^{N_o} \hat{z}_{ps} z_{kl})
\]

The simplex product space \( \mathcal{V} \) is defined by \( F_{ij}(Z) = -d_p z_{ij} + b_p + \sum_{l=1}^{N_o} S_2(\beta_p z_{il} + \beta_p \sum_{k \in I_p \setminus \{i\}} z_{kl} + \sum_{s \neq p}^{N_o} \sum_{k \in I_p} \sum_{l=1}^{N_o} \hat{z}_{ps} z_{kl}) \).

Let \( V_p(Z) = \sum_{p=1}^{N_o} V_p(Z), V_p(Z) = \frac{1}{2} \sum_{l=1}^{N_o} \sum_{k \in I_p} \sum_{s \neq p}^{N_o} (z_{kl} + \sum_{s \neq p}^{N_o} \sum_{k \in I_p} \sum_{l=1}^{N_o} \hat{z}_{ps} z_{kl}) \).

D. Proof of Theorem IV.1

For reduced order of magnitude.

E. Proof of Proposition IV.2

The proof of (1) follows analogously to that of [30] Theorem 2.5 with the additional coefficient \( d_i \) on the linear terms. It is omitted due to space constraints.
\[ \sum_{j=1}^{N_z} \left( \hat{\sigma}_j F_j(Z) \right) = \hat{\sigma}_j F_j(Z) \text{ for all } j = 1 \ldots N_z, \] and \( \rho \in D_{N_z} \) acts on \( V \) by permuting the order of the agent vectors \( Z \), in the total system vector \( \mathbf{Z} = (Z_1, \ldots, Z_{N_z}) \). The generators of \( D_{N_z} \) are the reflection element \( \rho_1 \) which reverses the order of elements in \( Z \), and a rotation \( \rho_2 \) which cycles forward the vector by one element, mapping each element \( i \) to \( i + 1 \) (and \( N_z \) to 1). Let \( F(Z) = (F_1(Z), \ldots, F_{N_z}(Z)) \) and observe that \( \rho_1 F(Z) = (F_{N_z}(Z), F_{N_z-1}(Z), \ldots, F_1(Z), F_1(Z)) \) and \( \rho_2 F(Z) = (F_2(Z), F_1(Z), F_{N_z}(Z), \ldots, F_{N_z-1}(Z)) \). For compactness we leave out the full expression for \( F_{ij}(\rho_i) \).
