Summary

We propose an efficient, accurate and robust implicit solver for the incompressible Navier-Stokes equations, based on a DG spatial discretization and on the TR-BDF2 method for time discretization. The effectiveness of the method is demonstrated in a number of classical benchmarks, which highlight its superior efficiency with respect to other widely used implicit approaches. The parallel implementation of the proposed method in the framework of the deal.II software package allows for accurate and efficient adaptive simulations in complex geometries, which makes the proposed solver attractive for large scale industrial applications.

Navier-Stokes equations, incompressible flows, Discontinuous Galerkin methods, implicit methods, ESDIRK methods, Mesh adaptation
1 | INTRODUCTION

The efficient numerical solution of the incompressible Navier-Stokes equations is one of the most relevant goals of computational fluid dynamics. A great number of methods have been proposed in the literature, see for example, among many others, the reviews in\cite{1} Since the seminal proposals,\cite{2} projection methods,\cite{3} have become very popular for the time discretization of this problem. Several spatial discretization approaches have been proposed and finite volume techniques using unstructured meshes\cite{4} have become the state of the art for industrial applications, in particular when implemented in parallel software packages like OpenFoam.\cite{5} Indeed, in previous work by one of the authors\cite{6} a wide range of projection methods was implemented in OpenFoam and their performance was compared, as a preliminary step towards the development of a computational fluid dynamics tool for combustion simulations of industrial interest. On the other hand, high order finite elements, both in their continuous and discontinuous versions,\cite{7,8} have gained increasing popularity in the academic community and also in many applications, but are still far from being the reference tool for industrial use. More specifically, Discontinuous Galerkin methods for the Navier-Stokes equations have been proposed by many authors, we refer for example to\cite{9,10,11,12,13}. In this work, we seek to combine, on the one hand, accurate and flexible discontinuous finite element spatial discretizations, and on the other hand, efficient and unconditionally stable time discretizations, following an approach that has been shown to be quite successful for applications to numerical weather prediction in\cite{14,15} Building on the experience of\cite{6}, we propose an accurate, efficient and robust projection method, based on the second order TR-BDF2 method\cite{16,17,18}. This solver is implemented using discontinuous finite elements, in the framework of the numerical library deal.II\cite{19} in order to provide a reliable and easily accessible tool for large scale industrial applications. It is important to remark that time discretizations of the Navier-Stokes equations based on accurate implicit solvers have been proposed in a number of papers, see among many others\cite{10,11,12,13}. The specific combination of techniques presented in this work does not entail major conceptual novelties with respect to any of the above references, but we claim that it constitutes an optimal combination for the development of a second order $h$–adaptive flow solver that can be competitive for industrial applications with more conventional finite volume techniques. Furthermore, while the TR-BDF2 method is only second order in time, the wide range of simulations presented in\cite{6} show that this method still allows to achieve quite accurate results even when coupled to higher order discretizations in space. The paper is organized as follows: the time discretization approach is outlined and discussed in Section 2. The spatial discretization is presented in Section 3. Some implementation issues, the validation of the proposed method and its application to a number of significant CFD benchmarks are reported in Section 4. Some conclusions and perspectives for future work are described in Section 5.

2 | THE NAVIER-STOKES EQUATIONS AND THE TIME DISCRETIZATION STRATEGY

Let $\Omega \subset \mathbb{R}^d, 2 \leq d \leq 3$ be a connected open bounded set with a sufficiently smooth boundary $\partial \Omega$ and denote by $x$ the spatial coordinates and by $t$ the temporal coordinate. We consider the classical unsteady incompressible Navier-Stokes equations, written in non-dimensional form as:

$$\begin{align*}
\frac{\partial u}{\partial t} + \nabla \cdot (u \otimes u) + \nabla p &= \frac{1}{Re} \Delta u + f \\
\nabla \cdot u &= 0
\end{align*}$$  \hspace{1cm} (1)

for $x \in \Omega, t \in (0, T]$, supplied with suitable initial and boundary conditions. Here $T$ is the final time, $u$ is the fluid velocity, $p$ is the pressure divided by density and $Re$ is the Reynolds number, which is usually defined as $Re = UL/\nu$, where $U$ denotes a reference value of the velocity magnitude, $L$ a reference length scale and $\nu$ the fluid kinematic viscosity. The velocity $u$ and the pressure $p$ are coupled together by the incompressibility constraint in (1), which leads, after space discretization, to a system of differential and algebraic equations whose numerical solution presents several difficulties widely discussed in the literature. Furthermore, in the specific case of projection methods, difficulties arise in choosing the boundary conditions to be imposed for the Poisson equation which is to be solved at each time step to compute the pressure, see e.g. the discussion in\cite{6}.

An alternative that allows to avoid or reduce some of these problems is the so-called artificial compressibility formulation, originally introduced in\cite{20}. In this formulation, the incompressibility constraint is relaxed and a time evolution equation for the pressure is introduced, which is characterized by an artificial sound speed $c$, so as to obtain
\[
\frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot (\mathbf{u} \otimes \mathbf{u}) + \nabla p = \frac{1}{Re} \Delta \mathbf{u} + \mathbf{f} \\
\frac{1}{c^2} \frac{\partial p}{\partial t} + \nabla \cdot \mathbf{u} = 0.
\]  
(2)

For the sake of simplicity, we shall only consider \( \mathbf{f} = 0 \) and Dirichlet boundary conditions for the velocity, i.e., \( \mathbf{u}|_{\partial \Omega} = \mathbf{u}_D(t) \), while we consider homogeneous Neumann boundary conditions for the pressure. While most commonly discretized by explicit methods, see e.g., among many others, implicit methods have also been applied to this formulation, see e.g., \( 32,33,34 \).

Our goal here is to extend the projection method based on the TR-BDF2 scheme introduced in \( 10 \) for the formulation \( 1 \) to the time discretization of system \( (2) \). This allows to avoid the introduction of stabilization parameters and to exploit the special properties of the TR-BDF2 method, which will be reviewed here briefly. Our development is also inspired by the first order semi-implicit methods, which were proposed originally for the compressible Navier-Stokes equations but which could also be applied in the pseudo-incompressible case. Introducing a discrete time step \( \Delta t = T/N \) and discrete time levels \( t^n = n\Delta t, \ n = 0, \ldots, N, \) for a generic time dependent problem \( \mathbf{u}' = \mathbf{N}(\mathbf{u}) \) the incremental form of the TR-BDF2 method can be described in terms of two stages, the first from \( t^n \) to \( t^{n+\gamma} \) and the second from \( t^{n+\gamma} \) to \( t^{n+1} \), which can be written as:

\[
\begin{align*}
\frac{u^{n+\gamma} - u^n}{\gamma \Delta t} &= \frac{1}{2} \mathbf{N}'(u^{n+\gamma}) + \frac{1}{2} \mathbf{N}'(u^n) \\
\frac{u^{n+1} - u^{n+\gamma}}{(1 - \gamma) \Delta t} &= \frac{1}{2 - \gamma} \mathbf{N}'(u^{n+1}) + \frac{1 - \gamma}{2(2 - \gamma)} \mathbf{N}'(u^{n+\gamma}) + \frac{1 - \gamma}{2(2 - \gamma)} \mathbf{N}'(u^n).
\end{align*}
\]

(3)

Here, \( u^n \) denotes the approximation at time \( n = 0, \ldots, N \). Notice that, in order to guarantee L-stability, one has to choose \( \gamma = 2 - \sqrt{2} \). This second order implicit method, originally introduced in \( 22 \) as a combination of the Trapezoidal Rule (or Crank-Nicolson) method and of the Backward Differentiation Formula method of order 2, has been fully analyzed in \( 22 \). While we will use here its original formulation, the method was shown in \( 23 \) to be an L-stable Explicit first step, Diagonally Implicit Runge Kutta method (ESDIRK). Explicit methods that complement TR-BDF2 as second order IMEX pairs have been introduced in \( 37 \) and successfully employed in \( 35,36 \). Unconditionally strong stability preserving extensions of TR-BDF2 have been derived in \( 29 \). While the third order method that constitutes an embedded pair with TR-BDF2 is only conditionally stable, see the discussion in \( 22 \), a first order embedded method is derived in \( 21 \) thus allowing for efficient time adaptation strategies. Finally, the analysis presented in \( 22 \) shows that the method is optimal among second order methods for typical structural mechanics equations, thus making it an excellent candidate also for applications to fluid-structure interaction problems. While we do not pursue these developments in the present work, we would like to highlight these features as strong motivations for our specific choice of the time discretization method.

Following then the projection approach described in \( 10 \) and applying method \( (3) \) to system \( (2) \), the momentum predictor equation for the first stage reads:

\[
\begin{align*}
\frac{u^{n+\gamma} \cdot \cdot \cdot - u^n}{\gamma \Delta t} - \frac{1}{2Re} \Delta u^{n+\gamma} \cdot \cdot \cdot + \frac{1}{2} \nabla \cdot \left( u^{n+\gamma} \otimes u^{n+\gamma} \right) = \\
\frac{1}{2Re} \Delta u^n - \frac{1}{2} \nabla \cdot \left( u^n \otimes u^n \right) - \nabla p^n \\
\left. u^{n+\gamma} \right|_{\partial \Omega} = u^n_{D}.
\end{align*}
\]

(4)

Notice that, in order to avoid solving a nonlinear system at each time step, an approximation is introduced in the nonlinear momentum advection term, so that \( u^{n+\gamma} \) is defined by extrapolation as

\[
\begin{align*}
u^{n+\gamma} = \left( 1 + \frac{\gamma}{2(1 - \gamma)} \right) u^n - \frac{\gamma}{2(1 - \gamma)} u^{n-1}.
\end{align*}
\]

Alternatively, \( u^{n+\gamma} \) can be replaced by \( u^{n+\gamma}^* \) in the left hand side and by \( u^n \) in the right hand side of \( (4) \), respectively, and \( u^{n+\gamma}^* \) can be determined by fixed point iteration. Numerical experiments show that this fully nonlinear formulation is necessary to achieve accurate results for larger Courant number values, see the discussion in Section \( 4 \). Following \( 22 \), we set then \( \delta p^{n+\gamma} = p^{n+\gamma} - p^n \) and impose
\[ \frac{u^{n+\gamma} - u^{n+\gamma,\ast}}{\gamma \Delta t} = -\nabla \delta p^{n+\gamma}, \]
\[ \frac{1}{c^2} \frac{\delta p^{n+\gamma}}{\gamma \Delta t} + \nabla \cdot u^{n+\gamma} = 0. \quad (5) \]

Substituting the first equation into the second in (5), one obtains the Helmholtz equation
\[ \frac{1}{c^2} \frac{\delta p^{n+\gamma}}{(1-\gamma)^2 \Delta t^2} - \Delta \delta p^{n+\gamma} = -\frac{1}{\gamma \Delta t} \nabla \cdot u^{n+\gamma,\ast}, \quad (6) \]
which is solved with the boundary condition \( \nabla \delta p^{n+\gamma} \cdot n \big|_{\partial \Omega} = 0 \). Once this equation is solved, the final velocity update for the first stage \( u^{n+\gamma} = u^{n+\gamma,\ast} - (1-\gamma)\Delta t \nabla \delta p^{n+\gamma} \) can be computed. Notice that the previous procedure is equivalent to introducing the intermediate update \( u^{n+\gamma,\ast\ast} = u^{n+\gamma,\ast} + \gamma \Delta t \nabla p^n \), solving
\[ \frac{1}{c^2} \frac{p^{n+\gamma}}{(1-\gamma)^2 \Delta t^2} - \Delta p^{n+\gamma} = -\frac{1}{\gamma \Delta t} \nabla \cdot u^{n+\gamma,\ast\ast} + \frac{1}{c^2} \frac{p^n}{(1-\gamma)^2 \Delta t^2}, \quad (7) \]
and then setting \( u^{n+\gamma} = u^{n+\gamma,\ast\ast} - (1-\gamma)\Delta t \nabla p^{n+\gamma} \). The second TR-BDF2 stage is performed in a similar manner. We first define the second momentum predictor:
\[ \begin{align*}
\frac{u^{n+1,\ast} - u^{n}}{(1-\gamma) \Delta t} &= -\frac{a_{33}}{Re} \Delta u^{n+1,\ast} + a_{33} \nabla \cdot (u^{n+1,\ast} \otimes u^{n+\gamma}) = \\
\frac{a_{32}}{Re} \Delta u^{n+\gamma} &= -\frac{a_{32}}{Re} \nabla \cdot (u^{n+\gamma} \otimes u^{n+\gamma}) + a_{31} \Delta u^n - a_{31} \nabla \cdot (u^n \otimes u^n) - \nabla p^{n+\gamma}
\end{align*} \quad (8) \]
where one has
\[ a_{31} = \frac{1}{2} \frac{1 - \gamma}{2(2-\gamma)}, \quad a_{32} = \frac{1}{2} \frac{1 - \gamma}{2(2-\gamma)}, \quad a_{33} = \frac{1}{2} \frac{1 - \gamma}{2(2-\gamma)}. \]

Again, in order to avoid solving a nonlinear system at each time step, an approximation is introduced in the nonlinear momentum advection term, so that \( u^{n+\gamma,\ast\ast} \) is defined by extrapolation as
\[ u^{n+\gamma,\ast\ast} = \left( 1 + \frac{1 + \gamma}{\gamma} \right) u^{n+\gamma} - \frac{1 - \gamma}{\gamma} u^n. \]
Alternatively, \( u^{n+\gamma,\ast\ast} \) can be replaced by \( u^{n+1,\ast} \), which can then be determined by fixed point iteration. We set then \( \delta p^{n+1} = p^{n+1} - p^{n+\gamma} \) and impose
\[ \frac{u^{n+1} - u^{n+1,\ast}}{(1-\gamma) \Delta t} = -\nabla \delta p^{n+1}, \]
\[ \frac{1}{c^2} \frac{\delta p^{n+1}}{(1-\gamma) \Delta t} + \nabla \cdot u^{n+1} = 0. \quad (9) \]

Substituting the first equation into the second in (9), one obtains the Helmholtz equation
\[ \frac{1}{c^2(1-\gamma)^2 \Delta t^2} \frac{\delta p^{n+1}}{c^2(1-\gamma)^2 \Delta t^2} - \Delta \delta p^{n+1} = -\frac{1}{(1-\gamma) \Delta t} \nabla \cdot u^{n+1,\ast}, \quad (10) \]
which is solved with the boundary condition \( \nabla \delta p^{n+1} \cdot n \big|_{\partial \Omega} = 0 \). Once this equation is solved, the final velocity update
\[ u^{n+1} = u^{n+1,\ast} - (1-\gamma)\Delta t \nabla p^{n+1} \]
can be computed. Also for this second stage, notice that the procedure is equivalent to setting \( u^{n+1,\ast\ast} = u^{n+1,\ast} + (1-\gamma)\Delta t \nabla p^{n+\gamma} \), solving
\[ \frac{1}{c^2} \frac{p^{n+1}}{c^2(1-\gamma)^2 \Delta t^2} - \Delta p^{n+1} = -\frac{1}{(1-\gamma) \Delta t} \nabla \cdot u^{n+1,\ast\ast} + \frac{1}{c^2(1-\gamma)^2 \Delta t^2} \frac{p^{n+\gamma}}{c^2(1-\gamma)^2 \Delta t^2}, \quad (11) \]
and then setting \( u^{n+1} = u^{n+1,\ast\ast} - (1-\gamma)\Delta t \nabla p^{n+1} \).
For the purposes of the comparisons that will be reported in Section 4, we also present two alternative and very popular second order projection methods, proposed respectively in Refs. [43] and [44], which are based on the parent methods of TR-BDF2, i.e. the Crank-Nicolson (or Trapezoidal Rule) method and the BDF2 method, respectively. We briefly recall the formulation of these schemes in the framework of the artificial compressibility formulation. The momentum predictor for the Bell-Colella-Glaz [43] projection method reads as follows

\[
\frac{u^{n+1,*} - u^n}{\Delta t} - \frac{1}{2Re} \Delta u^{n+1,*} + [(u \cdot \nabla) u]^{n+1,*} = \\
\frac{1}{2Re} \Delta u^n - \nabla p^n \\
\frac{u^{n+1,*}}{\delta \Omega} = u_B^{n+1}.
\]  

(12)

Notice that here we have set \( u^{n+1,*} = \frac{1}{2} (u^{n+1,*} + u^n) \), so that the scheme is fully nonlinear. On the other hand, setting \( \delta p^{n+1} = p^{n+1} - p^n \), we obtain the following Helmholtz equation for the projection stage

\[
\frac{1}{c^2 \Delta t^2} \delta p^{n+1} - \Delta \delta p^{n+1} = -\frac{1}{\Delta t} \nabla \cdot u^{n+1,*} \\
\nabla \delta p^{n+1} \cdot \mathbf{n} |_{\delta \Omega} = 0.
\]  

(13)

Eventually, the velocity has to be updated with the gradient of the pressure increment:

\[
u^{n+1} = u^{n+1,*} - \Delta t \nabla \delta p^{n+1}.
\]  

(14)

It is apparent that this method is essentially based on the Crank-Nicolson time discretization approach. A method based on the BDF2 scheme has been presented instead by Guermond and Quartapelle in Ref. [44]. The momentum predictor reads as follows

\[
\frac{3u^{n+1,*} - 4u^n + u^{n-1}}{\Delta t} - \frac{1}{Re} \Delta u^{n+1,*} + (u^{n,*} \cdot \nabla) u^{n+1,*} \\
+ \frac{1}{2} (\nabla \cdot u^{n,*}) u^{n+1,*} = -\nabla p^n \\
\frac{u^{n+1,*}}{\delta \Omega} = u_B^{n+1}.
\]  

(15)

The Helmholtz equation for the projection stage is

\[
\frac{1}{c^2 \Delta t^2} p^{n+1} - \Delta p^{n+1} = -\frac{1}{\Delta t} \nabla \cdot u^{n+1,**} + \frac{1}{c^2 \Delta t^2} p^n \\
\nabla \delta p^{n+1} \cdot \mathbf{n} |_{\delta \Omega} = 0
\]  

(16)

where \( u^{n+1,**} = u^{n+1,*} + \frac{2}{3} \Delta t \nabla p^n \). Eventually, the velocity is updated with the gradient of the computed pressure:

\[
u^{n+1} = u^{n+1,**} - \frac{2}{3} \Delta t \nabla p^{n+1}.
\]  

(17)

3 | THE SPATIAL DISCRETIZATION

For the spatial discretization, we consider discontinuous finite element approximations, due to their great flexibility in performing mesh adaptation. We consider a decomposition of the domain \( \Omega \) into a family of hexahedra \( T_h \) (quadrilaterals in the two-dimensional case) and denote each element by \( K \). The skeleton \( \mathcal{E} \) denotes the set of all element faces and \( \mathcal{E} = \mathcal{E}^I \cup \mathcal{E}^B \), where \( \mathcal{E}^I \) is the subset of interior faces and \( \mathcal{E}^B \) is the subset of boundary faces. We also introduce the following finite element spaces

\[
Q_k = \{ v \in L^2(\Omega) : v|_K \in Q_k \ \forall K \in T_h \}
\]

and

\[
Q_k = [Q_k]^d,
\]
where $Q_k$ is the space of polynomials of degree $k$ in each coordinate direction. Considering the well-posedness analyses in $[13,15]$, the finite element spaces that will be used for the discretization of velocity and pressure are $V_h = Q_k$ and $Q_h = Q_{k-1} \cap L^2(\Omega)$, respectively, where $k \geq 2$ and $L^2(\Omega) = \{ v \in L^2(\Omega) : \int_{\Omega} v \mathrm{d}\Omega = 0 \}$. Notice that, while for the sake of coherence with the time discretization and of comparison with second order finite volume methods we will mostly consider the case $k = 2$ in the following, the formulation we present is completely general and also the implementation validated in Section 4 supports arbitrary values of $k$. Furthermore, notice that the above choice for the finite element spaces corresponds to that implemented in the deal.II library, which will be employed for the numerical computation. The proposed approach can in principle also be applied to tetrahedral meshes and $P$-spaces. Suitable jump and average operators can then be defined as customary for finite element discretizations, see e.g. $[16]$. A face $\Gamma \in \mathcal{E}^I$ shares two elements that we denote by $K^+$ with outward unit normal $n^+$ and $K^-$ with outward unit normal $n^-$, whereas for a face $\Gamma \in \mathcal{E}^B$ we denote by $n$ the outward unit normal. For a scalar function $\varphi$ the jump is defined as

$$[[\varphi]] = \varphi^+ n^+ + \varphi^- n^- \quad \text{if} \quad \Gamma \in \mathcal{E}^I \quad \text{and} \quad [\varphi n] = \varphi n \quad \text{if} \quad \Gamma \in \mathcal{E}^B.$$ 

The average is defined as

$$\{(\varphi)\} = \frac{1}{2} (\varphi^+ + \varphi^-) \quad \text{if} \quad \Gamma \in \mathcal{E}^I \quad \text{and} \quad \{\varphi\} = \varphi \quad \text{if} \quad \Gamma \in \mathcal{E}^B.$$

Similar definitions apply for a vector function $\varphi$:

$$[[\varphi]] = \varphi^+ \cdot n^+ + \varphi^- \cdot n^- \quad \text{if} \quad \Gamma \in \mathcal{E}^I \quad \text{and} \quad [\varphi \cdot n] = \varphi \cdot n \quad \text{if} \quad \Gamma \in \mathcal{E}^B$$

$$\{(\varphi)\} = \frac{1}{2} (\varphi^+ + \varphi^-) \quad \text{if} \quad \Gamma \in \mathcal{E}^I \quad \text{and} \quad \{\varphi\} = \varphi \quad \text{if} \quad \Gamma \in \mathcal{E}^B.$$ 

For vector functions, it is also useful to define a tensor jump as:

$$\langle\langle \varphi \rangle\rangle = \varphi^+ \otimes n^+ + \varphi^- \otimes n^- \quad \text{if} \quad \Gamma \in \mathcal{E}^I \quad \text{and} \quad \langle\langle \varphi \rangle\rangle = \varphi \otimes n \quad \text{if} \quad \Gamma \in \mathcal{E}^B.$$ 

Given these definitions, the weak formulation of the momentum predictor equation for the first stage is obtained multiplying equation (4) by a test function $v \in V_h$, integrating over $K \in T_h$ and applying Green’s theorem. To impose the boundary conditions, we set $(u^{i+\tau, e})^- = -(u^{i+\tau, e})^+ + 2u^{i+\tau, e}$ with $\nabla (u^{i+\tau, e})^+ \cdot n = \nabla (u^{i+\tau, e})^- \cdot n$.

We now treat separately the discretization of the diffusion and advection contributions, respectively. The approximation of the diffusion term is based on the symmetric interior penalty method (SIP) $[17]$. We denote the scalar product between two second-order tensors by

$$A : B = \sum_{i,j} A_{ij} B_{ij}.$$

Following $[14]$, we set for each face $\Gamma$ of a cell $K$

$$\sigma^n_{\Gamma,K} = (k + 1)^2 \frac{\text{diam}(\Gamma)}{\text{diam}(K)}$$

and we define the penalization constant for the SIP method as

$$C_u = \frac{1}{2} \left( \sigma^n_{\Gamma,K^+} + \sigma^n_{\Gamma,K^-} \right)$$

if $\Gamma \in \mathcal{E}^I$ and $C_u = \sigma^n_{\Gamma,K}$ otherwise. Taking into account boundary conditions as previously discussed and summing over all $K \in T_h$, we can define the following bilinear form:
The approximation of the advection term employs the widely used local Lax-Friedrichs (LF) flux, see e.g. [11]. Setting \( \lambda = \max \left( \left\| \left( \mathbf{u}^{n+\frac{1}{2}} \right)^+ \cdot \mathbf{n} \right\|, \left\| \left( \mathbf{u}^{n+\frac{1}{2}} \right)^- \cdot \mathbf{n} \right\| \right) \) with \( \mathbf{n} = \mathbf{n}^\pm \) and taking into account boundary conditions, we define the trilinear form

\[
e^{(1)}(\mathbf{u}^{n+\frac{1}{2}}, \mathbf{u}, \mathbf{v}) = \frac{1}{2} \sum_{k \in \mathcal{T}_h} \int \nabla \mathbf{u}^n \cdot \nabla \mathbf{v} d\Omega \left( \mathbf{u} \otimes \mathbf{u}^{n+\frac{1}{2}} \right) - \frac{1}{2} \sum_{l \in \mathcal{E}_h} \int \left\{ \left\{ \nabla \mathbf{u} \right\} \right\} : \left\{ \langle \langle \mathbf{v} \rangle \rangle \right\} d\Sigma
\]

Finally, we also define the functional

\[
F^{(1)}_u(\mathbf{v})^{n+} = -\frac{1}{2} \sum_{k \in \mathcal{T}_h} \int \nabla \mathbf{u}^n \cdot \nabla \mathbf{v} d\Omega + \frac{1}{2} \sum_{l \in \mathcal{E}_h} \int \left\{ \left\{ \nabla \mathbf{u} \right\} \right\} : \left\{ \langle \langle \mathbf{v} \rangle \rangle \right\} d\Sigma
\]

which also includes the terms representing the weak form of Dirichlet boundary conditions. It is worth to point out that in the right-hand side no penalization terms have been introduced for the variables computed at previous time-steps. Moreover, for the sake of clarity, the face integrals related to the quantities at previous time-steps are reported on the whole skeleton \( \mathcal{E} \), without distinguishing between interior and boundary faces.

The complete weak formulation of the first stage velocity update reads then as follows: given \( \mathbf{u}^{n+\frac{1}{2}}, \mathbf{u}^n \in \mathbf{V}_h \) and \( p^\prime \in Q_h \), find \( \mathbf{u}^{n+\prime} \in \mathbf{V}_h \) such that:

\[
\sum_{k \in \mathcal{T}_h} \int \frac{1}{\gamma \Delta t} \mathbf{u}^{n+\prime} \cdot \mathbf{v} d\Omega + a^{(1)}_u(\mathbf{u}^{n+\prime}, \mathbf{v}) + e^{(1)}(\mathbf{u}^{n+\frac{1}{2}}, \mathbf{u}^{n+\prime}, \mathbf{v})
\]

\[
= \sum_{k \in \mathcal{T}_h} \int \frac{1}{\gamma \Delta t} \mathbf{u}^n \cdot \mathbf{v} d\Omega + F^{(1)}_u(\mathbf{v})^{n+} \quad \forall \mathbf{v} \in \mathbf{V}_h.
\]

(22)
For the projection steps defined by equation (7) we apply again the SIP method. In order to impose homogeneous Neumann boundary conditions we prescribe \( \n = - \mathbf{n} \) for this reason, no contribution from boundary faces arises. We then multiply by a test function \( q \in Q_h \), we apply Green’s theorem and we define:

\[
a_p(p, q) = \sum_{K \in \mathcal{T}_h} \int_K \nabla p \cdot \nabla q d\Omega - \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} \{ \{ \nabla p^{n+\gamma} \} \} \cdot \{ q \} d\Sigma
\]

\[= \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} [p] \cdot \{ \{ q \} \} d\Sigma + \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} C_p [p] \cdot \{ q \} d\Sigma \tag{23}\]

\[
F^{(1)}_p(q)^{n+\gamma} = \sum_{K \in \mathcal{T}_h} \int_K \frac{1}{\gamma \Delta t} \mathbf{u}^{n+\gamma,\ast} \cdot \nabla q d\Omega - \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} \frac{1}{\gamma \Delta t} \{ \{ \mathbf{u}^{n+\gamma,\ast} \} \} \cdot \{ q \} d\Sigma \tag{24}\]

and again we set

\[
\sigma_{r,K}^p = k^2 \frac{\text{diam}(\Gamma)}{\text{diam}(K)} \tag{25}\]

while, if \( \Gamma \in \mathcal{E}^t \), we set \( C_p = \frac{1}{2} \left( \sigma_{r,K}^p + \sigma_{r,K}^{p-} \right) \). Otherwise \( C_p = \sigma_{r,K}^p \). The weak formulation of equation (7) reads then: given \( p^n \in Q_h \), find \( p^{n+\gamma} \in Q_h \) such that

\[
\sum_{K \in \mathcal{T}_h} \int_K \frac{1}{c^2 \gamma^2 \Delta t^2} p^{n+\gamma} q d\Omega + a_p(p^{n+\gamma}, q) = \sum_{K \in \mathcal{T}_h} \int_K \frac{1}{c^2 \gamma^2 \Delta t^2} p^n q d\Omega + F^{(1)}_p(q)^{n+\gamma} \quad \forall q \in Q_h. \tag{26}\]

The second stage can be described in a similar manner. We start defining the bilinear forms for the second momentum predictor as:

\[
a_u^{(2)}(\mathbf{u}, \mathbf{v}) = \frac{a_{33}}{Re} \sum_{K \in \mathcal{T}_h} \int_K \nabla \mathbf{u} : \nabla \mathbf{v} d\Omega - \frac{a_{33}}{Re} \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} \{ \{ \nabla \mathbf{u} \} \} : \{ \{ \mathbf{v} \} \} d\Sigma
\]

\[
- \frac{a_{33}}{Re} \sum_{\Gamma \in \mathcal{E}^s} \int_{\Gamma} (\nabla \mathbf{u}) \cdot \mathbf{n} \cdot v d\Sigma - \frac{a_{33}}{Re} \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} \{ \{ \mathbf{v} \} \} : \{ \{ \nabla \mathbf{u} \} \} d\Sigma
\]

\[
- \frac{a_{33}}{Re} \sum_{\Gamma \in \mathcal{E}^s} \int_{\Gamma} (\mathbf{u} \otimes \mathbf{n}) : \nabla \mathbf{v} d\Sigma + \frac{a_{33}}{Re} \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} C_u \{ \{ \mathbf{u} \} \} : \{ \{ \mathbf{v} \} \} d\Sigma
\]

\[+ \frac{a_{33}}{Re} \sum_{\Gamma \in \mathcal{E}^s} \int_{\Gamma} 2C_u (\mathbf{u} \cdot \mathbf{v}) d\Sigma \tag{27}\]

\[
e^{(2)}(\mathbf{u}^{n+\gamma}, \mathbf{u}, \mathbf{v}) = -a_{33} \sum_{K \in \mathcal{T}_h} \int_K (\mathbf{u} \otimes \mathbf{u}^{n+\gamma}) : \nabla \mathbf{v} d\Omega + a_{33} \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} \{ \{ \mathbf{u} \otimes \mathbf{u}^{n+\gamma} \} \} : \{ \{ \mathbf{v} \} \} d\Sigma
\]

\[+ a_{33} \sum_{\Gamma \in \mathcal{E}^i} \int_{\Gamma} \lambda (\mathbf{u} \cdot \mathbf{v}) d\Sigma + a_{33} \sum_{\Gamma \in \mathcal{E}^s} \int_{\Gamma} \lambda (\mathbf{u} \cdot \mathbf{v}) d\Sigma, \tag{28}\]

where \( \lambda = \max \left( \left( |\mathbf{u}^{n+\gamma}|^2 + |\mathbf{n}| \right) \cdot |\mathbf{n}| \right) \) with \( \mathbf{n} = \mathbf{n}^\pm \).

We also define the linear functional:
For the first stage, we take functions for the space $V_h$. Therefore, the weak formulation for (11) reads as follows:

$$
\sum_{K \in T_h} \int_\Omega \frac{1}{(1-\gamma) \Delta t} u^{n+1,*} \cdot v d\Omega + \frac{a_2}{Re} \sum_{K \in T_h} \int_\Omega \left\{ \{ u^{n+1,*} \} \cdot \{ [v] \} \right\} d\Sigma.
$$

We can then immediately define the functional associated to the second projection step as

$$
F_p^{(2)}(q)^{n+1} = \sum_{K \in T_h} \int_\Omega \frac{1}{(1-\gamma) \Delta t} u^{n+1,*} \cdot v d\Omega + \frac{a_2}{Re} \sum_{K \in T_h} \int_\Omega \left\{ \{ u^{n+1,*} \} \cdot \{ [q] \} \right\} d\Sigma.
$$

Finally, the weak formulation for the equation (8) reads as follows: given $u^{n+\gamma}, u^{n+\gamma} \in V_h$ and $p^{n+\gamma} \in Q_h$, find $u^{n+\gamma,*} \in V_h$ such that:

$$
\sum_{K \in T_h} \int_\Omega \frac{1}{(1-\gamma) \Delta t} u^{n+1,*} \cdot v d\Omega + \frac{a_2}{Re} \sum_{K \in T_h} \int_\Omega \left\{ \{ u^{n+1,*} \} \cdot \{ [v] \} \right\} d\Sigma.
$$
After computing the integrals in the previous formulae by appropriate quadrature rules, one obtains the algebraic system

\[
\left( \frac{1}{\gamma \Delta t} M + A^{n+\gamma} + C \left( u^{n+\gamma} \right) \right) U^{n+\gamma,*} = \frac{1}{\gamma \Delta t} M U^{n+\gamma,*}_h + F_u^{n+\gamma},
\]

where \( U_h \) denotes the vector of the discrete degrees of freedom associated to the velocity field and \( F_u^{n+\gamma} \) is the vector obtained evaluating \( F_u^{(i)}(\varphi_i)^{n+\gamma}, i = 1, \ldots, \dim(V_h) \). The same procedure can be applied for the projection step, obtaining the matrices

\[
M_p^p = \sum_{k \in T_h} \int_{\Omega} \psi_j \psi_i \, d\Omega \quad (37)
\]

\[
K_{ij} = a_p(\psi_j, \psi_i).
\]

where again \( P_h \) denotes the vector of the discrete degrees of freedom associated to pressure and \( F_p^{n+\gamma} \) is the vector obtained evaluating \( F_p^{(i)}(\varphi_i)^{n+\gamma}, i = 1, \ldots, \dim(Q_h) \). For the second stage, we proceed in a similar manner; for the momentum predictor \( (30) \) we obtain

\[
\left( \frac{1}{(1-\gamma) \Delta t} M + A^{n+1} + C \left( u^{n+1,\gamma} \right) \right) U^{n+1,*} = \frac{1}{(1-\gamma) \Delta t} M U^{n+1,*}_h + F_u^{n+1},
\]

where we set

\[
A_{ij}^{n+1} = a_u^{(2)}(\varphi_j, \varphi_i) \quad C_{ij} \left( u^{n+1,\gamma} \right) = c^{(2)}(u^{n+1,\gamma}, \varphi_j, \varphi_i)
\]

(41)

and \( F_u^{n+1} \) is the vector obtained evaluating \( F_u^{(2)}(\varphi_i)^{n+1}, i = 1 \ldots \dim(V_h) \). Eventually, as algebraic counterpart of \( (32) \) we obtain

\[
\left( \frac{1}{c^2 (1-\gamma)^2 \Delta t^2} M_p + K \right) P^{n+1} = \frac{1}{c^2 (1-\gamma)^2 \Delta t^2} M P^{n+1} + F_p^{n+1},
\]

(42)

where again \( F_p^{n+1} \) is the vector obtained evaluating \( F_p^{(2)}(\varphi_i)^{n+1}, i = 1 \ldots \dim(Q_h) \). Notice that, in the evaluation of \( F_p^{n+\gamma} \) and \( F_p^{n+1} \), there is also a preliminary stage which is the projection of \( \nabla P^n \) and \( \nabla P^{n+\gamma} \) into \( V_h \) to compute \( u^{n+\gamma,*} \) and \( u^{n+1,*} \), respectively. In particular, we define the projection matrix \( P \)

\[
P_{ij} = \sum_{k \in T_h} \int_{\Omega} \nabla \psi_j \cdot \psi_i \, d\Omega
\]

(43)

and we solve the linear systems \( \tilde{M} u^{n+\gamma,*} = P \tilde{P} \) for the first stage and \( \tilde{M} u^{n+1,*} = P \tilde{P} \), where \( \tilde{u}^{n+\gamma,*} \) and \( \tilde{u}^{n+1,*} \) denote the two required projections. The same procedure has to applied also in the final update of the velocity; in particular, for the first stage we set

\[
u^{n+\gamma} = u^{n+\gamma,*} - \gamma \Delta t \left( \tilde{u}^{n+1,*} - \tilde{u}^{n+\gamma,*} \right),
\]

(44)

while for the second stage we solve \( \tilde{M} u^{n+1} = \tilde{P} \tilde{P} \) and then we compute

\[
u^{n+1} = u^{n+1,*} - (1-\gamma) \Delta t \left( \tilde{u}^{n+1} - \tilde{u}^{n+1,*} \right).
\]

(45)

4 | NUMERICAL EXPERIMENTS

The numerical method outlined in the previous Sections has been validated in a number of relevant benchmarks. Notice that, following e.g. \cite{10,29}, we set \( \mathcal{H} = \min \{ \text{diam}(K) | K \in T_h \} \) and we define the stability parameters:

\[
C = k U \Delta t / \mathcal{H}, \quad \mu = k^2 \Delta t / (Re \mathcal{H}^2),
\]

(46)

where \( U \) is the magnitude of a characteristic velocity and \( \mu \) defines the typical stability parameter in the discretization of parabolic terms. We also recall here that \( k \) is the polynomial degree of the finite element space chosen for the discretization of
the velocity. As stated before, the proposed method has been implemented using the numerical library deal.II, which is based on a matrix-free approach\textsuperscript{23}. The 9.2.0 version of deal.II was employed and most simulations have been run in parallel with MPI. No global sparse matrix is built and only the action of the linear operators defined in Section 3 on a vector is actually implemented. Another feature of the library employed during the numerical simulations is the mesh adaptation capability, as we will see in the presentation of the results. In the following tests, unless differently stated, we take $c = 10^3 \, m/s$, which is the order of magnitude of the speed of sound in water. Moreover, the preconditioned conjugate gradient method implemented in the function SolverCG of the deal.II library was employed to solve the Helmholtz equations, while the GMRES solver for the momentum equations is implemented in the function SolverGMRES of the same library. A Jacobi preconditioner is used for the two momentum predictors, whereas a Geometric Multigrid preconditioner is employed for the Helmholtz equations.

### 4.1 Case tests with analytical solution

In order to verify the correctness of our implementation and to assess the convergence property of the scheme, we first perform numerical convergence studies in two and three dimensions, respectively. In two dimensions, we consider as a benchmark the classical Taylor-Green vortex\textsuperscript{43} in the box $\Omega = (0, 2\pi)^2$, for which an analytical solution is available:

\begin{equation}
\begin{aligned}
\mathbf{u}(x, t) &= \left(\cos(x_1) \sin(x_2) e^{-\frac{t}{\text{Re}}} \right. \\
& \quad \left. - \sin(x_1) \cos(x_2) e^{-\frac{2t}{\text{Re}}} \right), \\
p(x, t) &= -\frac{1}{4} \left( \cos(2x_1) + \cos(2x_2) \right) e^{-\frac{t}{\text{Re}}}.
\end{aligned}
\end{equation}

In three dimensions, an analogous study has been carried out for the Arnoldi-Beltrami-Childress (ABC) flow, see e.g.\textsuperscript{49}, whose exact solution is \textcolor{red}{(49)}

\begin{equation}
\begin{aligned}
\mathbf{u}(x, t) &= \left(\sin(x_3) + \cos(x_2) \right) e^{-\frac{t}{\text{Re}}} \\
& \quad \left. \sin(x_1) + \cos(x_3) \right) e^{-\frac{2t}{\text{Re}}} \\
& \quad \left(\sin(x_2) + \cos(x_1) \right) e^{-\frac{2t}{\text{Re}}}.
\end{aligned}
\end{equation}

\begin{equation}
p(x, t) = -\sin(x_1) \cos(x_3) - \sin(x_2) \cos(x_1) - \sin(x_1) \cos(x_2).
\end{equation}

For the two dimensional case, we performed a convergence test at $T = 3.2$ for $\text{Re} = 100$ starting with an initial Cartesian mesh of $8 \times 8$ elements and doubling several times the number of elements $N_{el}$ in each direction. The time step was chosen so as to keep $C = 1.63$ constant for all resolutions (hyperbolic scaling), so as to test the accuracy of the method for values of the time steps beyond the stability limit of explicit schemes but not large enough to affect the second order accuracy. The results for the $Q_2 - Q_1$ and $Q_3 - Q_2$ cases are reported in Tables 1, 2 and 3, 4, respectively. It can be observed that the expected convergence rates are recovered without the necessity of employing fixed point iterations to determine the velocity in the two stages. Analogous results are obtained, see Table 5, 6 if distorted meshes with analogous characteristics are employed.

The same test was repeated, for the case of $Q_2 - Q_1$ elements, using the alternative method\textsuperscript{43,44} summarized in Section 2. It can be observed from the results reported in Tables 1, 2, 7, 8, 9, 10 that, while the convergence rates are analogous, the relative errors in the $L^2$ norm are about 50% smaller for the TR-BDF2 solver.

As mentioned in Section 2 when we increase the Courant number, also the TR-BDF2 scheme requires fixed point iterations in the momentum predictor stages in order to preserve its accuracy. As it can be noticed in Tables 11, 12 that the second order convergence rate is still maintained.

For the three dimensional case, an analogous convergence test was performed again at $T = 3.2$ but using $\text{Re} = 1$, due to the stability characteristics of the ABC flow, see e.g. the discussion in\textsuperscript{49}. We have considered an initial Cartesian mesh of $8 \times 8 \times 8$ elements and we have refined the mesh by doubling each time the number of elements $N_{el}$ in each direction, while keeping $C = 1.63$ constant (hyperbolic scaling). The results for the $Q_2 - Q_1$ and $Q_3 - Q_2$ cases are reported in Tables 13, 14 and 15, 16 respectively. It can be observed that the expected convergence rates are recovered for the lower degree case, also in this case without the necessity of fixed point iterations, while less accurate results are obtained in the higher degree case. Since in this case the problem is diffusion dominated, rather than advection dominated, the loss of accuracy can be readily explained by the very large values obtained in this test for the parabolic stability parameter $\mu$. Repeating the test at constant $\mu$ (parabolic
scaling), one obtains the results displayed in Tables [17, 18] and [19, 20] which show a clear improvement both in errors and convergence rates.

We have also used the two dimensional Taylor Green benchmark at \( Re = 100 \) to compare our results with analogous simulations carried out using the classical PISO method as implemented in the OpenFoam package. In both cases, the computation was carried out at a very small value of the Courant number, so that the spatial discretization error is dominant. We are aware of the difficulties of comparing different discretizations schemes both in space and time implemented in different frameworks and, therefore, the following analysis has to be interpreted merely as first stress test to highlight the superior flexibility of the proposed DG implementation. We have performed a test using both \( Q_2 - Q_1 \) and \( Q_3 - Q_2 \) elements on regular and distorted meshes. An example of the coarsest distorted mesh is shown in Figure 1, while the results of the convergence test for both \( L^2 \) and \( L^\infty \) norms are reported in Figure 2. While the OpenFoam discretization appears to outperform the \( Q_2 - Q_1 \) DG approximation at lower resolutions, it can be seen that it is much more sensitive to the mesh distortion than DG approximations, especially with respect to \( L^\infty \) errors. Furthermore, as expected from polynomial approximation theory, the \( Q_1 - Q_2 \) DG approximation clearly shows its faster convergence properties, which are achieved within the same mathematical and implementation framework. Instead, higher order accuracy for finite volume formulations entails the use of complex and often ad hoc reconstruction procedures with large stencils.

**FIGURE 1** Example of distorted mesh.
FIGURE 2 Taylor-Green vortex at Re = 100 and t = 3.2, absolute errors as function of the number of degrees of freedom, a) $L^2$ errors for the velocity, b) $L^2$ errors for the pressure, c) $L^\infty$ errors for the velocity, d) $L^\infty$ errors for the pressure. The black line denotes the solution with $Q_2 - Q_1$ on regular grids, the blue line represents the results with $Q_2 - Q_1$ on distort grids, the red line reports the results with $Q_3 - Q_2$ on regular grids, the green line denotes the solution with $Q_3 - Q_2$ on distort grids, the yellow line represents the results with OpenFoam on regular grids and the magenta line represents the results with OpenFoam on distort grids.

4.2 Two-dimensional lid driven cavity

The lid driven cavity flow is a classical benchmark for the two-dimensional incompressible Navier-Stokes equations. Reference solutions obtained with high order techniques are reported, among many others, in [51,52,53]. For this two-dimensional problem, it is customary to represent the flow also in terms of the streamfunction $\Psi$, which is defined as the solution of the Laplace problem

$$-\Delta \Psi = \nabla \times \mathbf{u} = \omega \quad \text{in } \Omega$$

$$\Psi|_{\partial \Omega} = 0$$

(51)

where the symbol $\nabla \times$ denotes the curl operator and the vorticity is the scalar field defined as

$$\omega = \frac{\partial v}{\partial x_1} - \frac{\partial u}{\partial x_2}.$$

We consider the case Re = 1000 computed with $Q_2 - Q_1$ elements on a Cartesian mesh composed of $N_e = 128$ square elements in each coordinate direction, with a time step chosen so that the Courant number is approximately 1.3. The computation is performed until the steady state is reached up to a tolerance of $10^{-7}$, which occurs around $T = 70$. The streamfunction contours at steady state are shown in Figure 3 using the same isoline values as in [53]. It can be observed that all the main flow structures are correctly reproduced.
For a more quantitative comparison, we report in Figure 4 the $u$ component of the velocity and the vorticity $\omega$ along the middle of the cavity, together with the reference results of [52]. Good agreement with the reference solution is achieved. The maximum horizontal velocity along the centerline was computed as $u_{\text{max}} = 0.3732$ which implies a relative error with respect to the reference solution of the order of $10^{-2}$. The vorticity value at the center of the cavity was computed as $\omega_{\text{cen}} = 1.9594$, which implies again a relative error with respect to the reference solution of the order of $10^{-2}$. For comparison, the same test was repeated also using for the time discretization the parent methods described in [33][34]. The results are plotted in Figure 5, highlighting the better performance of the proposed method based on TR-BDF2.

FIGURE 3 Lid driven cavity benchmark at $Re = 1000$: a) flow field, b) streamfunction contours. Contour values are chosen as in [53].
FIGURE 5 Lid driven cavity benchmark at $Re = 1000$: a) $u$ velocity component values along the middle of the cavity, b) $\omega$ values along the middle of the cavity. The continuous lines denote the numerical solutions with the methods $^{43,44}$ and with the present method, the circles the reference solution values from $^{52}$, c) absolute error on $u$ velocity component with respect to reference solution of $^{52}$ interpolated along the middle of the cavity. The continuous black line denotes the result with the proposed method, the red one the results of $^{44}$ and the blue dots the results of $^{43}$.

Moreover, we have compared the computational time required by the three methods for $H = \frac{1}{32}, \frac{1}{64}, \frac{1}{128}$, keeping the Courant number fixed. This assessment is important to show potential drawbacks of the two stage of the TR-BDF2 method with respect to the single stage methods employed in $^{43,44}$. As shown in Figure 6, the TR-BDF2 method shows superior efficiency with respect to the Bell-Colella-Glaz method, while it behaves similarly to the BDF2 method of $^{42}$. Multistep methods, however, entail a memory overhead that is not appealing for large scale applications.
We have also repeated this test using the adaptive tools present in the *deal.II* library, as mentioned at the beginning of the Section. In each element $K$ we define the quantity

$$\eta_K = \text{diam}(K)^2 \|\omega\|^2_K$$  \hspace{1cm} (52)

that acts as local refinement indicator. We then started from a uniform Cartesian mesh with $N_e = 8$ in each coordinate direction and we allowed refinement or coarsening based on the distribution of the values of $\eta_K$, refining 10% of the elements with largest indicator values and coarsening 30% of the elements with the smallest indicator values. This remeshing procedure was carried out every 1000 time steps. However, in order to avoid using a too coarse mesh for too long in the initial stages of the simulation, every 50 time steps the maximum difference between the velocities at two consecutive time steps was checked and the remeshing was performed whenever this quantity was greater than $10^{-2}$. The minimum element diameter allowed was $H = \frac{1}{128}$, so as to obtain again $C \approx 1.3$. A maximum element diameter equal to $\frac{1}{32}$ was also required, in order to avoid an excessive reduction of the spatial resolution. The final adapted mesh and the streamline contours are reported in Figure 7. It can be observed that the refinement indicator allows to enhance automatically the resolution along the top boundary of the domain and in other regions of large vorticity values.
FIGURE 7 Lid driven cavity benchmark at $Re = 1000$, adaptive simulation: a) final mesh after adaptive refinement, b) streamfunction contours. Contour values as in [53].

For a more quantitative point of view, we compare again in Figure 8 the $u$ component of the velocity and the vorticity $\omega$ along the middle of the cavity with the reference results in [52]. The maximum horizontal velocity along the centerline is now $u_{\text{max}} = 0.3739$ which implies a relative error of the order of $10^{-2}$, as in the corresponding non adaptive simulation. The vorticity value at the center of the cavity is now $\omega_{\text{cen}} = 1.9652$, which also implies a relative error with respect to the reference solution of the order of $10^{-2}$. In Figure 9, instead, the absolute difference between the velocities computed in the fixed mesh and adaptive simulations is plotted over the whole domain, showing that no substantial loss of accuracy has occurred. This result has been obtained with a reduction of about 25% of the required computational time. While showing the potential of the adaptivity procedures available in the present implementation, this is still far from optimal. Experiments with more specific error indicators and less restrictive options for the refinement parameters will be carried out in future work.

FIGURE 8 Lid driven cavity benchmark at $Re = 1000$, adaptive simulation: a) $u$ velocity component values along the middle of the cavity, b) $\omega$ values along the middle of the cavity. The continuous line denotes the numerical solution and the dots the reference solution values from [52].

4.3 Three-dimensional lid driven cavity

We now consider the three-dimensional analog of the previously studied lid driven cavity benchmark. Among several others, we consider the configuration and reference solutions provided in [54], which we summarize here for convenience. We consider
a rectangular cavity of the size $d \times h \times l$ in the $x$, $y$ and $z$ direction, respectively. The flow is driven by the wall at $x = d/2$, which moves tangentially in the $y$ direction with constant velocity $V$. The length $d$ is used to introduce non dimensional space variables, so that the effective computational domain is given by

$$
\Omega = \left[ -\frac{\Gamma}{2}, \frac{\Gamma}{2} \right] \times \left[ -\frac{1}{2}, \frac{1}{2} \right] \times \left[ -\frac{\Lambda}{2}, \frac{\Lambda}{2} \right],
$$

where the aspect ratios in the $x$ and $z$ directions are defined as

$$
\Gamma = \frac{h}{d}, \quad \Lambda = \frac{l}{d}. 
$$

We have considered here the $\Gamma = 1, \Lambda = 1$ case, computed with $Q_2 - Q_1$ elements on a Cartesian mesh composed of $64 \times 64 \times 48$ square elements, with a time step chosen so that the Courant number is approximately 1. Notice that the same mesh was employed in\cite{53}, which however employed a much more accurate spectral collocation method. The computation is performed until the steady state is reached up to a tolerance of $10^{-4}$, which is achieved around $T = 40$. We take as reference results those presented in Tables 5 and 6 in\cite{53}. Notice that, in that paper, a different non dimensional scaling is employed, so that their results have been appropriately rescaled in order to compare them with those obtained here. In Figure 10 we report the results for the $v$ velocity component values along the $x$ axis and the $u$ component of the velocity along the $y$ axis, respectively. We see that, in spite of the relatively coarse mesh, a reasonable accuracy is achieved.
FIGURE 10 3D lid driven cavity benchmark at $Re = 1000$, fixed mesh simulation, a) $v$ velocity component values along the $x$ axis b) $u$ velocity component values along the $y$ axis. The continuous line denotes the numerical solution and the dots the reference solution values from [54].

In Figure 11 and 12 we show instead the velocity field on the three median plane sections of the cavity, highlighting the presence of vortices near the centerline of the cavity. The results are in good qualitative agreement with those reported in [55].

FIGURE 11 3D lid driven cavity benchmark at $Re = 1000$, a) Flow field vectors for the plane $x = 0$, b) Flow field vectors for the plane $y = 0$, c) Flow field vectors for the plane $z = 0$.

FIGURE 12 3D lid driven cavity benchmark at $Re = 1000$, a) Vorticity ($\omega_x$) contours at $x = 0$, b) Vorticity ($\omega_y$) contours at $y = 0$, Vorticity ($\omega_z$) contours at $z = 0$. 
We have also exploited again the mesh adaptivity tool provided by *deal.II* with the same refinement indicator introduced for the two-dimensional test. In particular, we started from a coarse mesh with $N_e = 6$ elements along each direction and again we performed the refinement procedure on at most 10% of the elements with the largest indicator value every 1000 time steps, while coarsening on at most 30% of the elements with the smallest indicator values; moreover we have checked every 50 time steps if the refinement procedure had to be performed in advance in case the maximum difference between the velocities at two consecutive time steps was greater than $10^{-2}$. The minimum element diameter allowed was $H = \frac{1}{4\delta}$ in order to obtain $C \approx 1$. In Figure 13 and in Figure 14 we report again the results for the $v$ velocity component values along the $x$ axis and the $u$ component of the velocity along the $y$ axis, respectively, compared with the results obtained using a fixed grid with $N_e = 48$ elements along each direction. One can notice very good agreement between the two simulations, while the computational time required to perform the adaptive simulation is about half of that required by the fixed grid simulation. Moreover, we have compared in Figure 15 the errors of the two components for the velocity for the fixed and adaptive mesh, respectively. It is clear that, in spite of the different computational time, no significant differences arise.

**FIGURE 13** 3D lid driven cavity benchmark at $Re = 1000$, a) $u$ velocity component values along the $y$ axis for adaptive mesh simulation, b) $u$ velocity component values along the $y$ axis for fixed grid simulation. The continuous line denotes the numerical solution and the dots the reference solution values from [54].

**FIGURE 14** 3D lid driven cavity benchmark at $Re = 1000$, a) $v$ velocity component values along the $x$ axis for adaptive mesh simulation, b) $v$ velocity component values along the $x$ axis for fixed grid simulation. The continuous line denotes the numerical solution and the dots the reference solution values from [54].
FIGURE 15 3D lid driven cavity benchmark at $Re = 1000$, a) $u$ velocity component component for the plane $x = 0, z = 0$ with reference solution values from interpolated, b) $v$ velocity component comparison for the plane $y = 0, z = 0$ with reference solution values from interpolated. The continuous black line denotes the result with fixed mesh, the blue one denotes the results with adaptive mesh refinement.

The size of the configuration employed for this test (we have used 15925248 dofs for the velocity and 1572864 dofs for the pressure) makes this benchmark a good candidate for a parallel scaling test. More specifically, we have performed a strong scaling analysis executing the same simulation up to time $t = 0.6$ using from 16 up to 1024 2xCPU x86 Intel Xeon Platinum 8276-8276L @ 2.4Ghz cores of the HPC infrastructure GALILEO100 at the Italian supercomputing center CINECA. The results, reported in Figure 16, show a very good linear scaling, and even superlinear due to cache effects, up to 256 cores, while for a higher number of cores parallel performance is less optimal. A degradation of the performance for higher numbers of cores is observed, which we believe is mainly due to the fact that, given the size of the problem we were able to run, for these numbers of cores the amount of degrees of freedom owned by each core becomes very small so that the time needed by each core for computation is dominated by the time needed for communication. Indeed, using 1024 cores, the number of unknowns per core is only 15552 for the velocity and 1536 for the pressure. Similar results are obtained for the Bell-Colella-Glaz and the Guermond-Quartapelle BDF2 methods already discussed in the previous Section. The apparent better behaviour of the Bell-Colella-Glaz projection scheme for a larger number of processors is probably due to the fact that this method, in view of the presence of nonlinear iterations, is the slowest one as reported in Table 22 and therefore the least affected by communication costs.

FIGURE 16 3D lid driven cavity benchmark at $Re = 1000$, strong scaling for the proposed method. The speedup is computed with respect to the time required with 16 cores.
A weak scaling analysis has been performed using 124416 dofs per core for the velocity and 12288 dofs per core for the pressure. Figure 17 shows the results for the three schemes described. One can easily notice that a good parallel efficiency is maintained up to 1024 cores. The overperformance of the TR-BDF2 scheme up to 256 cores can be due to a number of factors, such as the topology of the communication network in the specific architecture employed or the handling of communications between different groups of cores. This is also confirmed by the behaviour of the Bell-Colella-Glaz method which, since it requires the solution of more linear systems, is less dependent on these factors.

**FIGURE 17** 3D lid driven cavity benchmark at $Re = 1000$, weak scaling for the proposed method. The efficiency is computed with respect to the time required with 16 cores.

### 4.4 Flow past a cylinder

In this section, we consider another classical benchmark for the incompressible Navier-Stokes equations, namely the flow past a cylinder. We use the configuration described in \[56\], that we summarize here for the reader’s convenience. More in detail, the employed geometry and boundary conditions are reported in Figure [18] where $H = 0.41$ m makes the domain non-symmetric and allows the vortex shedding in the wake of the cylinder. The inflow condition is

$$\mathbf{u}(0, y) = \begin{pmatrix} 4U_m \frac{y(H-y)}{H^2} \\ 0 \end{pmatrix},$$

with $U_m = 1.5$ m s$^{-1}$. As explained in \[56\], we consider as reference quantities the inflow velocity mean value $U = 1.0$ m s$^{-1}$, the diameter of the cylinder equal to $L = 0.1$ m and $\nu = 0.001$ m$^2$ s$^{-1}$, which yields $Re = 100$. 
We compute the drag and lift coefficients, defined as in \(56\). Other reference values are the pressure drop \(\Delta p(t) = p(0.15, 0.2, t) - p(0.25, 0.2, t)\) and the Strouhal number \(St = \frac{Df}{U}\), where \(f\) is the frequency of separation computed as a function of the lift coefficient \(C_L\). The final time is \(T = 400\), which corresponds to a dimensional time of 40 s, since the reference time value is \(\frac{L}{U} = 0.1\) s, and allows to obtain a fully developed wake. The grid is composed by 23552 elements and the time step \(\Delta t = 5 \cdot 10^{-3}\) is such that the maximum Courant number is around 1. Figure 19 shows the contour plot of the velocity magnitude at \(t = T\) and one can easily notice the formation of the vortices in the wake of the cylinder. Figure 20 reports the evolution of the lift and drag coefficients from \(t = 385\) to \(t = T\); it can be observed that the expected periodic behaviour is retrieved. The maximum drag coefficient and the pressure drop are 3.33 and 2.60, respectively, which are slightly larger values than the intervals [3.22, 3.24] and [2.46, 2.50] proposed in \(56\), even though they are in the overall range of the solutions proposed in the literature. The maximum lift coefficient is 1.01, which lies in the interval [0.99, 1.01] present in \(56\), while the Strouhal number is equal to 0.3, which is again in the interval [0.295, 0.305] reported in \(56\).
The same test has been repeated using adaptive mesh refinement with the same criterion described in Section 4.2. The initial mesh is composed by 5558 elements and we allowed up to two local refinements, whereas the maximum element diameter is kept equal to the one of the initial grid. The same remeshing procedure described in 4.2 was applied every 5000 time steps. Figure 21 reports the final mesh obtained and the values of the drag and lift coefficients. One can easily notice that more resolution is added in the wake of the cylinder and on its boundary and that the behaviour of the two coefficients is analogous to that in the uniform mesh case. The final mesh consists of 11630 elements and a reduction of computational time of about 50% is achieved with respect to the uniform mesh case.

4.5 Complex geometry

The matrix-free approach present in the deal.II library makes the proposed solver attractive also for industrial applications that involve a large number of degrees of freedom. For this purpose we have tested the solver on the complex geometry of an heat exchanger of industrial interest. More specifically, a four channels module of a designed checkerboard pattern heat exchanger...
has been considered, with the goal of simulating its pure fluid-dynamic behaviour (i.e., in absence of heat exchanges) between the inlet and the outlet. The channel is long 0.5 m.

We consider \( Re = 5000 \), assuming unitary inflow velocity considering the channel length as reference length. We set \( c = 300 \, m/s \), which is of the order of magnitude of the speed of sound in air. The mesh consists of 129696 \( Q_2 - Q_1 \) elements, which yields 10505376 degrees of freedom for the discrete velocity variables and 1037568 for the discrete pressure variables. In order to verify the results of the simulation at steady state, various simulations with an OpenFoam steady state solver have been performed. More in detail, three meshes with different resolutions have been used with the OpenFoam solver. The coarsest is the one previously described, an intermediate resolution one consists of 1382120 elements while the finest is composed by 2108119 elements. A comparison between the results obtained on each mesh is reported in Figure 23 for the midlines of the four channels depicted in Figure 22. For the sake of simplicity, the channels are denote by \( A, B, C \) and \( D \) from bottom to top, respectively.
FIGURE 23 Comparison between deal.II and OpenFOAM from line A (top) to line D (bottom) for $u$ component of the velocity, the one along $x$-axis (left), $v$ component of the velocity, the one along $y$-axis (center) and $w$ component of the velocity, the one along $z$-axis (right).

It can be observed that a good quantitative agreement between the two solvers has been obtained, taking into account the different features. Moreover, the solution computed with the DG approach is more similar to the results obtained with the OpenFoam solver on the finest meshes, as evident especially for the axial component $w$. This is further confirmed by the pressure drop computed for the four lines and reported in Table 21. Analogous considerations hold for the sections reported in Figure 22 where we have compared the contour of the velocity magnitude on the middle of the domain, at three-quarters of the domain and on the outlet in Figure 24, Figure 25 and Figure 26 respectively.

5 CONCLUSIONS AND FUTURE PERSPECTIVES

Building on the experience of we have proposed an accurate, efficient and robust projection method, based on the TR-BDF2 method. While time discretizations of the incompressible Navier-Stokes equations based on accurate implicit solvers have been proposed in many other papers, the specific combination of techniques presented in this work appears to be optimal under several viewpoints for the development of a second order adaptive flow solver.

The proposed fully implicit method has been implemented using discontinuous finite elements in the framework of the numerical library deal.II, with the aim of building a reliable, flexible and easily accessible tool for industrial applications that can ultimately be competitive with more conventional finite volume techniques. We have shown that the method has superior accuracy and efficiency with respect to some well known alternative schemes on a number of classical benchmarks.

In future work, besides application of the proposed approach to significant industrial applications and extensions to fully compressible and multiphase flow, an interesting development will be represented by the integration of more sophisticated a posteriori error estimation techniques to obtain optimal adaptive approaches. Furthermore, the multirate time integration version of the TR-BDF2 method could also be integrated in the discretization approach, so as to obtain a fully space-time adaptive technique based on a robust and unconditionally stable method.

ACKNOWLEDGEMENTS

We would like to thank the two anonymous reviewers for their useful and productive comments, which helped us improving the initial version of this paper. L.B. would also like to thank Roberto Ferretti, Elisabetta Carlini and Macarena Gómez Mármol for several useful discussions on numerical methods for incompressible flows. The parallel computations for the scaling test were performed at CINECA thanks to the computational resources made available through the SIDICoNS - HP10CLPLXI ISCRA C project.
