Crystallization-induced dual emission from metal- and heavy atom-free aromatic acids and esters†

Yongyang Gong, a Lifang Zhao, a Qian Peng, b Di Fan, b Wang Zhang Yuan,*a Yongming Zhang* a and Ben Zhong Tang d

Pure organic materials exhibiting room temperature phosphorescence (RTP) have significant fundamental importance and promising optoelectronic and biological applications. Exploration of metal- and heavy atom-free pure organic phosphors, however, remains challenging because achieving emissive triplet relaxation that outcompetes the vibrational loss is difficult without metal or heavy atoms. In this contribution, in contrast to aggregation-caused quenching (ACQ) normally observed in conventional chromophores, a unique phenomenon of crystallization-induced dual emission (CIDE), namely, simultaneously boosted fluorescence and phosphorescence upon crystallization, is observed in a group of pure organic aromatic acids and esters at ambient conditions. Moreover, two triplet-involved relaxations of delayed fluorescence (DF) and phosphorescence are activated. Such efficient intrinsic emission from both singlet and triplet states in a single compound without employing metal or heavy atoms is suitable for a variety of fundamental research and applications.

Introduction

Room temperature phosphorescence (RTP) has aroused extensive interest because of its unique photophysical processes and promising applications in organic light-emitting diodes (OLEDs),1 chemical and biological sensing,2 bioimaging,3 photovoltaic devices,4 etc. So far, however, phosphorescence is essentially confined to inorganic compounds or organometallic complexes, such as platinum (Pt), iridium (Ir) and gold (Au) complexes,5–7 as a result of the promotion of intersystem crossing (ISC) in organic ligands through the triplet metal-to-ligand charge-transfer state. Although pure organic luminogens can be more conveniently designed and tailored at much lower costs when compared to their inorganic and organometallic counterparts, they are generally believed to be unable to emit efficient RTP due to the following reasons:8 (1) transitions between singlet and triplet states involving spin flips are quantum mechanically forbidden; (2) occasionally, these transitions become partially allowed due to such perturbations as spin–orbit coupling or vibrational coupling induced by carbonyl (C==O) groups, hetero atoms and heavy atoms, active intramolecular motions and/or interacting with environmental quenchers can effectively extinguish the phosphorescence during the longevity of triplet excitons. Triplet states in organic luminogens are thus typically dark states. Although previous examples of solid substrate-RTP (SS-RTP),9 micelle stabilized-RTP (MS-RTP)10 and cyclodextrin-induced RTP (CD-RTP)11 have been reported, normally special and complex fabrication techniques are required and only instrument detectable signals are obtained.

In 2010, we observed a new phenomenon of “crystallization-induced phosphorescence (CIP)” in pure organic luminogens, namely, compounds like benzophenone and its derivatives are nonphosphorescent in solutions and amorphous states, while being efficiently phosphorescent upon crystallization.12 The discovery of CIP affords a crystal engineering approach to obtain efficient RTP. The mechanism of CIP is ascribed to the restriction of intramolecular motions (RIM) by effective intermolecular interactions in the crystals, which help to lock and rigidify the molecular conformations, thus minimizing the nonradiative loss of triplet excitons and boosting the phosphorescence emission.12 Meanwhile, crystalline lattices also prevent the luminogens from contacting with such quenching sites as oxygen and moisture.13

Later, Kim and co-workers found a similar phenomenon resulting from directed heavy atom effect (DHADE) in the aromatic aldehyde and bromide cococrystals.14 Subsequently, other examples of RTP based on pure organic luminogens have been reported by taking advantage of (co)crystallization,
halogen bonding, doping in rigid matrix, intermolecular interaction and singlet fission.\textsuperscript{15–19} Efficient pure organic RTP luminogens, however, remain rather limited,\textsuperscript{18–21} particularly for those without heavy atoms.

With continuous endeavors to construct pure organic phosphors with efficient RTP,\textsuperscript{21} in this work, we report on the efficient crystal emission from both singlet and triplet excitons in a group of metal- and heavy atom-free aromatic acids and esters (Chart 1). Recently, Reinecke and co-workers also reported the impressive work of efficient bioluminescence (fluorescence and phosphorescence) from N,N'-bis(4-benzyolphenyl)-N,N'-diphenyl-benzidine [(BzP)PB] embedded into a polymethyl methacrylate (PMMA) film.\textsuperscript{18} (BzP)PB is emissive in both solutions and solids, but suffers from an aggregation-caused quenching (ACQ) problem (Fig. S2, ESI†); moreover, no RTP is observed in its crystals (Fig. S3, ESI†). Distinctly different from (BzP)PB, our acids and esters are practically non-emissive in solutions and on TLC plates, however, they emit both fluorescence and phosphorescence upon crystallization, demonstrating crystallization-induced dual emission (CIDE) characteristics, which enable the possibility to quantify singlet-triplet spin correlations.\textsuperscript{22} Moreover, besides normal prompt fluorescence and phosphorescence, delayed fluorescence (DF) is also detected. Such CIDE feature not only eliminates the troublesome procedures normally adopted to observe phosphorescence at cryogenic temperatures, but also avoids the concentration quenching that is popular and particularly strong for long-lived triplets.\textsuperscript{23}

Results and discussion

For pure organic luminogens, to achieve efficient RTP, it is essential to promote spin–orbit coupling to enable efficient ISC to the triplet state and to suppress the vibrational dissipations. Herein, aromatic acids were chosen based on the following considerations: firstly, carbonyl groups can effectively enhance spin–orbit coupling and thus ISC process;\textsuperscript{24} secondly, acids readily form strong and effective intermolecular interactions such as hydrogen bonds in the condensed states,\textsuperscript{25} which can significantly impede the nonradiative depopulation of triplet excitons. As a typical aromatic diacid, terephthalic acid (TPA) was first investigated. In oxygen-free ethanol, TPA emits UV light with the maximum at 319 nm in a low solution efficiency ($\Phi_s$) of 0.57 ± 0.07%, indicating it is practically nonluminescent. When dotted on a TLC plate, also no emission is observed (Fig. S4, ESI†).

The low photoluminescence (PL) efficiency of TPA in solutions and disordered amorphous states should be ascribed to the active vibrational and rotational dissipations.\textsuperscript{12,14,21} Unlike these solutions and disordered solids, crystalline powders of TPA exhibit intense deep blue emission (388 nm, Fig. 1A and B) with the crystalline efficiency ($\Phi_c$)\textsuperscript{35} of 8.4 ± 0.3%. With the delay time ($\tau_d$)\textsuperscript{27} of 0.5 ms, no signal is recorded for the solution emission, whereas a peak (392 nm) and a shoulder (511 nm) assignable to DF and RTP are observed for the crystal emission. Further transient PL measurement reveals the presence of both short- and long-lived species with lifetimes ($\tau_i$) of 0.53 ns and 0.16 ms (monitored at 380 nm, Fig. 1C), indicating the coexistence of prompt fluorescence and DF for the crystal emission. These results clearly suggest the CIDE characteristics of TPA, which is seldom observed in pure organic luminogens. Notably, DF of TPA crystals is slightly red shifted compared to that of the prompt spectrum, which is also observed in other systems.\textsuperscript{26} Though the exact mechanism remains an open question, it is suggested that the red-shift of DF is caused by the difference in nuclear configuration in the singlet and triplet excited states.\textsuperscript{28,29}

the longer one should be ascribed to RTP. Further transient PL measurement demonstrates the $\langle \tau \rangle$ values of prompt fluorescence/RTP for IPA and TFTPA crystals are 1.81 ns/289.86 ms and 0.79 ns/17.93 ms (Fig. 2E, F and 3C), respectively. Meanwhile, besides the ultralong RTP, a durable lifetime of 9.57 ms is also detected for the DF emission of IPA crystals (Fig. 2E).

The above results disclose the CIDE nature of both IPA and TFTPA luminogens. Previously, crystallization-induced emission (CIE, normally fluorescence)\textsuperscript{29,30} and CIP\textsuperscript{12,21} phenomena were found and developed. However, CIDE for pure organic luminogens, particularly for those without heavy atoms, is virtually an unexplored research area. To gain further insights into the mechanism, crystal structures\textsuperscript{31} of the luminogens are investigated. As depicted in Fig. 4, numerous C–O···H–O (1.528, 1.623, 1.703, 2.008, 2.710 Å), C–O···H–C (2.639, 2.688 Å), C=O···O–H (2.581, 2.608, 2.682, 2.857, 2.903 Å), H–O···H–C (2.544 Å), O=···H–O (2.429, 2.502, 2.573, 2.574 Å), O–H···H–O (2.166, 2.200, 2.280, 2.296 Å), C–H···O–H (2.662 Å), H–O···π (3.154 Å), C–F···H–O (2.647 Å), H–O···H–O (1.746, 2.445 Å) and H–O···O–H (2.558 Å) short contacts, as well as partial edge-to-edge π–π interactions (3.396 Å) are present in the acid crystals, forming two-dimensional (2D, TPA, Fig. 4A) and three-dimensional (3D, IPA and TFTPA, Fig. 4B and S5, ESI\textsuperscript{†}) intermolecular interaction networks. Such abundant and effective interactions firmly lock the molecules and thereby rigidify their conformations. It is also noted that π–π interactions in IPA crystals demonstrate two competitive effects. On the one hand, they may decrease the crystal emission via the formation of excimers, however, this adverse effect should be limited because of only small overlaps of the π segments; on the other hand, they contribute to the conformation rigidification, which is favorable for the light emission due to decreased nonradiative dissipations.

Now it becomes clear that in solutions, the excitons of these luminogens are mainly deactivated through nonradiative channels because of the active intramolecular motions (rotations and vibrations) and intermolecular collisions, thus making the luminogenic molecules almost non-emissive. In crystals, however, such intramolecular motions and intermolecular collisions are significantly inhibited due to the
conformation rigidification resulting from the efficacious interactions, thus diminishing the radiationless relaxations and boosting the emissions. Such a mechanism is also supported by the cryogenic experiments. As exampled by IPA, when its ethanol solution was frozen by liquid nitrogen (77 K), it gets emissive upon irradiation, also with an afterglow being observed after the stopping of photoexcitation (Video S2, ESI†). Notably, the light emission in frozen solutions is much weaker compared to that in crystals. These results indicate that crystallization performs similarly and even better than the cryogenic conditions that are normally adopted to observe phosphorescence, therefore allowing the observation of phosphorescence at room temperature and alleviating constraints of troublesome cryogenic experiments.

The above results illustrate the CIDE characteristics of proper aromatic acids. Esters are the most common derivatives of acids. Despite the elimination of typical hydrogen bonds in crystals, the presence of carbonyl groups and possible new contacts prompted us to check whether their esters are also CIDE-active. Herein, dimethyl terephthalate (DMTPA) and dimethyl tetrafluoroterephthalate (DMTFTPA) were chosen as the representatives. In analogy to acids, both DMTPA and DMTFTPA do not show any noticeable emissions in ethanol, whose emission maxima/Φ values are 320 nm/0.09 ± 0.01% and 347 nm/0.40 ± 0.05%, respectively. The low efficiencies disclose the nonluminescent attribute of both esters in solutions. Under 300 nm UV light irradiation, no visible emission is observed for DMTPA crystals due to their inherent UV light emitting properties (*vide infra*), whereas bright blue light is observed for DMTFTPA crystals (Fig. 5A and B). Further measurements show the PL peaks/Φ values of 323 nm/1.5 ± 0.3% and 347, 492 nm/2.7 ± 0.3% for the crystals of DMTPA and DMTFTPA (Fig. 5C and E), respectively, exhibiting remarkable emission enhancement upon crystallization.

The delayed emission spectra (t = 0.1 ms) of DMTPA and DMTFTPA crystals show emission peaks at 331/446 and 352/492 nm (Fig. 5C and E), respectively. The former peaks are approaching to those of prompt crystal emissions and solution emissions, proving they are delayed fluorescence, whereas the latter peaks should be assigned to RTP, considering their large Stokes shifts and long (τ) values of ~2.69 (DMTPA) and 9.12 ms (DMTFTPA) (Fig. 5D and F). The mean lifetimes of the prompt fluorescence of both crystals were also determined, giving (τ) values of ~1.17 and 9.12 ns for DMTPA and DMTFTPA,
respectively. These results suggest that both ester crystals emit prompt fluorescence, DF and RTP, exhibiting similar CIDE characteristics as their acid parents.

Structure and perspective molecular packing of both crystals are depicted in Fig. 6. Large numbers of C==O···H–C (2.623 Å) and C==O···C–H (3.172 Å) short contacts form a 2D interaction network in DMTPA (Fig. 6A); meanwhile, even more abundant C–F···H–C (2.805 Å), C–F···F–C (2.615 Å), C–F···O–C (2.958 Å), C==O···O–C (2.704 Å) and C==O···π (2.981 Å) intermolecular interactions constitute a firmly locked 3D network (Fig. 6B–E) in DMTFTPA. These effective interactions yield rigidified molecular conformations in crystals, which decrease vibrational dissipations and afford enhanced emissions. Compared to TPA, DMTPA exhibits much lower crystal efficiency, which might be ascribed to the absence of powerful hydrogen bonds. However, DMTFTPA shows similar or even higher crystal efficiency than TTPA, possibly ascribed to the formation of 3D interaction networks.

To gain more insights into the photophysical processes of the above compounds, theoretical calculations (for computational details, see the ESI†) were conducted. The calculated energy gap and spin–orbit coupling between the involved singlet and triplet states in both gas phases (gas) and crystals (crst) are summarized in Tables S3 and S4 (ESI†). Based on the Franck–Condon principle, the ISC rate is mainly determined by the energy gap and spin–orbit coupling between singlet and triplet states. Small energy gap and large spin–orbit coupling are favorable for the ISC process. Taking TPA for example, for both gas phase and crystal, there are two excited triplet states (T1 and T2) lying below the first excited singlet state (S1), suggesting the possible occurrence of ISCs of $S_1 \leftrightarrow T_1$ and $S_1 \leftrightarrow T_2$. From gas phase to crystal, though the energy gap between $S_1$ and $T_1 (\Delta E_{S_1,T_1})$ is increased from 0.605 to 0.762 eV, that between $S_1$ and $T_2 (\Delta E_{S_1,T_2})$ is significantly decreased from 0.375 to 0.229 eV (Fig. 7, Table S3, ESI†). Moreover, upon crystallization, the spin–orbit coupling between $S_1$ and $T_1$ is increased from 4.71 to 11.02 cm$^{-1}$, far larger than those ($\alpha \approx 0.1$ cm$^{-1}$) of hetero-free pure organic molecules. Both above changes indicate ISC and reverse ISC processes become much easier through the effective $S_1 \leftrightarrow T_2$ path in the crystalline state. Meanwhile, the spin–orbit coupling between $S_0$ and $T_1$ is also boosted upon crystallization, suggesting more efficient phosphorescence emission. Notably, the oscillator strength is increased by 55 times in crystals compared to that in gas phase, indicating significantly enhanced radiative transition in the crystals. These calculation results agree well with the experimental results.

Photophysical properties of the aromatic acids and esters are summarized in Table 1. Clearly, while they only emit weak fluorescence with fairly low efficiency ($\Phi_F \leq 0.57\%$) in oxygen-free ethanol, they become more emissive in crystals with $\Phi_F$ up to 15.3%, giving an enhancement factor ($\Phi_F/\Phi_s$) as high as $\sim$46. In solutions (or any other disordered phases), triplet emission is not optimal, and only weak fluorescence from the singlet manifold is generated due to active molecular motions (rotations, vibrations and collisions, Fig. 8A). In crystals, aided by effective intermolecular interactions, molecular conformations become rigidified and molecular motions are significantly hindered, thus making nonradiative deactivations frustrated and subsequently leading to enhanced emissions. Moreover, due to the carbonyl group promoted spin–orbit coupling and singlet–triplet equilibrium, DF and RTP from singlet and triplet manifolds are simultaneously triggered, thus exhibiting CIDE characteristics (Fig. 8B).

Different to strictly fluorescence and purely phosphorescence emitting molecules, such efficient, simultaneous and intrinsic fluorescence and phosphorescence in a single pure organic compound at ambient conditions is unusual and remains virtually unexplored.\textsuperscript{19a,32} It not only holds great promise to study dynamic processes and the underlying spin correlations of organic semiconductors within the lifetime of the excitons, but also provides new opportunities for use as optical sensors and attenuators, and spin-independent intermediates for Förster resonant energy transfer.\textsuperscript{32,33}

Ethanol was used to prepare the solutions. Abbreviations: $\lambda_{ab}$ = absorption peak in solution (concentration = 20 μM, Fig. S6, ESI); $\lambda_{em,a}$ = emission peak in solution, $\lambda_{em,s}$ = crystal emission peak without delay, $\lambda_{delay}$ = peak of delayed crystal emission, $\tau_{em,c}$ = lifetime of delayed crystal emission, $\tau_{em,s}$ = lifetime of prompt fluorescence, $\tau_{DF}$ = lifetime of delayed fluorescence, $\tau_f$ = lifetime of phosphorescence, nd = not determined.

Fig. 8  Schematic illustration of the CIDE phenomenon: (A) highly active molecular motions induced weak fluorescence in solutions and (B) conformation rigidification boosted both fluorescence (prompt and delayed) and phosphorescence in crystals.

It is also noted that the fluorescent emission of the acid crystals are largely red-shifted (up to 75 nm) compared to those in solutions, which should arise from the configuration rigidification and/or dimerization of the molecules. As schematized in the medial part of Fig. 8B, intrinsic intermolecular hydrogen bonds result in the dimers with a more extended planar skeleton. Such a structural feature on one hand increases the rigidity of the molecules, expanding the molecular conjugation; on the other hand may further enhance the electronic delocalization through intermolecular electronic communication, thus resulting in red-shifted emission. For esters, the emissions of crystals and solutions are almost identical owing to the absence of such dimer-like stacking.

Conclusions

In summary, unprecedented CIDE phenomenon in a group of metal- and heavy atom-free aromatic acids and esters is observed under ambient conditions. While carbonyl groups readily promote the ISC processes, these luminogens are actually only faintly fluorescent in solutions due to active molecular motions (rotations, vibrations and collisions). However, they become highly emissive in the crystals due to abundant and effective intermolecular interactions, which rigidify the molecular conformations and diminish the vibrational dissipations. Moreover, besides prompt fluorescence from singlet states, crystallization also triggers simultaneous DF and RTP from the triplet manifold. Specifically, persistent RTP ($\tau_f$ = 290 ms) from IPA crystals is achieved at ambient conditions, which is rarely observed in pure organic luminogens. Such a unique CIDE phenomenon not only provides ideal model systems for fundamental research in revealing the underlying relationships between singlet and triplet states, but also paves the way for developing new materials with RTP and DF for biological (e.g. bioimaging and biosensing) and optoelectronic applications.
