Abstract

Mycobacterium tuberculosis residing within pulmonary granulomas and cavities represents an important reservoir of persistent organisms during human latent tuberculosis infection. We present a novel in vivo model of tuberculosis involving the encapsulation of bacilli in semidiffusible hollow fibers that are implanted subcutaneously into mice. Granulomatous lesions develop around these hollow fibers, and in this microenvironment, the organisms demonstrate an altered physiologic state characterized by stationary-state colony-forming unit counts and decreased metabolic activity. Moreover, these organisms show an antimicrobial susceptibility pattern similar to persistent bacilli in current models of tuberculosis chemotherapy in that they are more susceptible to the sterilizing drug, rifampin, than to the bactericidal drug isoniazid. We used this model of extracellular persistence within host granulomas to study both gene expression patterns and mutant survival patterns. Our results demonstrate induction of dosR (Rv3133c) and 20 other members of the DosR regulon believed to mediate the transition into dormancy, and that relMtb is required for Mycobacterium tuberculosis survival during extracellular persistence within host granulomas. Interestingly, the dormancy phenotype of extracellular M. tuberculosis within host granulomas appears to be immune mediated and interferon-γ dependent.

Key words: microarrays • gene expression • antibiotics • latency • persistence

Introduction

Mycobacterium tuberculosis infects approximately one third of the world's population, resulting in three million deaths annually (1). Soon after inhalation of tubercle bacilli, the organisms are phagocytosed by alveolar macrophages, resulting in potent cell-mediated immune responses and the formation of granulomas, which consist primarily of T cells and M. tuberculosis–infected macrophages (2, 3). 6–8 wk after infection in humans, and coincident with the development of a delayed-type hypersensitivity response manifested by tuberculin skin test positivity, these granulomas undergo caseous necrosis, resulting in the death of the majority of tubercle bacilli and destruction of surrounding host tissue (4). The small proportion of surviving bacilli are thought to exist in a nonreplicating hypometabolic state, as an adaptation to the unfavorable milieu in the solid caseous material (4).

This altered physiologic state, termed latent tuberculosis infection, can endure for the lifetime of the infected individual, but in ~10% of cases, through unknown mechanisms, these dormant bacilli reactivate many years to decades later to produce disease.

Efforts to gain insight into the adaptive mechanisms by which M. tuberculosis persists in the host have been impeded by the inability to recover sufficient quantities of M. tuberculosis RNA from host lesions consistent with contained latent tuberculosis infection (5). Consequently, several groups have turned to in vitro models that may reflect the persistent state, and have defined the gene expression profile of M. tuberculosis RNA from host lesions consistent with contained latent tuberculosis infection (5). Consequently, several groups have turned to in vitro models that may reflect the persistent state, and have defined the gene expression profile of M. tuberculosis under conditions of hypoxia (6, 7), nutrient starvation (8), low pH (9), low concentrations of nitric oxide (10), and in the phagosomal compartment of murine macrophages (11). Current work has focused on the role of the two-component response regulator dormancy survival regulator (DosR), which initially was found to be the primary

mediator of the hypoxic response in *M. tuberculosis* (6, 12). Bacilli exposed to low, nontoxic concentrations of nitric oxide in vitro enter a nonreplicating persistent state marked by the induction of a 48-gene regulon under the control of DosR, suggesting that the DosR regulon may mediate the transition of these bacilli into dormancy (10). Consistent with these findings, several DosR regulon genes, including *air* (*Rv2031c*), *Rv2623c*, and *Rv2626c*, are up-regulated in infected mouse tissues after the onset of Th1 immunity (10, 13).

We sought to mimic the caseous granuloma by physical containment of extracellular *M. tuberculosis* within mice as a means of comparing in vivo–cultivated persistent bacteria with in vitro latency models. Our model involves the encapsulation of tubercle bacilli in poly(vinylidene fluoride) (PVDF) hollow fibers (14, 15) and the implantation of these fibers into the subcutaneous space of mice (see Fig. 1). The PVDF fibers have a molecular mass cutoff of 500 kD, which allows for the diffusion of small soluble molecules, but prevents the entry of host immune cells and the exit of intact bacilli. The prevention of direct host–pathogen interactions imposed by the physical properties of the hollow fibers provides a unique opportunity to study the behavior of extracellular *M. tuberculosis* in the host.

**Materials and Methods**

**Strains.** *M. tuberculosis* H37Rv-expressing firefly luciferase (H37Rv-*lux*) was passaged twice through mice and used for all infections. The organisms were grown in plastic roller bottles at 37°C in Middlebrook 7H9 liquid broth (Difco Laboratories) supplemented with 10% OADC (Becton Dickinson), 0.5% glycerol, and 0.05% Tween-80.

**Hollow Fiber Assay.** Infection with *M. tuberculosis* was achieved in 6–8-wk-old female hairless, immunocompetent SKH1 mice (Charles River Laboratories) using the hollow fiber encapsulation/implantation technique as described previously (14, 15). In brief, liquid cultures of *M. tuberculosis* were inoculated into the lumen of PVDF hollow fibers (molecular mass cutoff 500 kD; Spectrum Laboratories) with a syringe and 20-gauge needle. The ends of the hollow fibers were heat sealed, and individual fibers were prepared by heat sealing at 2-cm intervals. Mice were anesthetized by intraperitoneal injection of 240 mg/kg of Avertin (2,2,2-tribromethanol; Sigma-Aldrich), and the dorsal skin surface was sterilized with 70% ethanol. A small incision was made at the nape of the neck, and one fiber was deposited into the subcutaneous space of each flank with a tumor trocar (two fibers/mouse). Incisions were closed with a small surgical clip (Fig. 1). For immunology studies, BALB-C/J and IFNγ−/− (B6-IFNγ−/−) mice were used (Jackson Immunoresearch Laboratories). For experiments involving hollow fiber–encapsulated *M. tuberculosis* incubated in vitro, hollow fibers were incubated on a shaker at 37°C in 50-ml conical tubes containing 20 ml Middlebrook 7H9 liquid broth (Difco Laboratories) supplemented with 10% OADC (Becton Dickinson), 0.5% glycerol, and 0.05% Tween-80. For determination of CFU counts, hollow fibers were recovered from mice at the time of killing, and their contents were plated on 7H10 agar plates (Fischer Scientific). Log-transformed CFU values were used to calculate averages and standard errors for graphing purposes.

**Luciferase Assay.** The luciferase reaction was initiated by the addition of 150 µL of luciferin (1 mM in 0.1 M Na citrate; Promega) to 50 µL of each undiluted sample. Luminescence was detected 20 s after the addition of substrate by a TD-20/20 luminometer (Turner Designs). Three successive measurements were made and the average relative light unit (RLU) values recorded. The log_{10} of average RLU values multiplied by 1,000 was represented graphically.

**Mice.** Hollow fibers containing 10⁶ bacilli were implanted into 15–20 SKH1 mice (two hollow fibers/mouse). Hollow fibers were retrieved from mice 10 d after hollow fiber encapsulation, and fiber contents were recovered and snap frozen. Pooled samples were suspended in TRizol reagent (GIBCO BRL), and *M. tuberculosis* membranes were disrupted using zirconia/silica beads in a bead beater. *M. tuberculosis* RNA was recovered by centrifugation, chloroform extraction, and isopropanol alcohol precipitation, and purified using RNeasy column (QIAGEN) as described previously (6, 8). The same steps were followed to extract and purify RNA from mid-logarithmic phase (A₆₀₀ 0.600–0.850) *M. tuberculosis* H37Rv--lux cultures grown in plastic roller bottles at 37°C in supplemented liquid broth. Fluorescently labeled cDNA was generated using Powerscript (CLONTECH Laboratories, Inc.), using fluorescent dyes Cy3 and Cy5. These cDNA were competitively hybridized on microarray slides containing commercially available (Operon) *M. tuberculosis* 70-mer oligonucleotides representing all opening reading frames annotated in the H37Rv genome sequencing project (16), and fluorescence intensity data were collected with a GenePix 4000 scanner (Axon Instruments, Inc.) with Pro 4.0 software. Data were normalized based on total intensity of good-quality spots above background for each channel, and ratios of in vivo hollow fiber to in vitro cDNA were calculated based on normalized data. In this assay, the ratio of the signal from in vivo hollow fiber samples to that of in vitro control samples for a given open reading frame (ORF) should represent the relative abundance of the transcripts of that ORF under the two conditions. Three biological replicates were performed, and microarray samples were reverse labeled in one experiment. Significant differential regulation of genes was defined by greater than or equal to twofold change in gene expression as compared with control samples and P < 0.01.

**Quantitative Real-Time RT-PCR.** RNA samples were treated with DNA-free kit (Ambion) according to the instructions of the manufacturer, and DNA contamination was excluded by PCR amplification using primers for *Rv2031* (*air*) and absence of PCR product on gel electrophoresis (unpublished data). Reverse transcription of RNA samples (∼0.5 µg RNA/sample) was accomplished using random hexamer primers (0.5 µg/reaction;
Invitrogen) and PowerScript Reverse Transcriptase (CLON-TECH Laboratories, Inc.). Real-time PCR was performed on cDNA using the SYBR green assay and Premix D (Epicentre) for all samples, and fluorescence was measured by iCycler (Bio-Rad Laboratories). Gene expression was compared with that of sigA, an M. tuberculosis housekeeping gene.

Transposon (Tn) Mutants. Random insertion mutagenesis of M. tuberculosis CDC 1551 strain was performed using the Himar1 Tn as described previously (17, 18). Tn insertion sites were identified by sequencing the insertion junction as described previously (18). 100 different mutants, each with Tn insertion within the proximal 80% or proximal to the distal 100 base pairs of the ORF, were randomly selected from the library of mutants. Each of the selected mutants was separately grown in 37°C in supplemented Middlebrook 7H9 liquid broth to an A600 of 0.8–1.0, and two master pools, each consisting of 50 mutants, were prepared by mixing an equal volume of culture of each mutant. This mixture was diluted to an A600 of 0.1, and the latter was used to inoculate the hollow fibers. In separate experiments, the relA-disrupted Tn insertion mutant was grown separately in vitro using the aforementioned conditions to an A600 of ~1.0, and diluted 1:10. The diluted culture was added in a 1:1 ratio to a similarly grown and diluted culture of wild-type CDC 1551. The ΔrelA/wild-type culture suspension was encapsulated in hollow fibers as described before and either implanted subcutaneously into mice or incubated in vitro. Recovered hollow fiber samples were plated on Middlebrook 7H10 plates (Difco Laboratories) and on 7H10 plates containing 20 μg/ml kanamycin (the Tn insertion contains a kanamycin resistance gene; reference 18).

Viability Assay. The LIVE/DEAD BacLight Bacterial Viability Kit (Molecular Probes) was used to assay for mycobacterial viability after removal from hollow fibers. In brief, component A (3.34 mM SYTO 9 green fluorescent nucleic acid stain) and component B (20 mM propidium iodide) were mixed in equal volumes. An equivalent of 3 μl of this 1:1 nucleic acid stain mixture was added to each 1 ml of sample, and samples were incubated in the dark for ≥15 min. As a control, in vitro–grown M. tuberculosis H37Rv–lux was treated for 3 h with 70% ethanol to promote mycobacterial death and highlight differences in fluorescence staining between live and dead bacilli (see Fig. 3 a). Samples were treated with 20 μl of 4% paraformaldehyde (which does not alter cell permeability characteristics) for ≥15 min, and samples were observed using epifluorescence microscopy (Nikon Eclipse E800). Images were obtained using a Nikon digital camera DXM1200 and processed using Spot Version 3.4 software.

Antibiotic Studies. Mice received a powdered diet containing 1% sugar with either 0.02% (by weight) rifampin (Sigma-Aldrich) or 0.05% isoniazid (Sigma-Aldrich), beginning 14 d after implantation of hollow fibers. Untreated control mice received powdered diet containing 1% powdered sugar alone. In separate experiments, mice received diet containing 2.5% sugar alone (untreated controls) or with 0.25% moxifloxacin beginning on day 1 after hollow fiber implantation. Mouse dietary consumption was measured and recorded for all groups on a daily basis. At the time of killing, blood was obtained from antibiotic-treated mice by cardiac puncture, mouse serum was separated, and serum samples were stored at −70°C until the time of analysis. Mouse serum samples were mailed overnight on dry ice to C. Peloquin (National Jewish Medical Research Center, Denver, CO) for determination of serum antibiotic concentrations.

Online Supplemental Material. A complete list of all Tn mutants used, including information on the gene mutated and the exact coordinate of Tn insertion, is presented as online supplemental material. DosR genes that fulfilled one, but not both, criteria for significant up-regulation (see Results) are presented in the online supplemental material. The complete lists of genes found to be significantly up-regulated or down-regulated by microarray analysis in hollow fiber–encapsulated bacilli in vivo, as well as all genes not found to be differentially regulated, are also presented. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20040646/DC1.

Results

Inhibition of Growth of Encapsulated Tubercle Bacilli In Vivo (Fig. 2). M. tuberculosis H37Rv–expressing firefly luciferase (H37Rvlux) was encapsulated in hollow fibers and implanted into the subcutaneous space of mice or incubated at 37°C in supplemented Middlebrook 7H9 broth. Although hollow fiber–encapsulated bacilli incubated in vitro multiply exponentially for 14–21 d before reaching a plateau, bacilli encapsulated in hollow fibers and implanted into mice rapidly achieve stationary-state CFU counts (Fig. 2). The continued growth of in vitro hollow fiber–encapsulated bacilli implies that the failure of in vivo hollow fiber–encapsulated bacilli to multiply is not simply a result of physical containment imposed by the internal dimensions of the hollow fibers.

Assessment of Bacillary Viability and Metabolic Activity. To further investigate the CFU equilibrium in hollow fiber–encapsulated bacilli in vivo, we examined the bacilli recovered from fibers using a bacterial viability assay in which live M. tuberculosis bacilli emit green fluorescence, whereas dead bacilli fluoresce red, based on differences in cell membrane permeability to the two nucleic acid stains used in the assay (Fig. 3). If the stationary-state CFU counts observed in hollow fiber–encapsulated bacilli in vivo represented an equilibrium, we would expect that live-staining bacilli would comprise a very small proportion of all staining bacilli, due to the vast accumulation of dead bacilli over time. However, approximately half of all staining organisms on days 21 (Fig. 3 b) and 28 (Fig. 3 c) after hollow fiber implantation were determined to be alive by their staining properties, consistent with the hypothesis that these organisms are in a slowly replicating or

Figure 2. Reduced growth of bacilli within hollow fibers in vivo. CFU counts per fiber of hollow fiber–encapsulated M. tuberculosis implanted into mice (HF in vivo) are compared with those of hollow fiber–encapsulated M. tuberculosis incubated in vitro (HF in vitro).
nonreplicating persistent state. In addition, we detected a significant lag time in the appearance of colonies after plating the in vivo–cultivated bacilli, as compared with hollow fiber–encapsulated bacilli incubated in vitro. At the day 21 time point, microcolonies were detected 10–11 d after plating in the in vitro hollow fiber samples, whereas these were not detectable in the in vivo hollow fiber samples until 14 d after plating (unpublished data). Furthermore, average colony size for in vivo hollow fiber samples was significantly smaller than corresponding in vitro hollow fiber samples when examined 17 d after plating (Fig. S1, available at http://www.jem.org/cgi/content/full/jem.20040646/DC1). These data are consistent with the hypothesis that hollow fiber–encapsulated \(M.\) tuberculosis implanted in mice rapidly enter a state of decreased replication.

Because the oxidation of luciferin to oxyluciferin and photons (which can be detected by a luminometer at \(\sim 560\) nm) is an ATP-dependent process, the luciferase assay may be used as an indirect measure of the ATP content of cells. In log-phase in vitro cultures of \(M.\) tuberculosis (i.e., not encapsulated in fibers), the relationship between CFUs and RLU is linear (Fig. 4 a). Hollow fiber–encapsulated \(M.\) tuberculosis grown in vitro maintains baseline metabolic activity, as reflected by RLU values that closely parallel CFU counts at the corresponding time points (Fig. 4 b). On the contrary, RLU values of in vivo–cultivated hollow fiber–encapsulated bacilli on days 14 and 21 after implantation (Fig. 4 b) were \(0.8 \log_{10}\) and \(0.93 \log_{10}\), respectively, less than predicted based on the corresponding CFU values (Fig. 2) and the proportionality of CFU:RLU (Fig. 4 a), suggesting reduced metabolic activity of these organisms as measured by the luciferase assay. These data suggest that in vivo hollow fiber–encapsulated \(M.\) tuberculosis bacilli rapidly enter a state of decreased metabolic activity.

**Antibiotic Susceptibility of Hollow Fiber–encapsulated Bacilli.**
Animal and human chemotherapy studies have pointed to several populations of \(M.\) tuberculosis in the mammalian host, including rapidly multiplying and nonreplicating or sporadically replicating persistent bacilli (19, 20). In keeping with this mixed bacterial population model, drug treatment studies have demonstrated that the sterilizing drug rifampin is more active against sporadically multiplying and persistent bacilli than the bactericidal drug isoniazid; the former drug requires a significantly shorter duration of therapy to achieve acceptable relapse rates (21–25). We reasoned that rifampin likewise should be more effective than isoniazid against hollow fiber–encapsulated \(M.\) tuberculosis implanted in mice if these bacilli were truly in a slowly replicating, metabolically quiescent state. To allow bacilli to enter this altered physiologic state, antibiotics were not initiated until 14 d after hollow fiber implantation. Experimental groups of mice received either powdered diet containing isoniazid 0.05% or rifampin 0.02% (by weight), whereas untreated mice received antibiotic-free diet. Serum concentrations of each antibiotic were measured in killed mice at each time point, and were found to be at least 10 times greater than their respective MIC \(_{90}\) (Table I). Daily area under the serum concentration–time curve properties of each dietary regimen in mice were found to be similar to the area under the serum concentration–time curve in humans after standard daily doses of each drug (26, 27). Although isoniazid was somewhat effective against bacilli in the hollow fiber model in vivo, the activity of rifampin was more consistent and the magnitude of its effect was greater than that of isoniazid at each time point, resulting in a three-log kill by 21 d after
initiation of therapy (Fig. 5). When mice were treated with the new 8-methoxyfluoroquinolone moxifloxacin, which has potent bactericidal activity against *M. tuberculosis* in mice (28), beginning on day 1 after hollow fiber implantation, fibers were culture negative by day 14 after daily therapy (Fig. S2, available at http://www.jem.org/cgi/content/full/jem.20040646/DC1). These data suggest that by 14 d after hollow fiber implantation, hollow fiber–encapsulated *M. tuberculosis* has entered an altered physiologic state in which bacilli are more resistant to the activity of antituberculosis drugs, but more susceptible to rifampin than to isoniazid, consistent with the antibiotic susceptibility of persistent bacilli in human latent tuberculosis infection (21–25).

Granuloma Formation Surrounding Bacilli-containing Hollow Fibers in Mice. Interestingly, we observed grossly the progressive formation of thick, granuloma-like lesions encasing hollow fibers containing *M. tuberculosis* H37Rv-lux (Fig. 6, d–f), but not those containing liquid broth alone (Fig. 6, a–c). By day 28 after hollow fiber implantation, histologic analysis revealed much greater cellular infiltration of macrophages, lymphocytes, and fibroblasts in the tissues surrounding hollow fibers containing tubercle bacilli (Fig. 6 l), as compared with those containing liquid broth (Fig. 6 i). Acid-fast staining of the surrounding tissue revealed no detectable bacilli, and inflammatory cells were not detected by microscopy within the hollow fibers (unpublished data). These results suggest the possibility that *M. tuberculosis* secretes soluble factors that diffuse from the fibers, leading to recruitment of host inflammatory cells. The formation of granulomatous lesions encasing hollow fibers may create a hostile microenvironment in which bacilli are forced to reduce their replication and metabolic activity, consequently becoming more susceptible to rifampin than to isoniazid.

Containment of Intrafiber Bacillary Growth In Vivo Is Immune Mediated and IFNγ Dependent. In addition to local granuloma formation, we detected significant spleen enlargement as early as 14 d after hollow fiber implantation in mice that had implanted fibers containing *M. tuberculosis* as compared with those that had implanted fibers containing media (Fig. 7 a), suggesting a systemic immune response in the former group of mice. To further investigate the phenomena of granuloma formation and splenomegaly and to exclude the possibility that intrafiber bacillary growth containment in vivo is mediated exclusively by nutrient starvation, we studied the growth of hollow fiber–encapsulated *M. tuberculosis* in IFNγ-deficient mice. In brief, ~500 bacilli were encapsulated in each hollow fiber, and fibers were implanted subcutaneously either into wild-type BALB-C/J mice or BALB-C/J IFNγ-deficient mice, and colony counts were measured 28 d after implantation. Interestingly, although there was some growth of bacilli in wild-type mice over 28 d, CFU counts of hollow fiber–encapsulated *M. tuberculosis* in IFNγ-deficient mice were 1.3 log10 higher at 28 d than those in wild-type mice, sug-

![Figure 5. Hollow fiber–encapsulated bacilli are more susceptible to rifampin than to isoniazid. The activities of isoniazid 0.05% in the diet (INH) and rifampin 0.02% in the diet (RIF) against hollow fiber–encapsulated bacilli in vivo are compared with no treatment (Control).](image-url)

suggesting that IFNγ plays a role in containment of intrafiber bacillary growth in vivo (Fig. 7 b).

**Reduced Survival of relMtb-deficient *M. tuberculosis* in Hollow Fibers Implanted into Mice.** As proof-of-principle to determine whether this model could predict genes essential for extracellular persistence within granulomas, we generated a library of mutants by Tn mutagenesis of *M. tuberculosis* CDC 1551 strain using the Himar1 Tn as described previously (18). 100 genetically defined mutants, each deficient in a specific gene (as defined by Tn insertion within the proximal 80% or proximal to the distal 100 base pairs of the ORF of each particular gene; reference 18), were selected from the library and divided into two master pools, each consisting of 50 mutants (Tables S1 and S2, available at http://www.jem.org/cgi/content/full/jem.20040646/DC1). Each pool was generated by mixing an equal volume of pure culture from each mutant to ensure equal representation. Individual pools were encapsulated into separate hollow fibers and these were either implanted subcutaneously into mice or incubated in vitro. Hollow fiber contents were recovered on day 1 (input pool) and day 21 (output pool) after implantation. Pathohistology of tissues surrounding hollow fibers containing liquid broth (g–i) and those containing *M. tuberculosis* H37Rv-lux (j–l) 28 d after hollow fiber implantation (hematoxylin-eosin stain). Arrows indicate hollow fiber membrane.
encapsulated wild-type bacilli implanted in mice demonstrated reduced growth as compared with those incubated in vitro after 21 d (growth $\sim 1.5 \log$ for in vivo wild type versus $\sim 3 \log$ for in vitro wild type), hollow fiber-encapsulated $relMtb::Tn$ showed markedly reduced survival as compared with wild-type bacilli implanted in vivo (Fig. 8 d).

CHP, conserved hypothetical protein; HP, hypothetical protein.
Significantly, the decreased survival of the relMtb-deficient mutant became apparent as early as 21 d after hollow fiber implantation, as compared with several months using the standard murine aerosol infection model (29). We observed no significant change in survival compared with wild type in an M. tuberculosis mutant containing a Tn insertion in an unrelated gene (MT2749, Rv2675), suggesting that the presence of the Tn insertion alone does not confer a survival disadvantage in the hollow fiber model in vivo.

**Gene Expression of Extracellular M. tuberculosis within Granulomas in Mice.** Next, we sought to gain insight into the adaptive response of tubercle bacilli in granulomatous lesions in vivo by studying their global gene expression (for complete gene expression profile, Table S6, available at http://www.jem.org/cgi/content/full/jem.20040646/DC1).

Significantly, the exclusion of host cells and containment of bacilli by the hollow fibers renders whole genome microarray analysis feasible. Hollow fibers containing M. tuberculosis were implanted subcutaneously into mice and retrieved 10 d later. Hollow fiber contents were recovered and immediately snap frozen, and bacilli from 30–40 implanted fibers were pooled to yield sufficient RNA for analysis. Hollow fiber–encapsulated M. tuberculosis gene expression was compared with that of log-phase in vitro–grown M. tuberculosis.

Significant differential gene regulation was defined by both of the following: (a) a greater than or equal to twofold change in gene expression as compared with control samples, and (b) a p-value < 0.01.

We found that in vivo hollow fiber–encapsulated M. tuberculosis demonstrates significant induction of ~260 genes, including several key regulatory genes (Table S4, available at http://www.jem.org/cgi/content/full/jem.20040646/DC1). Using the aforementioned strict criteria, we found significant up–regulation of Rv3133c (dosR) and 20 other members of the previously described DosR regulon (10), including hspX, Rv2623c, and Rv2626 (Table II), suggesting that the adaptive response of hollow fiber–encapsulated M. tuberculosis in vivo is similar to that of bacilli exposed to low concentrations of nitric oxide in vitro. The M. tuberculosis hspX gene encodes α-crystallin, a member of the small heat shock protein family with chaperone activity (30), which is powerfully induced under hypoxic conditions (6) and in lung specimens obtained from patients with active tuberculosis disease (31). Significantly increased expression of hspX, Rv2623c, and Rv2626 has been shown by real-time RT-PCR, after the onset of Th1-mediated immunity in the mouse model of tuberculosis (13) and in various models of latency in vitro (6, 8, 10, 13). In addition, we found up–regulation of 12 additional genes of the DosR regulon that fulfilled one, but not both, aforementioned criteria (Table S3, available at http://www.jem.org/cgi/content/full/jem.20040646/DC1). Hollow fiber–encapsulated M. tuberculosis in vivo also demonstrated significant up–regulation of sigB, sigC, and sigH, which belong to a family of alternative RNA polymerase σ factors shown to coordinate gene regulation in response to environmental conditions in M. tuberculosis and other bacterial species (32, 33). We detected significant up–regulation of dnaE2, which encodes a DNA polymerase in M. tuberculosis and in other organisms, and which has been shown to be up–regulated by several DNA-damaging agents and during infection of mice, contributing to in vivo survival and the emergence of drug resistance (34). In addition, hollow fiber–encapsulated M. tuberculosis in mice demonstrated significant induction of many other genes recently found to be up–regulated in the multibacillary model of murine tuberculosis (5), including Rv0967, Rv0970, Rv0978c (PE-PRGS 17), Rv0980c (PE-PRGRS 18), Rv0982 (mprB), and Rv0988.

Consistent with evidence that M. tuberculosis might switch to C2 carbon sources such as fatty acids during in vivo persistence (35), we detected significant up–regulation of several genes encoding enzymes involved in lipid degradation, including fadD10 (Rv0099), fadD19 (Rv3515c), fadD34 (Rv0035), fadE1 (Rv0131c), fadE10 (Rv0873), and fadE24 (Rv3139). In addition, we found significantly increased expression of pckA (Rv0211), suggesting limited availability of glucose within artificial granulomas in mice. De novo synthesis of glucose-6-phosphate in mycobacteria is achieved through the action of phosphoenolpyruvate carboxykinase (pckA), which converts oxaloacetate to phosphoenolpyruvate, thus diverting carbon derived from β-oxidation of fatty acids into gluconeogenesis (36). Increased gene expression of pckA has been reported in the mouse model of tuberculosis (31), and disruption of pckA in Mycobacterium bovis produced attenuated strains in animal models of infection (37, 38). In addition, we found a 1.5-fold induction of Rv0467 (accA) (P = 0.004) that encodes isoicitic lyase, the first enzyme of the glyoxylate cycle, which is strongly induced in mouse lungs (31) and is required for long-term persistence of M. tuberculosis in mice (35).

### Table III. Confirmation of Differential Regulation of a Subset of Genes by Quantitative Real-Time RT-PCR

| Rv. no. | Gene   | Protein function                  | Fold induction |
|--------|--------|-----------------------------------|----------------|
| 1997   | HP     |                                   | 32             |
| 2031c  | acr    | α-crystallin                       | 294.1          |
| 2623c  | CHP-UPSA motif |                                | 512             |
| 2626c  | CHP    |                                   | 68.6           |
| 2710   | sigB   | RNA polymerase σ factor            | 42.2           |
| 2744   | 35 kD Ag |                                  | 4.3            |
| 3130c  | CHP    |                                   | 168.9          |
| 3131c  | CHP    |                                   | 274.3          |
| 3133c  | dosR   | 2-comp. response regulator         | 78.8           |
| 3223c  | sigH   | RNA polymerase σ factor            | 17.1           |
| 3370c  | dnaE2  | DNA polymerase III                 | 9.8            |
| 3477   | PE family protein |                               | -4.3           |
| 3648c  | opA    | prob. cold shock protein           | -7             |

CHP, conserved hypothetical protein; HP, hypothetical protein.
Consistent with the hypothesis that hollow fiber–encapsulated bacilli in vivo display a reduced replication rate, we observed significantly decreased expression of certain genes encoding ribosomal RNA binding proteins, including \( \text{Rv0701 (rplC)}, \text{Rv0703 (rplW)}, \text{Rv0704 (rplB)}, \text{Rv0706 (rplV)}, \text{Rv0708 (rplP)}, \text{Rv0710 (rplQ)}, \) and \( \text{Rv0716 (rplE)} \). In agreement with our luciferase assay data suggesting that these bacilli have decreased intracellular energy stores (Fig. 4b), we found significant down-regulation of several genes encoding components of ATP synthase, including \( \text{Rv1304 (atpB)}, \text{Rv1306 (atpF)}, \text{Rv1308 (atpA)}, \text{Rv1310 (atpD)}, \) and \( \text{Rv1311 (atpC)} \). A complete list of significantly down-regulated genes in hollow fiber–encapsulated \( \text{M. tuberculosis} \) implanted into mice can be found in Table S5 (available at http://www.jem.org/cgi/content/full/jem.20040646/DC1). Differential regulation of a subset of 15 genes identified by microarray analysis was confirmed using quantitative real-time RT-PCR (Table III).

**Discussion**

The hollow fiber encapsulation/implantation technique provides a means to establish a paucibacillary infection with \( \text{M. tuberculosis} \) in which the bacilli are readily recoverable from infected animals for further analysis. In this model of infection, the tubercle bacilli rapidly enter an altered physiologic state characterized by stationary-state CFU counts and decreased metabolic activity. These bacilli are more susceptible to the antituberculous drug rifampin than they are to isoniazid, consistent with the antibiotic susceptibility profile of persistent bacilli in animal chemotherapy models (21, 23) and in human latent tuberculosis infection (22, 24, 25). In addition, expression of \( \text{relMtb} \), a gene that is essential for long-term persistence in the mouse model of chronic tuberculosis (29), is also necessary for short-term bacillary persistence in the hollow fiber granuloma model in vivo, suggesting a common adaptive strategy of \( \text{M. tuberculosis} \) in these two models of infection.

In this work, we present for the first time the whole-genome transcriptional profile of extracellular \( \text{M. tuberculosis} \) within granulomas in mice. In vivo hollow fiber–encapsulated \( \text{M. tuberculosis} \) demonstrates significant induction of several key regulatory genes, including \( \text{Rv3133c (dosR)}, \) as well as 20 other genes of the recently described DosR regulon (10); the \( \sigma \) factor genes \( \text{sigB, sigC, and sigH} \); the DNA polymerase–encoding \( \text{dnaE2}; \) and many other genes that were found to be significantly up-regulated in the mouse model of pulmonary tuberculosis (5). Increased expression of genes involved in lipid metabolism suggests depletion of glucose and the importance of fatty acids as a primary carbon source for extracellular \( \text{M. tuberculosis} \) in artificial granulomas in mice, which corroborates previous data in the mouse model of chronic tuberculosis (35). Consistent with the hypothesis that these organisms demonstrate an altered physiologic state characterized by reduced replication and metabolism, we detected significant down-regulation of genes encoding key ribosomal RNA binding proteins and ATP synthase, respectively. A subset of 13 genes identified by microarray analysis was confirmed to be significantly differentially regulated by quantitative real-time RT-PCR. The common transcriptional profile we observed lends further support to the hypothesis that the altered physiologic state of hollow fiber–encapsulated bacilli in vivo is similar to that of persistent bacilli in other models of latency.

It is important to note that, although the artificial subcutaneous granulomas surrounding hollow fibers containing \( \text{M. tuberculosis} \) resemble those formed in mouse lungs after aerosol infection with the same pathogen, granulomas in mice differ significantly from those in humans. In human infection, the granuloma is composed of a central core of macrophages, including multinucleated giant cells, surrounded by macrophages and lymphocytes, which include CD4 and CD8 T cells, and B cells (39). Although individual components of mouse granulomas are similar to those in humans, the architecture of the mouse granuloma is better characterized as a loose collection of activated and epithelioid macrophages and lymphocytic clusters (40). Unlike in human granulomas, multinucleated giant cells are absent in mouse granulomas, and necrosis and caseation are rarely observed (40). However, despite structural differences between granulomas in mice and humans, their function is likely to be similar, with respect to containment of infection and creation of a localized environment for the immune response to kill organisms.

Animal models of tuberculosis have shown that \( \text{M. tuberculosis} \) is an intracellular pathogen, residing within host macrophages (2). However, the precise location of persistent bacilli during human latent tuberculosis infection remains elusive. Specifically, autopsy data of persons who died of nontuberculosis-related causes have demonstrated that tubercle bacilli may be found outside lung granulomas, in normal-appearing lung tissue (41), and in nonmacrophage cell types, including alveolar epithelial cells (42). In addition, bacilli residing extracellularly in the caseous material of lung granulomas and cavities may represent an important reservoir of persistent organisms during human latent tuberculosis infection (4). Mouse-implanted hollow fibers containing \( \text{M. tuberculosis} \) induce splenomegaly and the accumulation of host inflammatory cells, including macrophages and lymphocytes, leading to the formation of artificial granulomas around the fibers. The precise microenvironment conditions prevailing within subcutaneously implanted hollow fibers are unclear, but may include hypoxia, nutrient starvation, and soluble immunologic factors (e.g., diffusible nitric oxide) secreted by surrounding host immune cells. Diminished ability to contain the growth of hollow fiber–encapsulated \( \text{M. tuberculosis} \) by IFNγ-deficient mice, as well as significant induction of the DosR regulon by these bacilli suggests that diffusible nitric oxide and/or hypoxia may contribute to the microenvironment experienced by intrafiber bacilli in vivo. The basis for mouse spleen enlargement and recruitment of host immune cells to the tissues surrounding the hollow fibers is unknown, but may involve diffusion of \( \text{M. tuberculosis} \)–secreted soluble factors across the hollow fiber membranes.
Experiments designed to address these questions are currently underway.

We thank L. Einck for suggesting use of the hollow fiber encapsulation/implantation technique, and M. Hollingshead for generous technical advice and assistance. The support of National Institutes of Health grants AI 37856, AI 36973, AI 43846, and AI 51668, and contract NOI 30036, as well as a contract from the Global Alliance for Tuberculosis Drug Development, is gratefully acknowledged. P.C. Karakousis received support from T32 AI 07608 and from a grant from the Pots Foundation. The authors have no conflicting financial interests.
