Abstract

Background: Homogeneous ventilation is important for prevention of ventilator-induced lung injury. Electrical impedance tomography (EIT) has been used to identify optimal PEEP by detection of homogenous ventilation in non-dependent and dependent lung regions. We aimed to compare the ability of volumetric capnography and EIT in detecting homogenous ventilation between these lung regions.

Methods: Fifteen mechanically-ventilated patients after cardiac surgery were studied. Ventilator settings were adjusted to volume-controlled mode with a fixed tidal volume (Vt) of 6–8 ml kg⁻¹ predicted body weight. Different PEEP levels were applied (14 to 0 cm H₂O, in steps of 2 cm H₂O) and blood gases, Vcap and EIT were measured.

Results: Tidal impedance variation of the non-dependent region was highest at 6 cm H₂O PEEP, and decreased significantly at 14 cm H₂O PEEP indicating decrease in the fraction of Vt in this region. At 12 cm H₂O PEEP, homogenous ventilation was seen between both lung regions. Bohr and Enghoff dead space calculations decreased from a PEEP of 10 cm H₂O. Alveolar dead space divided by alveolar Vt decreased at PEEP levels ≤6 cm H₂O. The normalized slope of phase III significantly changed at PEEP levels ≤4 cm H₂O. Airway dead space was higher at higher PEEP levels and decreased at the lower PEEP levels.

Conclusions: In postoperative cardiac patients, calculated dead space agreed well with EIT to detect the optimal PEEP for an equal distribution of inspired volume, amongst non-dependent and dependent lung regions. Airway dead space reduces at decreasing PEEP levels.

Ventilator-induced lung injury (VILI) is a well-recognized complication of mechanical ventilation, which occurs in both patients with acute respiratory distress syndrome (ARDS) and healthy lungs. The deleterious effects of mechanical ventilation are caused by large amounts of stress and strain acting on lung tissue, as a result of inhomogeneous ventilation of the lungs. Although, protective lung strategies using low tidal volumes have been strongly recommended to prevent the development of VILI, the amount of PEEP that should be applied is still under debate. The positive effect of PEEP depends on the recruitable fraction of lung tissue, which varies between patients, but also from day to day. Therefore, setting the PEEP level without a reliable tool to estimate the distribution of inspiratory tidal volume (VT) at the bedside is a challenging activity.

Volumetric capnography (Vcap) is a non-invasive technique that describes the CO₂ exhalation during one breath, and can be used to calculate alveolar and airway dead space. Because elimination of CO₂ depends on alveolar ventilation and pulmonary perfusion, V/Q mismatches in either hyperinflated or collapsed lung areas will affect the amount of exhaled CO₂ and thereby Vcap. Recently, a multi-centre observational study showed that an increased dead space fraction in patients with ARDS was associated with an increased mortality. Several studies showed the capability of Vcap in detecting optimal PEEP level during mechanical ventilation in various lung pathological conditions.

Böhm and colleagues showed in 11 morbidly obese patients that describes the CO₂ exhalation during one breath, and can be used to calculate alveolar and airway dead space. Because elimination of CO₂ depends on alveolar ventilation and pulmonary perfusion, V/Q mismatches in either hyperinflated or collapsed lung areas will affect the amount of exhaled CO₂ and thereby Vcap. Recently, a multi-centre observational study showed that an increased dead space fraction in patients with ARDS was associated with an increased mortality. Several studies showed the capability of Vcap in detecting optimal PEEP level during mechanical ventilation in various lung pathological conditions.

Editor’s key points

- This pilot study compared volumetric capnography and electrical impedance tomography (EIT) in detecting distribution of ventilation after cardiac surgery.
- EIT values approximated to calculated dead space and detected optimal PEEP to equalize gas distribution in dependent and non-dependent lung regions.
- At 12 cm H₂O PEEP, ventilation was distributed homogeneously between dependent and non-dependent regions.
- However, excessive PEEP applied to healthy lungs caused airway distension rather than improving alveolar ventilation.

Methods

Study population

In this pilot-study, 15 mechanically ventilated patients, who had undergone coronary-artery bypass grafting and/or cardiac-valve surgery, admitted to the cardiothoracic intensive care unit (ICU) were included. The local medical ethical committee approved the study protocol and written informed consent was obtained from each patient or their relatives. Data were collected between January and July 2014.

The inclusion criteria were age >18 yrs, written informed consent, haemodynamically stable. Exclusion criteria were: presence of a cardiac pacemaker, pneumothorax, thoracic deformations and severe airflow limitation (defined as forced expiratory volume in 1 s below 70% of forced vital capacity).

Study protocol

For Vcap measurements a mainstream CO₂ sensor was placed between the tracheal tube and ventilator tubing’s, and was connected to a NICO-capnograph (Novametrix, Wallinford, Connecticut, USA). Specific software (Analysis plus, Novametrix, Wallinford, Connecticut, USA) was used to record all Vcap data. In order to perform electrical impedance tomography (EIT) measurements, a silicon belt with 16 electrodes was placed around the thoracic cage between the 5th and 6th intercostal space (Pulmovista 500, Dräger, Lübeck, Germany). Ventilator settings were set to volume-controlled mode (Evita-infinity, Dräger, Lübeck, Germany), with a fixed tidal volume of 6–8 ml kg⁻¹ predicted body weight and inspiration/expiration (I/E) ratio of 1:2. We deliberately choose volume control in order to avoid a change in the min volume because of differences in lung compliance at different levels of PEEP. The initial setting of the respiratory rate and fraction of inspired oxygen was adjusted to maintain an end-tidal carbon dioxide tension and oxygen saturation within a range of 35–45 mm Hg and 97–100%, respectively. PEEP was set according to the attending physician. VT, respiratory rate (RR), I/E ratio remained unchanged throughout the entire study period.

We are reluctant to apply high levels of PEEP (>15 cm H₂O) in postoperative patients after cardiac surgery who obviously have no ALI or ARDS, as these patients are generally prone to haemodynamic instability. Therefore, the patients were not subjected to recruitment manoeuvres. After baseline measurements of Vcap and EIT, the PEEP level was increased to 14 cm H₂O. This PEEP level was maintained for 15–20 min in order to reach a steady state situation, as assessed by a stable signal of the volume of exhaled carbon dioxide (VCO₂). Thereafter, the PEEP was decreased from 14 to 0 cm H₂O PEEP in steps of 2 cm H₂O. Each PEEP level was applied for five to 10 min depending on haemodynamically stability. Blood gas analysis, Vcap and EIT were measured during each PEEP step.
Data analysis

Volumetric capnography; model fitting and parameters

Vcap, which is constructed from expired CO₂ concentration and expired volume, can be represented by a mathematical function, which is previously introduced by Tusman and colleagues.²⁷ ²⁸ This makes the analysis of the Vcap data less susceptible to noise. To obtain this mathematical function from Vcap data, a non-linear least square curve fitting algorithm according to Tusman and colleagues was used in a custom-made Matlab® (The MathWorks, Natick, MA, USA) program. From this model, parameters were derived for further analysis. First, the Vcap curve was divided into three phases (Phase I, II and III) (Fig. 1). Phase I indicates the CO₂ volume originated from the airways, whereas phase III is the CO₂ from the alveoli. Phase II therefore is the phase with CO₂ from both the airways and alveoli. The inflection point of Phase II (Point A), which is determined by the maximum of the first derivative of the fitted model, was defined as the mean airway-alveolar interface that separates the airway from the alveolar compartment. Airway dead space (VDaw) is the volume from the beginning of the expiration until point A. Slope II (SII) is the slope of the inflection point of Phase II. Slope III (SIII) is the slope of phase III, which is calculated according to Tusman and colleagues.²⁷ ²⁸ Therefore, SIII was divided into three even sized segments. A line was fitted through the second segment of SIII by the least-square method. The slope of this fitted line was determined as SIII. Thereafter slope III was divided by the fraction of end tidal CO₂ (FECO₂) in order to normalize the value and make it comparable between patients.²⁸ ²⁹

Normalized Slope III (SnIII) represents the homogeneity of ventilation and pulmonary perfusion, which is considered as a good indicator of the global V/Q matching. SnIII increases in lung conditions associated with a mismatch of ventilation and perfusion such as atelectasis or pulmonary artery embolism, whereas low values indicate homogeneous V/Q matching.

Physiological dead space was calculated according to the formula developed by Bohr, and the Enghoff modification of Bohr’s formula³⁰ (formula 1+formula 2):

\[ \text{VD}_{\text{Bohr}}/\text{VT} = \frac{\text{PaCO}_2 - \text{P}_{\text{E}}\text{CO}_2}{\text{PaCO}_2} \] (1)

\[ \text{VD}_{\text{Enghoff}}/\text{VT} = \frac{\text{PaCO}_2 - \text{P}_{\text{E}}\text{CO}_2}{\text{FACO}_2} \] (2)

Alveolar dead space (VDalv) was computed by subtracting VDaw from VDEnghoff. We chose to subtract VDaw from VDEnghoff as the VDEnghoff contains all causes of V/Q inhomogeneity, whereas the Bohr formula is not supposed to contain shunts and low V/Q regions. The ratio of VDalv to alveolar tidal volume (VTalv) was obtained by dividing VDalv by VTalv (VTalv=VT–VDaw), in which VTalv represents alveolar tidal volume.

EIT parameters

EIT data were recorded with a sample frequency of 20 Hz. Data was reconstructed and analysed using special software (EITdiag, Dräger, Lübeck, Germany). For each PEEP level, 10 to 20 consecutive breaths at the end of each PEEP step were selected for analysis, with the assumption that the lungs were best adapted to the ventilator settings at that time. EIT data contains signals induced by the respiratory system and the circulatory system. Therefore, to filter out signals related to the circulatory system, EIT data was filtered using a low pass-filter set to 40 beats min⁻¹. The reconstructed image was represented as a ventilation distribution map, which was generated by tidal impedance changes caused by inspiration and expiration. These impedance changes are presented as tidal impedance variation (TIV) and have been shown to correlate well with gas volume changes, as measured by CT-scans.¹⁶–¹⁸ The surface area of the distribution map was divided into two equal regions of interest (ROIs), to know the non-dependent and dependent lung regions (Supplementary data, Fig. S1). The surface area of the EIT map was kept equal for all PEEP steps.

The intratidal gas distribution (ITV) was developed by Löwhagen, and colleagues (formula 3). The ITV describes the amount of the impedance distributed to each region of interest within one inspiration. For this calculation Löwhagen and colleagues divided the inspiratory part of the global impedance curve into eight equal volume sections. In other words each part of the inspiration is 12.5% of the entire inspiration. Thereafter, they transposed the time needed for each section of the inspiration to the regional curves. In this way they were able to calculate the contribution of four different regions of interest to the inspiration, during a single breath. According to our previous publications we calculated the ITV for two instead of four regions of interest. Using the ITV calculation one is able to analyse the ventilation homogeneity during the inspiration. In order to reliably calculate the ITV, the filtered EIT signals were re-sampled with a frame rate of 40 Hz. This step is important in

Fig 1 Schematic model of three phases of the expiration. The Vcap curve is divided in three phases. Phase I represents exhaled CO₂ from the airways, whereas phase III represents exhaled CO₂ from the alveoli. Phase II is a mixed phase with CO₂ from both the airways and alveoli. Point A is the inflection point of phase II, which is the theoretical point where the airway compartment is separated from the alveolar compartment. VDaw, airway dead space, VTalv, alveolar tidal volume, VT, tidal volume.
order to divide the inspiratory part of the global TIV curve reliably into eight iso-volume sections (ITV, Intratidal Gas Distribution; TIV, Tidal Impedance Variation; ROI, Region of Interest; t, iso-volume part).  

\[
\text{Fractional regional } ITV_{1-t} = \frac{ITV_{1-t} \cdot TV_{ROI}}{ITV_{1-t} \cdot TV_{Global}} 
\]

(3)

In addition to the capnography and EIT parameters we also calculated the dynamic compliance. Dynamic compliance was calculated by dividing the expiratory tidal volume by Peak Inspiratory Pressure (PIP) minus PEEP.

**Statistical analysis**

Statistical analyses were carried out using SPSS 21 (Chicago, IL, USA). Data are presented as mean (±SD) unless otherwise specified. Normal distribution of the data was tested using the Kolmogorov-Smirnov test, whereas homoscedasticity was tested using the Brown-Forsythe test. Changes in Vcap and EIT parameters during the entire protocol were tested using mixed linear models. Differences between two sequential PEEP steps were tested using the paired Student’s t-test for normal distributed data, and using the Wilcoxon rank sum test for not normal distributed data. For all statistical test P<0.05 was considered statistically significant.

**Results**

The initial physiological data, measured shortly before 14 cm H_2O was applied, is summarized in Table 1. During the different PEEP levels, blood gases and dynamic compliance remained stable, down to a PEEP level of 2 cm H_2O and decreased significantly at 0 PEEP (ZEEP) (Table 2).

Figure 2 shows the TIV for the dependent and non-dependent lung region. The 14 cm H_2O PEEP step was chosen as reference, and the TIV of both lung regions together was set to 100% at 14 cm H_2O. Therefore, at lower PEEP levels the sum of TIV of both regions can be more or less than 100%, as compared with PEEP 14 cm H_2O. At 14 cm H_2O of PEEP, most of the ventilation was distributed to the dependent lung region and from PEEP level of 10 cm H_2O and lower, the non-dependent lung region became predominant ventilated (Fig. 2). TIV in the dependent lung region decreased during each PEEP step reduction from a PEEP of 12 cm H_2O, indicating less ventilation at lower PEEP levels as a result of collapse (Fig. 2). TIV in the non-dependent region had the highest value at 6 cm H_2O of PEEP (Fig. 2). In addition, ventilation was evenly distributed among dependent and non-dependent regions at 12 and 10 cmH_2O PEEP (Fig. 3).

Table 2 shows changes in different Vcap parameters. VDBohr/VT and VDEnghoff/VT significantly decreased from a PEEP of 10 cm H_2O and less as compared with 14 cm H_2O PEEP. The ratio of alveolar dead space to alveolar tidal volume significantly decreased from a PEEP level of 6 cm H_2O and less as compared with 14 cm H_2O PEEP. The normalized slope of phase III significantly changed at a PEEP levels of 4 cm H_2O or less, whereas volume of phase III corrected for tidal volume (Vcap/VT) increased significantly, as compared with 14 cm H_2O PEEP at ≤8 cm H_2O PEEP, indicating more alveolar ventilation at lower PEEP levels. In addition, VDaw decreased significantly from a PEEP level of 8 cm H_2O or less. Shunt fraction calculated as the difference between arterial CO_2 minus end-tidal CO_2 (Pa-tCO_2) only significantly differed at ZEEP.

Figure 4A shows the effect of PEEP on the Vcap curve. When lower PEEP levels are applied the Vcap curve is shifted to the left, as a consequence of decreased VDaw. VDaw/VT significantly decreased at 10 cm H_2O and lower as compared with 14 cm H_2O PEEP (Table 2).

**Discussion**

In this study we found that dead space calculations according to Bohr and Enghoff agreed well with the PEEP level, resulting in

homogeneous ventilation as measured by EIT. In contrast, VT\textsubscript{alv}/VT\textsubscript{aw} and S\textsubscript{HII} were insensitive to detect lung inhomogeneity. In addition, we found that in relatively healthy lungs, without the application of a RM, higher PEEP levels mainly induce airway distention rather than improve alveolar ventilation.

Recently, we demonstrated that homogeneous ventilation by means of ITV agreed well with a PEEP level, with the highest dynamic compliance.\textsuperscript{20} We compared the whole dependent non-dependent lung region and found that the dependent lung region had the highest TIV at 12 cm H\textsubscript{2}O PEEP and decreased with each decremental PEEP step, indicating collapse in that region. At a PEEP level of 12 cm H\textsubscript{2}O the dependent and non-dependent lung regions were in balance. Above this PEEP the dependent region received most of the tidal volume, whereas below this PEEP the non-dependent region was predominantly ventilated. Thus EIT is the first device able to visualize collapse and hyperinflation of lung tissue at the bedside.

In an experimental study by Tusman and colleagues\textsuperscript{12} a RM followed by decremental PEEP trial from 24 to 0 cm H\textsubscript{2}O in steps of 2 cm H\textsubscript{2}O was performed, in eight lung lavaged pigs. They investigated the ability of V\textsubscript{cap} to detect optimal PEEP, as compared with computed tomography scans (CT), and found that dynamic compliance, VT\textsubscript{alv}/VT\textsubscript{aw} and Pa\textsubscript{aCO\textsubscript{2}} correlated best with the amount of non-aerated lung tissue as detected by CT-scans. Yang and colleagues\textsuperscript{35} performed a decremental PEEP trial on eight lung-lavaged piglets. After a RM they stepwise reduced the PEEP from 20 cm H\textsubscript{2}O to 4 cm H\textsubscript{2}O in steps of 4 cm H\textsubscript{2}O. At PEEP levels below 16 cm H\textsubscript{2}O they found that VT\textsubscript{alv}/VT\textsubscript{aw} was well correlated to non-aerated and normally aerated lung tissue as assessed by CT-scans. In addition, they found that the lowest S\textsubscript{HII} value was closely related to best lung function. They concluded that VT\textsubscript{alv}/VT\textsubscript{aw} and S\textsubscript{HII} are best predictors for alveolar collapse or hyperinflation. Therefore, from these two studies it can be concluded that V\textsubscript{cap} is a reliable tool to detect both collapse and hyperinflation of lung tissue, as confirmed by CT-scans, which is the golden standard to assess alveolar collapse or hyperinflation.

Maisch and colleagues\textsuperscript{34} performed an incremental and decremental PEEP trial in 20 anesthetized patients with healthy lungs, undergoing faciomaxillary surgery. During the PEEP trial, PEEP levels between 0 and 15 cm H\textsubscript{2}O were applied in PEEP steps of 5 cm H\textsubscript{2}O. They showed that after a RM physiological dead space was the lowest at 10 cm H\textsubscript{2}O PEEP, whereas static compliance of the respiratory system was the highest at that PEEP level. In addition, functional residual capacity and P\textsubscript{aO\textsubscript{2}} were insensitive parameters for detection of alveolar hyperinflation as

---

they decreased with each PEEP step. Therefore, they concluded that physiological dead space and static compliance of the respiratory system are suitable parameters for PEEP titration. Interestingly, we found that the PEEP level at which \( V_{\text{Bohr}}/VT \) and \( V_{\text{Enghoff}}/VT \) significantly decreased (Table 2), suggesting a reduction in V/Q mismatch, agreed well with the PEEP level at which the inspired air was homogeneously distributed to the dependent and non-dependent lung regions, as measured by EIT (Figs 2 and 3). However, at lower PEEP levels, \( V_{\text{Bohr}}/VT \) and \( V_{\text{Enghoff}}/VT \) keep decreasing indicating that this parameter adds no additional information about ventilation homogeneity at lower PEEP. In addition, the exhaled CO\(_2\) per breath (V\(\text{CO}_2,\text{br}\)) and the Sn\(\text{III} \) both showed that elimination of CO\(_2\) improved at lower PEEP levels (Table 2), but no optimum could be found. Therefore, in the present study design and study population, V\(\text{cap} \) is not able to detect homogeneous ventilation.

Our finding in V\(\text{cap} \) that PEEP mainly increases the airway-volume rather than improves alveolar ventilation is apparently in contradiction with the results of other studies published earlier.\(^{14 32 33}\) Lower PEEP levels cause a shift of the V\(\text{cap} \) curve to the left (Fig. 4A), indicating increased airway dead space at higher PEEP levels. These opposing results could be explained by the fact that post-cardiac surgery patients have relatively healthy lungs. Although the patients in our study may have atelectasis,
there is no question of surfactant depletion and we assume that the atelectasis is recruited without the need for high PEEP levels. In contrast, the previous studies used the lung-lavaged models with large amount of shunt area, which are recruitable at high PEEP levels. However, Nieman and colleagues found during in vivo microscopy in normal and surfactant deactivated pigs, during ventilation with tidal volumes of 6, 12 and 15 ml kg$^{-1}$, that in normal lungs the alveolar area at end-inspiration and end-expiration (I-E$_A$) did not differ between the three different tidal volumes, whereas in the surfactant deactivated lungs I-E$_A$ increased significantly at higher tidal volumes. In a next study they used different tidal volumes (6, 12, 15 ml kg$^{-1}$) and PEEP levels (5, 10, 20 cm H$_2$O) and found that I-E$_A$ did not change in normal lungs, whereas in surfactant deactivated lungs the alveolar size significantly increased, as compared with normal lungs with equal settings. From these studies it can be concluded that in normal lungs with stable alveoli, PEEP volume results in airway distention, whereas in ALI/ARDS lungs, PEEP keeps the alveoli open and stabilized. In addition, airway distention as a result of high PEEP might also explain why physiological dead space calculated according to Enghoff, increases at higher PEEP levels, whereas PaCO$_2$, did not significantly differ during the different PEEP levels, except at ZEEP. This explains the absence of a change in SII and the left shift of SII in the Vcap curves at decreasing PEEP levels in our patients.

There are limitations to this study. Firstly, we did not apply a RM before the PEEP reduction, in order to avoid serious deterioration of haemodynamics in the direct postoperative period. It has been shown that Vcap parameters after an RM are more sensitive to detect changes in CO$_2$ elimination, as compared with PEEP trials without an RM. Secondly, EIT describes the ventilation distribution in a lung slice of approximately 5–10 cm thick. Therefore, the image obtained from the single cross-section does not represent the entire lung. In addition, PEEP increases results in changed chest size and intrathoracic blood volume. However, by using two large regions of interest, the corresponding lung tissue to the individual pixel is limited. The effect of changed intrathoracic blood volume is limited, as EIT is a hundred times more sensitive to impedance changes caused by aeration, as compared with impedance changes caused by the cardiac system. Thirdly, the time intervals of 5–10 min at each PEEP level might be too short to achieve a steady state for obtaining reliable data. However, a recent study showed that elimination of CO$_2$ reached a new stable period within 5 min of a PEEP change. It is known that Vcap is influenced by both the cardiac system and the pulmonary system. In this study we did not perform cardiac output measurements. Therefore we cannot assess Vcap changes induced by reduced cardiac output at higher PEEP levels. However, we found no significant differences in bp and heart rate between PEEP 14 and ZEEP. Therefore, we assume that the influence of the change in cardiac output with different PEEP levels on dead space was not profound.

**Conclusion**

In postoperative cardiac patients with low shunt fractions, dead space calculations according to Bohr and Enghoff agreed well with EIT. EIT is able to detect the optimal PEEP level for equal distribution of inspired air, among the non-dependent and the dependent regions of the lungs. In contrast, VDaw/VTaw and SV$_{aw}$ were unable to detect this distribution. In addition, we found that in relatively healthy lungs, applying higher PEEP levels mainly induced airway distention rather than improvement of alveolar ventilation.
