ABSTRACT

We study the entanglement entropy of gauged internal degrees of freedom in a two dimensional symmetric product orbifold CFT, whose configurations consist of \( N \) strands sewn together into “long” strings, with wavefunctions symmetrized under permutations. In earlier work a related notion of “entwinement” was introduced. Here we treat this system analogously to a system of \( N \) identical particles. From an algebraic point of view, we point out that the reduced density matrix on \( k \) out of \( N \) particles is not associated with a subalgebra of operators, but rather with a linear subspace, which we explain is sufficient. In the orbifold CFT, we compute the entropy of a single strand in states holographically dual in the D1/D5 system to a conical defect geometry or a massless BTZ black hole and find a result identical to entwinement. We also calculate the entropy of two strands in the state that represents the conical defect; the result differs from entwinement. In this case, matching entwinement would require finding a gauge-invariant way to impose continuity across strands.
1 Introduction

Over the past ten years, entanglement entropy has turned out to be a crucial quantity to organize our way of thinking about quantum field theory. It characterizes the amount of information an observer with access to a subsystem of the degrees of freedom can learn about the complementary subsystem. As such it is a measure of correlations in field theory. For example, an observer who only has access to a spatial region $A$, can infer from the entropy how much he or she can learn about the complementary region $\bar{A}$. Because of its extensive nature, one typically expects the entanglement entropy to scale with the volume of the subsystem. However it turns out that the entanglement entropy in the ground state of local Hamiltonians scales with the area of the subsystem, either strictly or in a logarithmically violated way [1–5]. Area law scaling of entropy has first been identified in the context of black hole physics [6, 7] and has later been made more precise in the context of holography [8, 9]. The vast majority of literature on entanglement entropy in holography and in field theory focuses on entanglement of a spatial subregion $A$. However, its definition as von Neumann entropy of a reduced density matrix only relies on a bipartite splitting of the Hilbert space. In field theories with multiple degrees of freedom, one is not forced to consider a splitting in terms of spatial subregions but one can consider more general splittings such as a bipartition in momentum space [10, 11] or in terms of the internal degrees of freedom. Especially in holographic field theories it is interesting to study the entanglement between internal degrees of freedom, because investigating their correlations and entanglement might be important for understanding the physics of the dual bulk theory at
scales smaller than the AdS radius [12, 13]. For example, in the BFSS matrix model, the holographic spacetime can be described as a bound state of $N$ D0 branes. It is natural to investigate the entanglement between the D0 branes to understand better the emergence of the holographic spacetime [14–16]. As another example, consider the D1-D5 brane system of $N_1$ D1 branes and $N_5$ D5 branes on $M^{4,1} \times S^1 \times T^4$. At low enough energies, this system is described by gravity on $\text{AdS}_3 \times S^3 \times T^4$, and has a dual description as a marginal deformation of the symmetric product orbifold $(T^4)^{N_1 N_5}/S_{N_1 N_5}$. Because of the duality, we expect the entanglement entropy of a subset of degrees of freedom of the orbifold theory to have a representation in the dual gravity theory. Motivated by this, a field theoretic quantity called ‘entwinement’ [17,18] has been defined, which is holographically represented by the lengths of non-minimal geodesics in 2+1 dimensional asymptotically AdS spacetimes. Similar questions about the entanglement between internal degrees of freedom could be posed in matrix string theory [19].

Most of the known field theories with holographic duals have internal gauge symmetries. This complicates the study of entanglement entropy. Even the study of ordinary spatial entanglement entropy is involved in the presence of gauge symmetry because of the non-factorization of the Hilbert space due to non-local gauge invariant degrees of freedom such as Wilson loops that cross the entangling surface [20–26]. The gauge symmetry further complicates the computation of entanglement entropy of a subset of internal degrees of freedom, because typically these dynamical variables are not gauge invariant. In a symmetric product orbifold of $N$ free bosons for example, the bosons transform under the permutation group $S_N$, so one needs a way to appropriately specify a subset of the $N$ bosons to compute a gauge invariant reduced density matrix. A prototypical example where this issue has been considered is the quantum mechanics of identical particles [27–30].

Say that one has a system of $N$ identical particles, labelled by position operators $x_1, \ldots, x_N$. The permutation invariance puts a constraint on states of the physical Hilbert space and as such we could view the $S_N$ group as a gauge symmetry. A system of identical particles contains analogous features to gauge theories. For example, we will argue that the non-factorization of the Hilbert space that is apparent when studying spatial entanglement entropy in gauge theories, is analogous to what happens for entanglement entropy of modes of the identical particles. Also, entanglement between gauged degrees of freedom is similar to entanglement between identical particles. One can study for example the one particle reduced density matrix, also called one body density functional, by simply integrating out $x_2, \ldots, x_N$ in the full density matrix. The one particle reduced density matrix will be permutation invariant because the wavefunction is, even if the measure on $x_2, \ldots, x_N$ is not permutation invariant. As we will explain in this paper, the reduced density matrix obtained in this way does not have support on a subalgebra of operators, but rather on a linear subspace. \(^1\)

\(^1\)In [31] a definition of entwinement in terms of the entropy associated to state-dependent subalgebras was proposed. Here we point out that we do not need to find a closure under multiplication, i.e. an algebra, in order to talk about entropy. It suffices to discuss a linear subspace of operators that closes under the adjoint operation.
In this paper, we will consider a natural extension of this construction for identical particles to the symmetric product orbifold CFT. Namely, the orbifold CFT describes identical strands (i.e., elementary pieces of string) in a collection of multiwound strings. We will study the resulting density matrices and corresponding entanglement entropies in a set of states that are interesting from the point of view of holography and represent ground states of specific twisted sectors. More specifically, we focus our attention on twisted sectors that are holographically modeled by conical defects and massless BTZ black holes in the D1-D5 system. We will explicitly compute the single strand entropy in these states as well as the entropy of two strands in the state that represents the conical defect. As we will argue, the entropy of a single strand is proportional to the length of a (not necessarily minimal) geodesic in the dual geometry and equals the entwinement studied in [17, 18]. However, the entropy of two or more strands does not agree with entwinement. This is because entwinement seems to be related to entanglement entropy of multiple continuously connected strands, rather than just entanglement entropy of multiple strands. We will comment more on this point in sec. 4.

The plan of the paper is as follows. In sec. 2 we review the definition and construction of entanglement entropy in a system of identical particles. We first discuss the entanglement between modes in sec. 2.1 and then review the entanglement entropy between identical particles in sec. 2.2. We end this section with a remark on the algebraic definition of the entropy in section 2.3 and point out that this entropy is associated to a linear subspace of operators rather than a subalgebra. In sec. 3 we present the computation of entanglement entropy of strands in symmetric product orbifolds. After a short review on symmetric product orbifolds in sec. 3.1, we show how to compute entanglement entropy of multiple strands generically in sec. 3.2. In sec. 3.3 we compute the entropy of a single strand in the conical defect state and the massless BTZ black hole state. The entropy of multiple strands in the conical defect state is presented in sec. 3.4. We conclude with a summary and with some comments on the entanglement entropy of continuously connected strands in sec. 4.

2 Entanglement entropy in a system of identical particles

2.1 Entanglement between modes of identical particles

While the main subject of this work is not entanglement between spatially organized degrees of freedom in a gauge theory, it is useful to explicitly point out how some of the usual difficulties in this field have simple analogues in a system of identical particles. The problem in gauge theories essentially arises because they obey non-local constraints, like Gauss’s law. This introduces ambiguities in defining a spatial subsystem, because the total Hilbert space does not factorize, i.e. \( \mathcal{H} \neq \mathcal{H}_A \otimes \mathcal{H}_{\bar{A}} \) for a subregion \( A \). To understand this, recall that a typical algebra \( \mathcal{A}_A \) of operators associated to region \( A \) will have a nontrivial center \( \mathcal{Z} \) because of the constraints on the Hilbert space (see e.g. [22, 25, 32]). For example, by Gauss’s law, in a \( U(1) \) theory without matter the electric flux operator at a location just inside boundary of a subregion must equal the flux just outside, but the latter must
commute with all operators inside the region. Because the elements of the center commute, we can pick a basis on the total Hilbert space in which all operators in $\mathcal{Z}$ are diagonal. In this basis, the elements of $\mathcal{A}_A$ and $\bar{\mathcal{A}}_A$ which also commute with $\mathcal{Z}$ are block diagonal. This implies that, instead of factorizing completely, the total Hilbert space now only factorizes on these blocks, i.e. one has

$$\mathcal{H} = \bigoplus_\alpha \mathcal{H}_A^\alpha \otimes \mathcal{H}_{\bar{A}}^\alpha,$$

where $\alpha$ labels the invariant subspaces of $\mathcal{A}_A$. (See [22]; the proof that this is true in finite dimensions is given in, e.g., [32].) The physical interpretation of $\alpha$ is roughly the value of the electric flux going through the interface between $\mathcal{A}$ and $\bar{\mathcal{A}}$, which is forced to be the same on the two subalgebras because of Gauss’s law. Entanglement can be discussed in this algebraic setup [22,25,32], and, in particular, reduced density matrices can be uniquely defined, as we will review in sec. 2.3.

The purpose of the present subsection is to point out that a system of $N$ identical particles also realizes this structure in a simple way. The point is that one can think about the permutation symmetry as being gauged and introducing constraints between particles inside and outside a subregion. To see this explicitly, let us consider the Hilbert space $\mathcal{H}_N$ for $N$ identical particles, which is the symmetric tensor power $\vee^N \mathcal{H}_1$ for bosons and the antisymmetric tensor power $\wedge^N \mathcal{H}_1$ for fermions, with $\mathcal{H}_1$ being a single particle Hilbert space. The algebra of observables acting on the $N$ particle Hilbert space is

$$\mathcal{A}_N = \text{span}\{a^\dagger_{i_1}...a^\dagger_{i_k} a_{j_1}...a_{j_k} | k = 0, 1, ...\},$$

where $a_i$ are annihilation operators satisfying the canonical commutation relations for bosons and the canonical anticommutation relations for fermions. The index $i$ runs through a basis of the single particle Hilbert space $\mathcal{H}_1$. $\mathcal{A}_N$ is the von Neumann algebra of the operators on Fock space that commute with the total particle number $N = \sum_i a^\dagger_i a_i$.

Now suppose we split the single particle modes in sets $\mathcal{A}$ and $\bar{\mathcal{A}}$, corresponding to splitting the one particle Hilbert space as

$$\mathcal{H}_1 = \mathcal{H}_1^\mathcal{A} \oplus \mathcal{H}_1^{\bar{\mathcal{A}}}.$$  

Denoting with $\alpha, \beta, ...$ the labels running through a basis of $\mathcal{H}_1^\mathcal{A}$ and with $\bar{\alpha}, \bar{\beta}, ...$ the labels running through a basis of $\mathcal{H}_1^{\bar{\mathcal{A}}}$, the algebra of operators associated to $\mathcal{A}$ is

$$\mathcal{A}_N^\mathcal{A} = \text{span}\{a^\dagger_{\alpha_1}...a^\dagger_{\alpha_k} a_{\beta_1}...a_{\beta_k} | k = 0, 1, ...\} \subset \mathcal{A}.$$ 

The analogously defined algebra associated to the complement $\mathcal{A}_N^{\bar{\mathcal{A}}}$ is in the commutant of this algebra within $\mathcal{A}_N$. Now $\mathcal{A}_N^{\bar{\mathcal{A}}}$ has a nontrivial center, which is the number of particles in $\mathcal{A}$: $N_A = \sum_\alpha a^\dagger_{\alpha} a_{\alpha}$. This plays the role analogous to the flux between the two subsystems in a gauge theory. Correspondingly, the Hilbert space does not factorize, instead we have the superselection sectors\(^2\)

$$\mathcal{H}_N = \bigoplus_{k=0}^{N} \left( \mathcal{H}_k^\mathcal{A} \otimes \mathcal{H}_{N-k}^{\bar{\mathcal{A}}} \right).$$

\(^2\)For fermions with a finite number of modes, the dimensions work out due to the Chu-Vandermonde identity for binomial coefficients.
which follows the structure (2.1).

We note in passing that in the case of identical particles, the above structure disappears if we allow for particle number changing operators, i.e., we consider the entanglement in the complete Fock space

\[ \mathcal{F} = \bigoplus_N \mathcal{H}_N. \]  

(2.6)

In this case, the full algebra of observables and the subalgebra acting on \( \mathcal{H}^A \) are both larger since they include operators that change particle number. They correspond to all polynomials that can be written down\(^3\) with \( a_i (a_\alpha) \) and \( a_i^\dagger (a_\alpha^\dagger) \). In this case the subalgebra has a trivial center, and we have the isomorphism\(^4\)

\[ \mathcal{A} \cong \mathcal{A}_A \times \mathcal{A}_{\bar{\alpha}}. \]  

(2.7)

Acting with operators satisfying the above relation on the Fock vacuum produces a Fock space that factorizes. Another way to see this, is to label the basis of the Fock space with occupation numbers \( n_i \) of different modes. In this case it is clear that \( |\{n_\alpha\}\rangle \otimes |\{n_\alpha\}\rangle = |\{n_i\}\rangle \) (up to a sign for fermions).

### 2.2 Entanglement between identical particles

There is another notion of entanglement between identical particles, different from the one presented in the previous section, which is akin to what we ultimately want to study in gauge theories. The question we want to ask is how say \( k \) particles are entangled with the remaining \( N - k \) particles, without specifying which particles we are talking about, and without any restriction on the modes they can occupy [27–30]. Let’s say we have a position space wavefunction

\[ \psi(x_1, \ldots, x_N), \]  

(2.8)

satisfying \( \psi(x_1, \ldots, x_N) = (\pm 1)^{\pi(\theta)} \psi(x_{\theta(1)}, \ldots, x_{\theta(N)}) \) for all permutations \( \theta \in S_N \). Here \( \pi \) is the parity of the permutation and bosons correspond to the upper sign, while fermions for the lower one. In quantum chemistry, the \( k \)-body density functional is defined as

\[ \rho^{(k)}(x_1, \ldots, x_k; x'_1, \ldots, x'_k) = \int dx_{k+1} \ldots dx_N \psi(x_1, \ldots, x_k, x_{k+1}, \ldots, x_N) \psi^\ast(x'_1, \ldots, x'_k, x_{k+1}, \ldots, x_N), \]  

(2.9)

i.e., it is a formal partial trace over \( N - k \) of the coordinates. More abstractly, for an \( N \) particle state\(^5\)

\[ |\Psi\rangle = \sum_{i_1, \ldots, i_N} \Psi_{i_1 \ldots i_N} a_{i_1}^\dagger \ldots a_{i_N}^\dagger |0\rangle, \]  

(2.10)

the \( k \)-particle reduced density matrix is

\[ \rho^{(k)}_{i_1 \ldots i_k} j_1 \ldots j_k \sim \Psi_{i_1 \ldots i_k i_{k+1} \ldots i_N} (\Psi^\ast)_{j_1 \ldots j_k i_{k+1} \ldots i_N}, \]  

(2.11)

---

\(^3\)For fermions, this is just the Clifford algebra over the vector space \( \mathcal{H} \oplus \mathcal{H}^\ast \).

\(^4\)For fermions, this is actually a graded product.

\(^5\)We omit here the normalization because it is different for fermions and bosons.
where we have traced over $i_{k+1}\cdots i_N$ and omitted combinatorial factors. These are valid density matrices on the $k$-particle Hilbert space $\mathcal{H}_k$. They are positive semidefinite, Hermitian, and have finite trace that can be normalized to one. Therefore, it is meaningful to talk about von Neumann entropy for them. Note that for example for the one particle reduced density matrix for fermions this entropy is bounded from below by the log of the number of particles, instead of zero. This minimal value is obtained if and only if the $N$ particle state is a single Slater determinant, i.e., it is of the form

$$v_{i_1}^{i_1}\cdots v_{i_N}^{i_N}a_{i_1}^\dagger\cdots a_{i_N}^\dagger|0\rangle$$  \hspace{1cm} (2.12)

with $v_{i_a}^{i_a}$ arbitrary vectors in the single particle Hilbert space for $a = 1, \ldots, N$. Therefore this minimal entropy corresponds to undistillable statistical correlations. Nevertheless, one can produce states that cannot be written in this form and these contain genuine entanglement, which can be equally diverse as in the case of distinguishable constituents [30,33–37].

2.3 Subalgebras versus subspaces

Because the Hilbert space of identical particles does not factorize, it is not immediately clear how to interpret (2.11) as a partial trace. In gauge theories the analogous difficulty can be evaded by resorting to the algebraic definition of a reduced matrix matrix. Given a state $|\psi\rangle \in \mathcal{H}$ and a von Neumann subalgebra $\mathcal{A}_s$ acting on $\mathcal{H}$, we can define a unique density operator $\rho_{\mathcal{A}_s} \in \mathcal{A}_s$ by requiring that

$$\text{Tr}(O \rho_{\mathcal{A}_s}) = \langle \Psi | O | \Psi \rangle, \hspace{1cm} \forall O \in \mathcal{A}_s.$$  \hspace{1cm} (2.13)

This is one way in which reduced density matrices are defined in a gauge theory [22], and also essentially how they are defined in the setup of mode entanglement in identical particle systems [38–40], using subalgebras such as (2.4). For the definition (2.13) to be well-posed, $\mathcal{A}_s$ need not actually close into a subalgebra. Uniqueness of this definition requires only that $\mathcal{A}_s$ is a linear subspace of an algebra acting on $\mathcal{H}$ and that it is closed under the adjoint operation. Then, $\rho_{\mathcal{A}_s}$ is just a projection of $|\Psi\rangle\langle\Psi|$ to $\mathcal{A}_s$.

Let us spell this out in more detail. The statement that $\mathcal{A}_s$ is a linear space implies that it has a basis $\{O_i\} \subset \mathcal{A}_s$ in which every element of $\mathcal{A}_s$ can be expanded. Let us denote with $\{O^i\}$ the dual basis\(^6\) under the trace over $\mathcal{H}$, i.e.

$$\text{Tr}((O^i)^\dagger O_j) = \delta^i_j.$$  \hspace{1cm} (2.14)

Using this, the requirement (2.13) has a unique solution

$$\rho_{\mathcal{A}_s} = \langle \Psi | O_j | \Psi \rangle (O^j)^\dagger,$$  \hspace{1cm} (2.15)

\(^6\)In finite dimensions one can find the trace dual basis by inverting the matrix $\text{Tr}(O_i^\dagger O_j)$. Suppose we have the inverse $g^{ij}$ of the matrix $\text{Tr}(O_i^\dagger O_j)$. Define the operator $(O^i)^\dagger = g^{ik}O_k^\dagger$. Then by construction $\text{Tr}[(O^i)^\dagger O_j] = \delta^i_j$. For $g^{ij}$ to exist $\text{Tr}(O_i^\dagger O_j)$ must be nondegenerate, which is always true. To see this, suppose that it is degenerate, i.e. there is a $v^j$ such that $\text{Tr}(O_i^\dagger O_j)v^j = 0$ for all $i$. This, in turn, implies that $\text{Tr}[(O_i v^i)^\dagger (O_j v^j)] = 0$ and therefore $O_j v^j = 0$. Since $O_j$ is a basis, we must have $v^j = 0$. 

as can be checked by expanding $\rho_{A_s}$ in the $(O^j)^\dagger$ basis and determining the coefficients. This expression gives a Hermitian, but in general not necessarily positive semidefinite density matrix. Whether $\rho_{A_s}$ is positive depends on both the state and the choice of $A_s$ and it can be positive even if $A_s$ is not an algebra.

Now let us return to the density matrix (2.11), which is positive semidefinite. In this case, we have to consider the following linear subspace of operators, closed under the adjoint

$$A_{k\text{-particle}} = \text{span}\{a_i^\dagger a_j \ldots a_k^\dagger a_{j_k} \ldots a_{j_k}\}. \quad (2.16)$$

Now $A_{k\text{-particle}}$ does not close under multiplication, so it defines a subspace of operators rather than a subalgebra. This is clearest if we focus on the space of one-particle operators

$$A_{\text{one particle}} = \text{span}\{a_i^\dagger a_j\}. \quad (2.17)$$

The algebra constructed from this subspace by multiplying its operators would actually generate the entire algebra (2.2) on $\mathcal{H}_N$. Nevertheless, one can check that using the subspace of operators (2.16) in the definition (2.13) results in the density matrix (2.11).

Thus, systems of identical particles provide toy versions of two possible types of entanglement in a gauge theory. Mode entanglement, discussed in sec. 2.1, is analogous to entanglement across spatial regions in a gauge theory. By contrast, entanglement between subsets of identical particles, discussed in sec. 2.2, corresponds to entanglement between internal, gauged, degrees of freedom.

## 3 Entanglement entropy in symmetric product orbifolds

### 3.1 Introduction to symmetric product orbifolds

A symmetric product orbifold CFT is formed by starting from a two dimensional seed conformal field theory with target space $M$. We will collectively denote the fields on $M$ as $X(\sigma, t)$ (a free boson in the simplest example). The orbifold CFT arises by taking $N$ copies of $X$ and demanding that the fields are indistinguishable under permutations. The resulting target space is $M^N/S_N$. The orbifold CFT describes a collection of $N$ indistinguishable free strings. Because of the $S_N$ gauging fields need not have period $2\pi$ but can belong to a twisted sector in which the boundary conditions are

$$X_i(2\pi, t) = X_{h(i)}(0, t), \quad \forall i = 1, \ldots, N \quad (3.1)$$

for an element $h \in S_N$. Twisted sectors are created by the action of a twist operator on the untwisted sector. For example, suppose that the fields with indices 1 to $m$ are sewn together into a long string of winding number $m$ by

$$\sigma_{(1\ldots m)}(t \to -\infty) : \quad X_i(2\pi, t) = X_{(i+1)}(0, t) \quad \forall i = 1, \ldots, m - 1 \quad (3.2)$$

with $X_m(2\pi, t) = X_1(0, t)$. If the twisted sector labeled by $h$ contains $k$ long strings, with winding numbers $m_i$ satisfying $\sum_i m_i = N$, then the corresponding twisted sector vacuum state can be represented by the action of $k$ twist operators

$$|\psi_h\rangle = \sigma_{(1\ldots m_1)}\sigma_{(m_1+1\ldots m_1+m_2)}\cdots\sigma_{(N-m_k+1\ldots N)}|0\rangle. \quad (3.3)$$
All physical states should be $S_N$ invariant so the twisted sector state really corresponds to the conjugacy class $[h]$, such that
\[
| \Psi[h] \rangle = \sum_{g \in S_N} \psi_{ghg^{-1}} ,
\]
\[
= \sum_{g \in S_N} \sigma(g(1), \ldots, g(m_1))\sigma(g(m_1+1), \ldots, g(m_1+m_2)) \ldots \sigma(g(N-m_k+1), \ldots, g(N)) |0\rangle .
\] (3.4)

Strictly speaking, the state should also be appropriately normalized. In the $X_i$ basis, the gauge invariant wavefunction is
\[
\Psi[h] (X_1, \ldots, X_N) = \langle X_1, \ldots, X_N | \Psi[h] \rangle = \sum_{g \in S_N} \psi_{ghg^{-1}} (X_1, \ldots, X_N) ,
\]
\[
= \sum_{g \in S_N} \psi_h (X_{g(1)}, \ldots, X_{g(N)}). 
\] (3.5)

Note that the wavefunctions $\psi_h$ can be decomposed into a product of wavefunctions of single long strings which we could specify by $\psi_{m_j}$ such that
\[
\Psi[h] (X_1, \ldots, X_N) = \sum_{g \in S_N} \psi_{m_1} (X_{g(1)}, \ldots, X_{g(m_1)}) \ldots \psi_{m_k} (X_{g(N-m_k+1)}, \ldots, X_{g(N)}) .
\] (3.7)

In this paper we will focus on two states which are interesting from the point of view of holography. The first state contains $N/m$ strings of length $m$ whose wavefunction is
\[
\Psi_m (X_1, \ldots, X_N) = \sum_{g \in S_N} \prod_{j=1}^{N/m} \psi_m (X_{g(jm+1)}, \ldots, X_{g((j+1)m)}) .
\] (3.8)

In the context of the D1-D5 brane system this wavefunction is holographically dual to a $(\text{AdS}_3 \times S^3) / \mathbb{Z}_m \times T^4$ spacetime [41, 42]. We therefore call this a ‘conical defect state’. A second state of interest contains $N_m$ strings of length $m$ where
\[
N_m = \frac{8}{\sinh \left( m \sqrt{\frac{2\pi}{N}} \right)} .
\] (3.9)

This state is dual in the D1-D5 system to $\text{BTZ}_0 \times S^3 \times T^4$, where $\text{BTZ}_0$ is the massless three dimensional black hole [42, 43].

The wavefunctions described above only have support on continuous configurations. To see this, consider a twisted sector vacuum state. Suppose that a factor of a particular term of the gauge invariant wavefunction has support on a discontinuous configuration of string of length $m$. This factor can be written in terms of the on-shell action for the configuration
\[
\psi_m (X_{g(1)}, \ldots, X_{g(m)}) \equiv \psi_m (X(\sigma)) \sim e^{-S_{\text{on-shell}}[X]} ,
\] (3.10)
because we are discussing a vacuum state constructed from the Euclidean path integral. When the seed CFT is that of a single free boson $X(\sigma)$, the on-shell action can be computed by solving the Laplace equation on a disk with boundary conditions $X(\sigma)$ at Euclidean time $\tau = 0$ and from it computing the Euclidean action. The simplest discontinuous boundary profile is a piecewise constant $X(\sigma) = 0$ when $0 \leq \sigma \leq \alpha$ and $X(\sigma) = X_0 \neq 0$ when $\alpha \leq \sigma \leq 2\pi m$. The Laplace equation is conformally invariant, so the disk with such a boundary condition can be mapped to the infinite strip with $X = 0$ on the lower boundary and $X = X_0$ on the upper boundary. Physically, the problem of determining the Euclidean action of a free field on the infinite strip with two constant boundary conditions is the same as determining the potential energy between two capacitor plates each at constant potential. Clearly the energy between the capacitor plates is infinite. The on-shell action thus diverges and the wavefunction correspondingly vanishes. The same conclusion holds for excited states because adding oscillations to a discontinuous configuration will not remove the divergence of the action.

Similar considerations dictate that the overlap between different twisted sectors is zero [44–46]. We can argue this by observing that the boundary conditions do not match in the overlap of different twisted sectors. Physically speaking, the overlap vanishes because, in a free orbifold of the kind we are considering, the winding strings cannot split and rejoin into a different configuration.

In summary, states of the physical Hilbert space satisfy two important constraints: (1) they are invariant under $S_N$, and (2) their wavefunctions vanish on discontinuous configurations.

### 3.2 Reduced density matrix and entanglement entropy

Having defined gauge invariant wavefunctions in the symmetric product orbifold CFT, it is easy to define a gauge invariant reduced density matrix. We define it analogously to (2.9) in a system of identical particles. In this definition, the reduced density matrix that has support on the full circle on $l-1$ strands and on an interval $A$ of size $\ell$ on one strand is

$$\rho_A^{(l)} (X_1, \ldots, X_{l-1}, X_{lA}; X'_1, \ldots, X'_{l-1}, X'_{lA})$$

$$= \int DY_{l+1} \ldots DY_N D\Psi^*_{[h]} (X'_1, \ldots, X'_{lA}, Y_{lA}, \ldots, Y_N) \Psi_{[h]} (X_1, \ldots, X_{lA}, Y_{lA}, \ldots, Y_N),$$

where $DY_i = \frac{2\pi}{\sigma=0} dY_{i+1}(\sigma)$ and $D\Psi_{lA} = \prod_{\sigma=\ell} dY_{i+1}(\sigma)$. Compared to the identical particle case a subtlety here is that the measure is infinite dimensional. In this definition, therefore, the reduced density matrix is defined in terms of functional integrals rather than ordinary integrals. Because the wavefunction is gauge invariant, the reduced density matrix will be gauge invariant as well even if the measure has not been symmetrized over $S_N$. Another way to write the reduced density matrix is

$$\rho_A^{(l)} = \frac{\text{Tr}}{\langle |Y_{lA}, Y_{l+1}, \ldots, Y_N \rangle | \langle \Psi_{[h]} \rangle \langle \Psi_{[h]} \rangle \rangle}.$$
Because the state is a sum over gauge copies in \( S_N \), we get a double sum over \( S_N \),

\[
\rho_A^{(l)} = \sum_{g,\tilde{g}\in S_N} \langle Y_{l,A,Y_{l+1},...Y_N} \rangle \left( \left\langle \psi_{ghg^{-1}} \right| \left\langle \psi_{gh\tilde{g}^{-1}} \right\rangle \right). \tag{3.13}
\]

One of the two sums can be further split into elements \( \tilde{g} = gc \) where \( c \) belongs to the centralizer of \( [h] \), i.e., \( c \in C_h \subseteq S_N \), and elements \( \tilde{g} = gc \) for which \( c \notin C_h \). Elements \( c \in C_h \) by definition satisfy \( ch = hc \) hence in this case \( \tilde{g}h\tilde{g}^{-1} = ghg^{-1} \). The reduced density matrix correspondingly takes the form

\[
\rho_A^{(l)} = |C_h| \sum_{g \in S_N} \langle Y_{l,A,Y_{l+1},...Y_N} \rangle \left( \left\langle \psi_{ghg^{-1}} \right| \left\langle \psi_{gchc^{-1}g^{-1}} \right\rangle \right) + \sum_{g \in S_N} \sum_{c \notin C_h} \langle Y_{l,A,Y_{l+1},...Y_N} \rangle \left( \left\langle \psi_{ghg^{-1}} \right| \left\langle \psi_{gchc^{-1}g^{-1}} \right\rangle \right). \tag{3.14}
\]

If we focus on \( l = 1 \) or \( l = 2 \) where one of the strands only has support on an interval of size \( \ell < 2\pi \), then the sums over \( c \notin C_h \) do not contribute, as we now explain.

First consider tracing out everything and look at an overlap \( \left\langle \psi_{ghg^{-1}} \right| \left\langle \psi_{gchc^{-1}g^{-1}} \right\rangle \) where \( c \notin C_h \). The wavefunction \( \psi_{ghg^{-1}} \) only has support on continuous configurations that should satisfy the continuity constraints of the twisted sector \( [h] \) with a specific ordering of the fields specified by \( ghg^{-1} \). Similarly the conjugated wavefunction should satisfy continuity constraints of \( [h] \) with an ordering of fields specified by \( gchc^{-1}g^{-1} \). Since \( c \notin C_h \), the two sets of constraints are different and the configurations in the overlap can only meet both of them on a submanifold of the integration space. Hence, overlaps of this type vanish.

When we consider a reduced density matrix instead, the question is whether the difference in continuity constraints between the wavefunction and its conjugate affect the integration variables or not. In the case of \( l = 1 \) or \( l = 2 \) (with one strand having support only on \( \ell < 2\pi \)) there clearly does not exist any permutation \( c \) that leaves the integrated variables unaffected. Therefore, the sum over \( c \notin C_h \) will again not contribute. The reduced density matrix in these cases becomes

\[
\rho_A^{(l)} = |C_h| \sum_{g \in S_N} \langle Y_{l,A,Y_{l+1},...Y_N} \rangle \left( \left\langle \psi_{ghg^{-1}} \right| \left\langle \psi_{ghg^{-1}} \right\rangle \right). \tag{3.15}
\]

For \( l = 2 \) and \( \ell = 2\pi \), or for \( l > 2 \) it is possible to have permutations \( c \) that do not affect the integrated variables, and these can lead to contributions from the \( c \notin C_h \) terms.

From the algebraic perspective, consider the linear subspace of non-twist observables

\[
\mathcal{A}_l = \text{span}\{[O_1 \otimes ... \otimes O_l \otimes I \otimes ... \otimes I]_{\text{sym}}\}, \tag{3.16}
\]

where \( O_1,...,O_l \) are (not necessarily local) operators in the seed CFT and \( [\ ]_{\text{sym}} \) denotes summing over the images over \( S_N \). Because of the symmetrization, the subspace contains operators that act on any subset of \( l \) strands, and thus multiplying elements would have generated the entire non-twisted operator algebra. Following sec. 2.3 it is self-consistent to define a reduced density matrix as the element of the subspace that computes expectation
values of operators in the subspace via tracing. Since this density matrix must be constructed out of non-twist operators it cannot contain any elements linking strings twisted by different group elements (even if the group elements in question belong to the same conjugacy class). This means including just the \( c \in C_h \) terms in (3.14).

For \( l > 2 \), for which the second term in (3.14) need not vanish, if one wants to construct the density matrix restricted to the subspace (3.16) of non-twist operators, one must project out the \( c \notin C_h \) terms. For the cases we treat in this paper, namely \( l = 1 \) and \( l = 2 \) with \( \ell < 2\pi \), \( \rho^{(l)}_A \) automatically belongs to this subspace.

Once the reduced density matrix has been computed, the von Neumann entropy can be calculated in the usual way via

\[
S\left(\rho^{(l)}_A\right) = -\text{Tr} \left( \rho^{(l)}_A \log \rho^{(l)}_A \right). \tag{3.17}
\]

### 3.3 Single strand

In this section we will compute the single strand reduced density matrix on a spatial interval \( A \) and compute its corresponding entanglement entropy. We will do so in the conical defect state and in the massless BTZ state. We will show that the single strand entanglement entropy agrees with the entwinement of a single strand [17].

#### 3.3.1 Conical defects: reduced density matrix and entanglement entropy

Because the conical defect state describes \( N/m \) strings, all of equal length \( m \), every term in (3.15) contributes equally. \( N/m - 1 \) of them can be integrated out completely. Elements of \( \rho^{(1)}_A \) are therefore computed by

\[
\rho^{(1)}_A (X_{1,A}, X'_{1,A}) = |S_N| |C_h| \int D Y_{1,A} \ldots D Y_m \psi_m (X_{1,A}, Y_{1,A}, \ldots, Y_m) \psi^*_m (X'_{1,A}, Y_{1,A}, \ldots, Y_m) \tag{3.18}
\]

If we assume that the wavefunctions \( \psi_m \) are normalized to unity, the properly normalized density matrix is

\[
\hat{\rho}^{(1)}_A (X_{1,A}, X'_{1,A}) \equiv \frac{\rho^{(1)}_A (X_{1,A}, X'_{1,A})}{\text{Tr} \rho^{(1)}_A} = \int D Y_{1,A} \ldots D Y_m \psi_m (X_{1,A}, Y_{1,A}, \ldots, Y_m) \psi^*_m (X'_{1,A}, Y_{1,A}, \ldots, Y_m). \tag{3.19}
\]

Remember that \( \psi_m \) is the vacuum wavefunction of a CFT on an \( m \)-wound string on the extended Hilbert space (i.e., without symmetrization). If \( \ell \) is the angular extent of the interval \( A \), then by a conformal map, the reduced density matrix can be represented as a path integral on the plane with a cut on the unit circle of angular extent \( \ell/m \) [2,47]. We
know by the usual replica trick that such a density matrix has an entanglement entropy equal to

\[ S \left( \hat{\rho}_A^{(1)} \right) = - \text{Tr} \left( \hat{\rho}_A^{(1)} \log \hat{\rho}_A^{(1)} \right) = \frac{c}{3} \log \left[ \frac{2m}{\epsilon} \sin \left( \frac{\ell}{2m} \right) \right] . \] (3.20)

As usual the entanglement entropy is UV divergent and is proportional to the central charge. The central charge that appears here is the seed central charge of the CFT with target space \( M \), which makes sense since we have computed the entropy of a single (collective) field \( X_1 \) on \( A \). In contrast, the spatial entanglement entropy of a collection of \( N \) fields would be proportional to the central charge of the orbifold theory \( c_N = Nc \). Notice that the entwinement studied in [17] is also given by (3.20).

It is interesting to compare this to the holographic spatial entanglement entropy. When specializing to the D1-D5 orbifold CFT, the single strand entanglement entropy agrees with the length of a minimal geodesic in the dual conical defect geometry when \( \ell < \pi \). When \( \ell > \pi \), then (3.20) computes the length of a non-minimal but non-winding geodesic in the conical defect background. The spatial entanglement entropy, on the other hand, as computed by the Ryu-Takayanagi formula [8], would agree with the length of a minimal geodesic both when \( \ell < \pi \) and \( \ell > \pi \). Note that these matches are somewhat surprising because the orbifold CFT is at a different point in the moduli space of the D1-D5 system than the regime where classical supergravity is valid [48, 49]; perhaps the form of the entanglement entropy and entwinement are sufficiently constrained by conformal symmetry that they remain the same at different points in moduli space.

### 3.3.2 Massless BTZ: reduced density matrix and entanglement entropy

A twisted sector state is characterized by the set \( \{N_m\} \) of numbers of \( m \)-wound strings with \( \sum_{m=1}^{N} mN_m = N \). Suppose we wish to compute the reduced density matrix \( \rho_A^{(1)} (X_{1,A}, X_{1,A}) \). Because (3.15) involves a sum over \( S_N \), the elements \( X_{1,A} \) and \( X'_{1,A} \) can occur in strings of various lengths \( m \). As is clear from the structure of (3.15), both \( X_{1,A} \) and \( X'_{1,A} \) have to belong to the same strand. For a fixed embedding of \( X_{1,A} \) and \( X'_{1,A} \) there are \( (N - 1)! = |S_N|/N \) terms that give the same contribution. On top of that there are \( mN_m \) possible embeddings into strings of length \( m \). After integrating out all strings to which \( X_{1,A} \) and \( X'_{1,A} \) do not belong, elements of the one strand reduced density matrix for general \( \{N_m\} \) take the form

\[
\rho_A^{(1)} (X_{1,A}, X'_{1,A}) = \sum_{m=1}^{N} \frac{mN_m}{\sum_{m=1}^{N} mN_m} \left| S_N \right| |C_h| \int \cdots \int D Y_{1,\bar{A}} \cdots D Y_m \psi_m (X_{1,A}, Y_{1,\bar{A}}, \ldots, Y_m) \psi^*_m (X'_{1,A}, Y_{1,\bar{A}}, \ldots, Y_m) .
\] (3.21)
We will use the notation \( \hat{\chi}^{(1)}_{m,A} \) for the single strand density matrix on an interval \( A \) in an \( m \)-mound string. After normalization this becomes

\[
\hat{\rho}^{(1)}_A (X_{1,A}, X'_{1,A}) = \sum_{m=1}^{N} \frac{mN_m}{N} \hat{\chi}^{(1)}_{m,A} (X_{1,A}, X'_{1,A}).
\]  

(3.22)

The massless black hole typical state has \( \{N_m\} \) given by (3.9). We will bound the von Neumann entropy of the reduced density matrix on this typical state both from above and from below and show that in the large \( N \) limit, both limits converge to the same value. The reduced density matrix (3.22) is written as a convex combination of density matrices. By concavity of von Neumann entropy, there is a simple lower bound namely

\[
S\left( \hat{\rho}^{(1)}_A \right) \geq \sum_{m=1}^{N} \frac{mN_m}{N} S\left( \hat{\chi}^{(1)}_{m,A} \right).
\]  

(3.23)

In [17] it was shown that the expression on the right hand side to leading order in the large \( N \) limit reduces to the one strand reduced density matrix of a single \( \sqrt{N} \)-wound string, so

\[
S\left( \hat{\rho}^{(1)}_A \right) \geq S\left( \hat{\chi}^{(1)}_{\sqrt{N},A} \right) \approx \frac{c}{3} \log \left( \frac{\ell}{\epsilon} \right).
\]  

(3.24)

To establish the upper bound, we use positivity of the relative entropy \( S\left( \hat{\rho}^{(1)}_A \mid \hat{\chi}^{(1)}_{\sqrt{N},A} \right) \). Its definition is

\[
S\left( \hat{\rho}^{(1)}_A \mid \hat{\chi}^{(1)}_{\sqrt{N},A} \right) \equiv \text{Tr} \left( \hat{\rho}^{(1)}_A \log \hat{\rho}^{(1)}_A \right) - \text{Tr} \left( \hat{\rho}^{(1)}_A \log \hat{\chi}^{(1)}_{\sqrt{N},A} \right),
\]  

(3.25)

\[
= -S\left( \hat{\rho}^{(1)}_A \right) + S\left( \hat{\chi}^{(1)}_{\sqrt{N},A} \right) - \langle K_{\chi_{\sqrt{N},A}} \rangle_{\chi_{\sqrt{N},A}} + \langle K_{\chi_{\sqrt{N},A}} \rangle_{\rho_A},
\]  

(3.26)

where \( K_{\chi_{\sqrt{N},A}} \equiv -\log \hat{\chi}^{(1)}_{\sqrt{N},A} \) is the modular Hamiltonian of \( \hat{\chi}^{(1)}_{\sqrt{N},A} \). Positivity of the relative entropy implies that

\[
S\left( \hat{\rho}^{(1)}_A \right) - S\left( \hat{\chi}^{(1)}_{\sqrt{N},A} \right) \leq \langle K_{\chi_{\sqrt{N},A}} \rangle_{\rho_A} - \langle K_{\chi_{\sqrt{N},A}} \rangle_{\chi_{\sqrt{N},A}}.
\]  

(3.27)

\( K_{\chi_{\sqrt{N},A}} \) is the vacuum modular Hamiltonian on an arc of length \( \ell \) in a circle of size \( 2\pi \sqrt{N} \). Such a modular Hamiltonian can be written as an integral of the vacuum stress tensor [50, 51]:

\[
K_{\chi_{\sqrt{N},A}} = 4\pi \sqrt{N} \int_{0}^{\ell} \frac{d\theta}{\sin \left( \frac{\ell}{2\sqrt{N}} \right)} T_{00} (\theta).
\]  

(3.28)

The expectation value of the modular Hamiltonian thus becomes an expectation value of the stress tensor in the reduced density matrix on \( A \). The expectation value of any local
operator $O$ should satisfy $\langle O \rangle_{\chi_{A,m}} = \langle O \rangle_{\chi_{m}}$ where $\chi_{m}$ is the full state of an $m$-wound string. The vacuum expectation value of the stress tensor on a cylinder of circumference $2\pi m$ is \[ \langle T_{00} \rangle_{\chi_{m}} = -\frac{c}{12m^2}. \] (3.29)

Because $\hat{\rho}_{A}$ is a convex combination of single string reduced density matrices $\hat{\chi}_{m,A}$, the expectation value (3.29) can be used to compute the expectation value of the modular Hamiltonian. This turns the inequality (3.27) into

\[ S\left(\hat{\rho}_{A}^{(1)}\right) - S\left(\hat{\chi}_{\sqrt{N},A}^{(1)}\right) \leq \frac{\pi c}{3\sqrt{N}} \left[ 1 - \sum_{m=1}^{N} \frac{N_{m}}{m} \right] \int_{0}^{\ell} d\theta \frac{\sin \left(\frac{\ell - \theta}{2\sqrt{N}}\right) \sin \left(\frac{\theta}{2\sqrt{N}}\right)}{\sin \left(\frac{\ell}{2\sqrt{N}}\right)}. \] (3.30)

We define the variable $x = m\sqrt{2\pi/N}$ which is $1/\sqrt{N}$ spaced. This becomes a continuous variable if $N$ is large enough, and the sum is converted into an integral. The integral is dominated by the small $x$ behaviour of the integrand, and is estimated by

\[ \sum_{m=1}^{N} \frac{8}{m \sinh \left(\frac{2\pi}{N} m\right)} = \frac{\sqrt{2\pi N}}{\sqrt{2\pi N}} \int_{0}^{\sqrt{2\pi N}} \frac{8dx}{x \sinh x} \approx 8\sqrt{\frac{N}{2\pi}}. \] (3.31)

The integral in (3.30) can easily be computed and equals

\[ \int_{0}^{\ell} \frac{d\theta}{\sin \left(\frac{\ell}{2\sqrt{N}}\right)} \approx \frac{\ell^2}{12\sqrt{N}}. \] (3.32)

Combining all terms we find that the upper bound (3.30) is proportional to $1/\sqrt{N}$ and together with the lower bound (3.24) we find that to leading order in the large $N$ limit the entanglement entropy of $\hat{\rho}_{A}$ is that of an interval on a single $\sqrt{N}$-wound string in the vacuum,

\[ S\left(\hat{\rho}_{A}^{(1)}\right) \approx S\left(\hat{\chi}_{\sqrt{N},A}^{(1)}\right) = \frac{c}{3} \log \left(\frac{\ell}{\epsilon}\right). \] (3.33)

The entanglement entropy shows a functional dependence on $\ell/\epsilon$ that one expects from the RT formula [8] in a massless BTZ background, but $c$ in our formula is the central charge of the seed CFT instead of the orbifold central charge. This is expected since we have computed the entanglement entropy of a single strand on a spatial interval, not the entanglement entropy of all strands on the spatial interval. The single strand entanglement entropy also agrees with the single strand entwinement as defined in [17]. In particular, the single strand entanglement entropy does not have a transition as the size of the interval continues from $\ell < \pi$ to $\ell > \pi$. In the massless BTZ geometry the spatial entanglement entropy does have a transition. For $\ell < \pi$ it is dominated by a minimal geodesic, while for $\ell > \pi$ it is dominated by a disconnected configuration consisting of a minimal geodesic and a surface that wraps the horizon with vanishing area.
3.3.3 A comment on Rényi entropy and replica symmetry breaking

Suppose we wish to compute the Rényi entropy

\[ S^{(n)}(\hat{\rho}_A) = \frac{1}{1-n} \log (\text{Tr}(\hat{\rho}_A^n)) . \]  

(3.34)

Because \( \hat{\rho}_A \) is a convex combination of the density matrices on a single multiwound string, the trace can be expanded into

\[ \text{Tr}(\hat{\rho}_A^n) = \frac{1}{N^n} \sum_{(m_1, \ldots, m_n)} m_1 N_{m_1} \cdots m_n N_{m_n} \text{Tr}(\hat{\chi}_{A,m_1} \cdots \hat{\chi}_{A,m_n}) . \]  

(3.35)

The Rényi entropies contain cross terms, where not all \( m_i \) are equal. These terms can be represented as path integrals over manifolds that are not replica symmetric, namely \( n \) cylinders with different radii \( m_1, \ldots, m_n \) sewn together. It is an interesting open problem to compute path integrals on such genus zero manifolds.\(^7\)

3.4 Multiple strands

3.4.1 Conical defects: reduced density matrix and entanglement entropies

Our formalism of integrating out strands in principle also allows us to compute the entanglement entropy of multiple strands. As an example we will show how it works in the case of the entropy of two strands in the conical defect state, where we integrate out all but a union of a complete strand and an interval \( A \) of another strand.

As we have argued in sec. 3.2, the overlap between terms in the wavefunction and its conjugate that are non-trivially permuted compared to one another, vanishes. The two strand reduced density matrix thus consists of two kinds of overlaps: either the two strands belong to the same \( m \)-wound string, or they do not. It has the structure\(^8\)

\[ \rho^{(2)}_A (X_1, X_{2,A}; X'_1, X'_{2,A}) = N(N-2)! |C_h| \sum_{q=2}^m \int_{D_2} \psi_m (X_1, Y_3, \ldots, X_{2,A}, Y_{q+1}, \ldots, Y_m) \psi^*_m (X'_1, Y_3, \ldots, X'_{2,A}, Y_{q+1}, \ldots, Y_m) \]  

\[ +(N-m) \int \psi_m (X_1, Y_3, \ldots, Y_{m+1}) \psi^*_m (X'_1, Y_3, \ldots, Y_{m+1}) \]  

\[ \times \int_{D_2} \psi_m (X_{2,A}, Y_{2,A}, Y_3, \ldots, Y_m) \psi^*_m (X'_{2,A}, Y_{2,A}, Y_3, \ldots, Y_m) \]  

\[ \times \int_{D_2} \psi_m (X_{2,A}, Y_{2,A}, Y_3, \ldots, Y_m) \psi^*_m (X'_{2,A}, Y_{2,A}, Y_3, \ldots, Y_m) \] .  

\(^7\)Perturbatively in the subsystem size one can use “cutting and sewing” techniques to calculate this, such as in [53–55].

\(^8\)To explain the normalization factors, we first note that \((N-2)!\) terms contribute equally in (3.15) for \( l = 2 \). Second, there are \( N \) possible embeddings of \( X_1 \) and \( X'_1 \). Third, either \( X_{2,A} \) and \( X'_{2,A} \) belong to the same string as \( X_1 \) and \( X'_1 \) or they don’t. In the latter case there are \((N-m)\) possible embeddings of \( X_{2,A} \) and \( X'_{2,A} \) that all contribute equally to \( \rho^{(2)}_A \).
To make the structure of such a density matrix clearer we can write it schematically as
\[
\rho_A^{(2)}(X_1, X_2; X'_1, X'_2) \propto (N - m) \chi_{A,m}^{(1)}(X_1, X'_1) \otimes \chi_{A,m}^{(1)}(X_2, X'_2) + \sum_{q=2}^{m} \chi_{A,m}^{(2,q)}(X_1, X_2; X'_1, X'_2),
\]
where \( q \) denotes how many strands \( X_2 \) is shifted compared to \( X_1 \) inside the long string. All of the reduced density matrices \( \chi \) involve single multiwound strings of length \( m \), so as long as \( m \) is smaller than \( O(N) \), \( \rho_A^{(2)} \) will be dominated by the configurations \( \chi \) where \( X_1 \) and \( X_2 \) belong to different strings. To leading order in \( N \) the two strand entanglement entropy of the properly normalized density matrix \( \hat{\rho}_A^{(2)} \) is the sum of single string vacuum entropies, namely
\[
S\left(\hat{\rho}_A^{(2)}\right) = S\left(\chi_{m}^{(1)}\right) + S\left(\chi_{A,m}^{(1)}\right) + O\left(\frac{1}{N}\right),
\]
\[
= \frac{c}{3} \log \left[\frac{2m}{\epsilon} \sin\left(\frac{\pi}{m}\right)\right] + \frac{c}{3} \log \left[\frac{2m}{\epsilon} \sin\left(\frac{\ell}{2m}\right)\right] + O\left(\frac{1}{N}\right).
\]

Notice in particular that the two strand entanglement entropy will not be equal to the entwinement of a long strand. Entwinement is expected to be related to the entanglement entropy of continuously connected strings. Here we have in no sense imposed continuity between the strands in the reduced density matrix, so we do not expect agreement with entwinement.

4 Discussion and outlook

Entanglement entropy of spatial subregions has proven to be a central quantity in the study of holography. The RT formula for spatial entanglement entropy has led to a wealth of discoveries concerning the nature of the holographic dictionary at least up to scales of the order of the AdS radius. To study holography at scales below the AdS radius, it has been argued that one needs to know about the internal degrees of freedom, which are typically gauged \([12,13]\). Hence it is natural to ask what the entanglement entropy of gauged internal degrees of freedom is. Moreover, since entanglement entropy in field theory is based on a bipartite splitting of the Hilbert space, rather than on a splitting of physical space itself, it is just as natural to study the entanglement entropy of internal degrees of freedom as it is to study the entropy of spatial subregions.

In this paper we studied a symmetric product orbifold CFT. Such a CFT describes the low energy limit of the D1-D5 system and thus appears naturally in the context of holography. States of a symmetric product orbifold describe a collection of multiwound strings, of which the elementary strands are indistinguishable. Physical states therefore necessarily have to be invariant under permutations. This is reminiscent of a system of identical particles. The entanglement entropy of \( k \) out of \( N \) internal gauged degrees of freedom in field theory is then analogous to the entropy of \( k \) out of \( N \) identical particles. We showed that the reduced density matrix on \( k \) particles does not have support on a subalgebra of operators, but rather on a linear subspace of operators.
We presented a formula for the reduced density matrix for a general splitting of the internal degrees of freedom of an orbifold CFT into two subsets, and worked out the associated von Neumann entropy for two specific states that are dual in the context of the D1-D5 system to conical defect geometries and to massless BTZ black holes. In both cases we find that the entropy of a single strand is computed in the dual geometry by the length of a geodesic. When the strand has spatial support on an interval of angular extent $\ell < \pi$ it reproduces the length of a minimal geodesic. As such it has the same functional dependence on $\ell$ as the spatial entanglement entropy, but in contrast with the spatial entropy it does not scale with the full central charge of the orbifold theory but rather with the central charge of the seed CFT. This makes sense because the spatial entropy involves having access to all strands on a spatial interval of size $\ell$, in contrast with the single strand entropy. When $\pi < \ell < 2\pi$ the single-strand entanglement that we compute is proportional to the length of a non-minimal but non-winding geodesic. It agrees with the single strand entwinement.

We also studied the entropy of two strands in the conical defect state, and showed that in the large $N$ limit it does not agree with the two strand entwinement. Instead it equals the sum of the entwinement of a single strand with support on the full circle and the single strand entwinement on an interval of size $\ell$. This is because the reduced density matrix is dominated by contributions where the two strands are located on different strings. Whereas the entropy that we have studied in this paper quantifies the entanglement of several strands with the rest of the system, we expect entwinement to quantify the entanglement of several continuously connected strands with the rest of the system. To prove that this is really the case, we need a way to specify continuity across the strands. This would reflect the replica definition of entwinement [17], where one starts with two elementary twist operators on the same strand, averages over $S_N$ permutations, and then moves one of the twist operators to adjacent strands using continuity. In the construction of the present paper, an interval may span multiple strands that are separately permuted by the gauge group $S_N$. In order to make contact with entwinement the challenge is to define a reduced density matrix associated to continuously connected strands in a way that is manifestly gauge invariant.

We applied our method to the D1-D5 system, but it can also be used for entanglement entropy in matrix string theory, which is also a symmetric product orbifold. Permutation symmetry appears there as the Weyl group of $U(N)$.

Acknowledgements

We would like to thank Alex Belin, Alice Bernamonti, William Donnelly, Federico Galli, Arjun Kar, Aitor Lewkowycz and Onkar Parrikar for useful discussions. This research was supported in part by FWO-Vlaanderen (projects G044016N and G006918N), by the Vrije Universiteit Brussel through the Strategic Research Program “High-Energy Physics”, by the Simons Foundation (385592, VB) through the It From Qubit Simons Collaboration, and by the US DOE through Grant FG02-05ER-41367. Work on this project at the Aspen Center for Physics was supported by NSF grant PHY-1607611. TDJ is aspirant FWO.
