Abstract. Modern scientific research particularly radio astronomical spectroscopic observations cannot be imagined without appropriate software suite. That is necessary because of two reasons 1) data are in digital form and 2) data processing is a complex multi-step process. In this paper created in VIRAC data processing suite for a single radio telescope, space maser observations are presented. Software Defined Radio (SDR) backend data processing is described. Implementation of the frequency switching algorithm, acquisition of observation data and their format for storing are discussed. Multiple ways to display the observation results are highlighted.

Key words: Python, GUI, Maser, Monitoring.

1 Introduction

In the year 2017 Ventspils International Radio Astronomy Centre (VIRAC) team of astronomers and engineers started to work on the maser monitoring programme [Aberfelds et al., 2017]. That included technical and scientific development. The technical development was creating the radio telescope backend and software package for data processing. The scientific development...
was the creation of source catalogue, developing mathematical background for data processing, creating observation planning method and studying the observed radio sources variability. Observations have been done with VIRAC 16 m and 32 m radio telescopes RT16 and RT32. Initially, both telescopes had Digital Base Band Converter (DBBC) (Tuccari, 2003) backend, recently SDR (Bleiders et al., 2020) based backend has been developed. Afterwards tool complex for single-dish radio telescope space maser observation data processing named Maser Data Processing Suite (MDPS). MDPS discussed in this paper was developed in VIRAC. It is open-source software, with user-friendly Graphical User Interface GUI distributed via GitHub repository https://github.com/sklandrausis/Maser-Data-Processing-Suite.

There exist many other software packages for single dish data processing like Common Astronomy Software Applications (CASA), GILDAS (it is used to reduce all data acquired with the IRAM 30M telescope and the NOnter Extended Millimetre Array NOEMA), GBTIDL (is an interactive package for reduction and analysis of spectral line data taken with the Robert C. Byrd), but none of existing software packages are compatible with VIRAC SDR based backend setup for example maser data reducing software used for Effelsberg telescope is not publicly available and pipeline code is very tailored to Effelsberg, so it would be a major effort to adapt it to VIRAC needs. It is also tied to the Multi-Beam FITS Raw Data Format (MBFITS) format and if MBFITs format is not used, it would be better off with a complete re-write anyway (Information obtained in personal communication with Benjamin Winkel). VIRAC setup produces the specific format of data that these packages do not support. And these packages do not have monitoring module. Additionally frequency shifting algorithm is not wide spread maser calibration method, because of that MDPS is one of that first this kind of software.

2 Overview of MDPS

MDPS currently allows 1) process SDR output, 2) display maser sources spectral components variability over time monitoring and 3) Visualise data for publications. MDPS also uses several Python libraries. The most important of them are PyQt5 (riverbankcomputing.com, 2020), Astropy (Robitaille et al., 2013) [Günther et al., 2018], Matplotlib (Hunter, 2007), Numpy (Oliphant, 2006), H5py (Collette, 2013), SciPy (Virtanen, 2020), jplephem (Rhodes, 2022).
2011) and experimentsLogReader (Steinbergs, 2020). It also needs planetary ephemeris parameter file de435.bsp, that can be required by https://naif.jpl.nasa.gov/pub/naif/generic_kernels/spk/planets/de435.bsp. Processing suite also uses two configuration files – Python library Matplotlib configuration file to modify plotting view, custom made configuration file, that specifying used directories and hard-coded variables. Most important of them are 1) velocity line parameters, 2) signal cut values, 3) observed source parameters (Right ascension, Declination, epoch), 4) base frequencies of observed maser species and 5) station coordination’s. Velocity line parameter is used to compute the local maximum of the spectrum and signal cut values are used to compute signal to noise ratio. Base frequencies of species are laboratory determined maser frequencies for specific chemical specie and are used to compute Doppler effect. Station coordination’s are three geocentric values in metres (x,y,z) used to compute local standard of rest.

3 SDR backend output processing

3.1 SDR backend description

As backed on-the-shelf SDR Ettus Research USRP X300 equipped with TwinRX daughterboard is used. (Bleiders et al., 2020) It is a multi-channel SDR transceiver, that allows obtaining complex sample rates and since USRP X300 is used together with TwinRX front-end daughterboard, it allows dual-polarization spectroscopy. (Bleiders et al., 2020) Optimal linearity receiver is find using calibration noise injection function. (Bleiders et al., 2020) Since power values is measured with noise source on and off, it should not depend on input signal level, that allows to find optimum attenuation values for USRP unit, telescope receiver and IF signal chain itself. (Bleiders et al., 2020)

3.2 Implementation of frequency switching algorithm

3.2.1 Mathematical implementation of frequency switching algorithm

Observations are done in a frequency-switching mode described by (Winkel et al., 2012) with four typically 15 seconds long integration stages. First two stages are with noise diode turned off, the last two stages with noise diode turned on.
These stages are marked as $ref_{off}$, $sig_{off}$, $ref_{on}$ and $sig_{on}$. Definitions of $ref$, $sig$ correspond to the shift of the local oscillator frequency to up and down from the calculated central frequency. Shifting local oscillator frequencies allow to remove the bandpass dependence. Indexes $on$ and $off$ correspond to noise diode turned on and off respectively. Sequential SDR backend creates a file for each of these stages. Each of these files contains a matrix with three columns – the first is frequency, the second and third are amplitudes of left and the right polarisation. The system also generates a log file. It is parsed and necessary information for calibration is extracted by using Python library experimentsLogReader. The first step of telescope data processing is to rearrange data by shifting the centre-frequency component to the centre of the array after that calibration process can start. The calibration process is a multi-step process beginning with a conversion from telescope backend relative amplitude units to Kelvins. Thereafter the system temperature for noise diode turned off must be computed. This is done for both $sig$ and $ref$ stages. For the first, it is done by the help of formula 1. For the next one, the formula is similar only there is a $P_{ref}$ instead of $P_{sig}$.

\[
T_{sys_{off}} = T_{cal} \frac{P_{sig_{on}} + P_{sig_{off}} - (P_{sig_{on}} - P_{sig_{off}})}{2(P_{sig_{on}} - P_{sig_{off}})}
\]  

Here $T_{cal}$ is the temperature of noise diode obtained from the observation log file. When observation log file is generated $T_{cal}$ value is written 3.820791 K for both telescope, that is temperature of noise diode corresponing the value of its generated signal. $P_{sig_{on}}$ and $P_{sig_{off}}$ is $sig$ stage on and off amplitude. $(P_{sig_{on}} - P_{sig_{off}})$ is an average value from the subtraction of $P_{sig_{on}}$ and $P_{sig_{off}}$. Next calibrated amplitude for all four stages must be computed. Since computation for $sig$ and $ref$ stage is similar only for $sig$ stage it will be shown. First $T_{cal_{off}}^{sig}$ for off-stage is computed using formula 2, thereafter $T_{cal_{on}}^{sig}$ for on stage using formula 3.

\[
T_{cal_{off}}^{sig} = T_{sys_{off}} \frac{P_{sig_{off}} - P_{ref_{off}}}{P_{ref_{off}}}
\]

where $P_{sig_{off}}$ is $sig$ stage off amplitude.

\[
T_{cal_{on}}^{sig} = (T_{sys_{off}} + T_{cal}) \frac{P_{sig_{on}} - P_{ref_{on}}}{P_{ref_{on}}}
\]

Next step is to compute average amplitude from their on and off stage values, that can be done by formula 4.
\[ T_{\text{sig}} = (T_{\text{cal}}^{\text{sig \ off}} + T_{\text{cal}}^{\text{sig \ on}})/2 \quad (4) \]

After that data are shifted by shifting factor, computed by formula \[^5]\text{n}_{\text{shift}} = \lfloor f_{\text{shift}}/f_{\text{step}} \rfloor \quad (5)\]

where \( f_{\text{step}} \) is the distance between frequencies points and \( f_{\text{shift}} \) are computed by the formula \[^6]\]

\[ f_{\text{shift}} = \frac{bw}{df_{\text{div}}} \quad (6) \]

where \( bw \) is bandwidth and \( df_{\text{div}} \) is division factor. Both values are obtained from the observation log. After that average of \text{sig} and \text{ref} stages are computed by using formula \[^7]\]

\[ T = (T_{\text{sig}} + T_{\text{ref}})/2 \quad (7) \]

where \( T_{\text{ref}} \) is calibrated \text{ref} stage amplitude obtained similar to \( T_{\text{sig}} \). Finally, conversion from amplitude in Kelvins to amplitude in Janskys is done by formula \[^8]\]

\[ S = \frac{T}{DPFUPol(y)_{val}(g_{el}, \text{elevation})} \quad (8) \]

where \( S \) is amplitude in Janskys, \( T \) is calibrated amplitude, DPFU is degrees-per-flux-unit and \( Pol(y)_{val}(g_{el}, \text{elevation}) \) is evaluated ordinary polynomial, where the \( g_{el} \) is polynomial coefficients. Elevation, \( g_{el} \) and DPFU are obtained from separately performed calibration sessions, targeting well known continuum sources [Perley and Butler, 2013] and also are stored in log files. Polynomial is evaluated using Python library \textit{Numpy} function \textit{polyval}. The final part is to extract valuable part of data, that is done by computing two indexes. These indexes \( i \) and \( j \) are 1/4 and 3/4 of sampling points. Example of a frequency switching algorithm result screenshot is shown in figure \[^1]\]

3.2.2 Practical details

SDR backend creates a file for each of calibration stages (\textit{ref\ off}, \textit{sig\ off}, \textit{ref\ on}, \textit{sig\ on}) for each scan. Data in these files are stored in American Standard Code for Information Interchange (ASCII) format. Each of these files
contains a matrix with three columns – the first is frequency, the second and third are amplitudes of left and the right polarisation, no header information. These files are read using Python library *Numpy* function `loadtxt`. Before reading the data files they are sorted for each scan and is checked if every scan have all four files, if not scan are deleted and user are warned about that.

SDR backend file naming scheme is this `<source>_f⟨frequency⟩_⟨station⟩_⟨iteration⟩_no⟨nOandstage⟩.dat`. Where *nO* and *stage* is scan number and calibration stage index, example 001r0. All scan number and calibrator stage index contains two parts scan number in example 001 and calibration stage index r0. Calibration stage index is string that contains two parts identification for *sig* and *ref* stages - letter *r* and *s* and identification for *on* and *off* stages numbers 1 and 0. Theses files are read as *Numpy* arrays and all mathematical computations mention in 3.2.1 are done using matrix operation.

### 3.3 Computation of Doppler effect

After amplitudes are calibrated next step of data processing is to compute the Doppler effect and transform data from the frequency domain to the velocity domain, that is done using formula (9).

\[ v = v_r - \left( \frac{f_o}{f_b} - 1 \right) c \]  

(9)

where \( f_o \) is observed frequency, \( f_b \) is laboratory determined maser frequency, \( c \) is the speed of light and \( v_r \) is the velocity of the receiver.
Observed frequency is frequency from data file plus local oscillator frequency. The velocity of the receiver in Local Standard of Rest frame is the sum of Sun apex velocity, Earth orbital velocity and Earth rotation.

### 3.4 Observation data quality estimation

Data quality is determined by signal to noise ratio. This ratio is computed in the velocity domain. To extract a signal from data MDPS configuration file has section *cuts*, that contain velocities ranges where signal are located. This information is used to compute indexes of ranges for a signal. Knowing where a signal is in data, it is possible to know where noise is in data. Then the signal to noise ratio is computed by the maximum value of signal divided by 3 multiply by Standard deviation of the noise.

Additional option to estimate the quality of observation is to see the system temperature over time. In a normal situation, it will be stable. The result screenshot example is shown in figure 2.

![Figure 2](image)

**Figure 2**: Upper panel amplitude as a function from velocity. The Bottom panel left side system temperature as a function of time, right side signal to noise ratio as a function of time. Source G109.871+2.114/Cepheus A was selected as example.

### 3.5 Data normalisation and monitoring values extraction

After transformation to velocity domain is done scans of observation are aligned so that the maximum value index is the same for all scans, then all scans are averaged to avoid velocity drift during the observation time. When a single spectrum is created from all scans in one observation, data must
be normalised. It is necessary because during observations the effect from system instabilities will correspond to no flat noise floor in the spectrum. It is done by computing ordinary polynomial from the noise part of the spectrum and this polynomial is subtracted from the spectrum. By default, MDPS use polynomial order $3$. An example screenshot is shown in Figure 3.

![Figure 3: Black dots data points of signal noise part, blue line polynomial. Source G109.871+2.114/Cepheus A was selected as example.](image)

After data are normalised, amplitudes for maser components can be obtained. To do that maser component velocity values are used. First indexes for component velocities are computed, after that ranges of local maximum areas are constructed. This is done by using previously computed indexes for component velocities and index range for local maximum are added and subtracted to these indexes. For ranges of local maximum areas, a maximum value for amplitude is computed and stored for monitoring. The result for found amplitude values for maser components result screenshot is shown in Figure 4.

![Figure 4: Blue line spectrum, red dots amplitude values for maser components. Source G109.871+2.114/Cepheus A was selected as example.](image)
3.6 Output data products of SDR backend data processing and their formats

After processing SDR backend data MDPS creates two outputs 1) calibrated spectrum data and 2) data for spectra variability with time monitoring. For calibrated spectrum data file format following specifications were selected 1) It must have read and written a library in most popular programming languages (output files can be distributed to other researchers and they can use any tools they like to process these files) 2) It should be possible to store data for each data processing stage in one file (it is necessary to avoid complicated file naming schemes and that allow reprocessing data from any data processing stage). To store and process astronomical data many data formats are used. In this paper authors only will discuss these data file formats (CSV, FITS \cite{Wells1979}, HDF5 \cite{Folk2011}, NPY \cite{community2020}, MS \cite{Kemball2000}). They are given in table \ref{tab:3.6}.
| File format | Programming languages supporting format | Comments |
|-------------|----------------------------------------|----------|
| CSV         | Most of languages                      | Cannot store multiple matrices in one file |
| FITS        | C, Fortran, C++, C#, Python, IDL, Java, JavaScript, Julia, TCL, Perl, MatLab, Mathematica, R, Go, Swift (McGlynn, 2020) | Primarily used for image transport and archiving |
| HDF5        | C, C++, Java, Python, C#, Fortran, R, S-Lang, MatLab, Mathematica (hdfgroup.org/, 2020)) | Can be used for storing complex data structures |
| NPY         | Only Python                            | NumPy matrix output format. Cannot be used store multiple matrices and meta data |
| MS          | C++, Python                            | Primarily used for image transport |

Table 1: Overview of data files used in Astronomy

We see that both criteria are satisfying only by two data formats FITS and HDF5. Although FITS file format has the support of more programming languages, we favour HDF5, because of advantages that have HDF5. These advantages are as improved I/O speed, compression (Price et al., 2015) and HDF5 data format is used in new modern telescopes like LOFAR, CCAT and MeerKat (Price et al., 2015) and will be used in the future telescope SKA (Comrie et al., 2020) software. The Output file contains tables `amplitude`, `amplitude_corrected`, `amplitude_corrected_not_smoothed`, `specie` and `system_temperature`. Table `amplitude` is the result of frequency switching algorithm, table `amplitude_corrected_not_smoothed` contains normalises data, `amplitude_corrected` smoothed data table specie a specie of observed source and table `system_temperature` contains system temperature as a function of
time.

For variability monitoring data following specifications were selected 1) It must allow monitoring meta-data to change over time 2) It must have reading and writing library in most popular programming languages. Therefore JavaScript Object Notation (JSON) was chosen as data format.

4 Variability monitoring

4.1 Single source monitoring

This consists of two components: single source monitoring and multiple source calibrator line monitoring. The monitoring result is a maser spectre components amplitude as a function of time. A simple example can be seen in figure 5. An additional option is to compute power as a function of periods, as seen in figure 6. Power as a function of periods is obtained by computing Lomb-Scargle periodogram as described in (VanderPlas and Ivezić, 2015). To compute periodogram Python library Astropy, modules time series function LombScargle was used. Monitoring module also can compute amplitude changes not only for specific maser velocity component, but also can compute amplitude change as a function in time for all spectrum. That is done by computing triangulation between the velocity of maser and observed time. After that contour of the created triangular grid is drawn, contour colours correspond to observed fluxes. The result can be seen in figure 7.
Figure 6: G33.641-0.228 power of velocity 60.99 component as a function of periods.

Figure 7: G107.298+5.639 Amplitude change as a function in time for all spectrum (spectrogramm).

4.2 Multiple source calibrator line monitoring

From all sources included in the maser monitoring programme, stable velocity components are selected. Currently these G32.744-0.076 (30.49, 39.18), G49.490-0.388/W51 (59.29), G59.783+0.065 (19.2), G69.540-0.976/ON1 (14.64), G188.95+0.89/S252 (10.84), G111.542+0.777/NGC7538 (-58.04), G133.947+1.064/W3(OH)) (-44.6) components are selected. This kind of monitoring allows detecting instrumental errors. Because selected velocity components have different amplitude values, before plotting data must be normalised, that is done by dividing each selected velocity components with an average for that component. For each of these components, a second-order polynomial is computed. The result can be seen in figure ☺.
5 Performance testing

Running Python scripts with option -m cProfile print in terminal profile info (function calls, primitive calls, execution time in seconds) or importing Python library cProfile to script it will allow to get profile info from any part of script. In figure 9 show SDR backend output processing execution with different number of scans, but all observations had 4096 numbers of points.

Viewing figure 9 we can see that execution time is between functions O(logn) and O(nlogn) that means that complexity of SDR backend data processing algorithms is O(n).

Similar analyses are shown spectrogramm computation, results of that can be seen in figure [10] but execution speed of spectrogramm computation is determined by numbers of observation in monitoring and numbers of spectral components.
6 Conclusions

This paper presents the developed Maser line monitoring processing suite. It enables process SDR output, display monitoring and visualises data for publications and presentation. The suite was entirely written in programming language Python. For data storing modern and efficient technologies were used, like HDF5. Implementation of the frequency switching algorithm was described in detail. Variability monitoring module was described and different ways to display monitoring results were shown. Also, data formats for storing the processed data were discussed.
