Abstract

Article comments can provide supplementary opinions and facts for readers, thereby increase the attraction and engagement of articles. Therefore, automatically commenting is helpful in improving the activeness of the community, such as online forums and news websites. Previous work shows that training an automatic commenting system requires large parallel corpora. Although part of articles are naturally paired with the comments on some websites, most articles and comments are unpaired on the Internet. To fully exploit the unpaired data, we completely remove the need for parallel data and propose a novel unsupervised approach to train an automatic article commenting model, relying on nothing but unpaired articles and comments. Our model is based on a retrieval-based commenting framework, which uses news to retrieve comments based on the similarity of their topics. The topic representation is obtained from a neural variational topic model, which is trained in an unsupervised manner. We evaluate our model on a news comment dataset. Experiments show that our proposed topic-based approach significantly outperforms previous lexicon-based models. The model also profits from paired corpora and achieves state-of-the-art performance under semi-supervised scenarios.

Introduction

Making article comments is a fundamental ability for an intelligent machine to understand the article and interact with humans. It provides more challenges because commenting requires the abilities of comprehending the article, summarizing the main ideas, mining the opinions, and generating the natural language. Therefore, machine commenting is an important problem faced in building an intelligent and interactive agent. Machine commenting is also useful in improving the activeness of communities, including online forums and news websites. Article comments can provide extended information and external opinions for the readers to have a more comprehensive understanding of the article. Therefore, an article with more informative and interesting comments will attract more attention from readers. Moreover, machine commenting can kick off the discussion about an article or a topic, which helps increase user engagement and interaction between the readers and authors.

Because of the advantage and importance described above, more recent studies have focused on building a machine commenting system with neural models (Qin et al. 2018). One bottleneck of neural machine commenting models is the requirement of a large parallel dataset. However, the naturally paired commenting dataset is loosely paired. Qin et al. (2018) were the first to propose the article commenting task and an article-comment dataset. The dataset is crawled from a news website, and they sample 1,610 article-comment pairs to annotate the relevance score between articles and comments. The relevance score ranges from 1 to 5, and we find that only 6.8% of the pairs have an average score greater than 4. It indicates that the naturally paired article-comment dataset contains a lot of loose pairs, which is a potential harm to the supervised models. Besides, most articles and comments are unpaired on the Internet. For example, a lot of articles do not have the corresponding comments on the news websites, and the comments regarding the news are more likely to appear on social media like Twitter. Since comments on social media are more various and recent, it is important to exploit these unpaired data.

Another issue is that there is a semantic gap between articles and comments. In machine translation and text summarization, the target output mainly shares the same points with the source input. However, in article commenting, the comment does not always tell the same thing as the corresponding article. Table\textsuperscript{1} shows an example of an article and several corresponding comments. The comments do not directly tell what happened in the news, but talk about the underlying topics (e.g. NBA Christmas Day games, LeBron James). However, existing methods for machine commenting do not model the topics of articles, which is a potential harm to the generated comments.

To this end, we propose an unsupervised neural topic model to address both problems. For the first problem, we completely remove the need of parallel data and propose a novel unsupervised approach to train a machine commenting system, relying on nothing but unpaired articles and comments. For the second issue, we bridge the articles and comments with their topics. Our model is based on a retrieval-based commenting framework, which uses the news as the query to retrieve the comments by the similarity of their topics. The topic is represented with a variational topic, which helps increase user engagement and interaction between the readers and authors.

\textsuperscript{*}Contribution during internship at Microsoft Research Asia.
The generative model, such as the popular sequence-to-sequence model, is a direct choice for supervised machine commenting. One can use the title or the content of the article as the encoder input, and the comments as the decoder output. However, we find that the mode collapse problem is severed with the sequence-to-sequence model. Despite the input articles being various, the outputs of the model are very similar. The reason mainly comes from the contradiction between the complex pattern of generating comments and the limited parallel data. In other natural language generation tasks, such as machine translation and text summarization, the target output of these tasks is strongly related to the input, and most of the required information is involved in the input text. However, the comments are often weakly related to the input articles, and part of the information in the comments is external. Therefore, it requires much more paired data for the supervised model to alleviate the mode collapse problem.

**Falsely Negative Samples** One article can have multiple correct comments, and these comments can be very semantically different from each other. However, in the training set, there is only a part of the correct comments, so the other correct comments will be falsely regarded as the negative samples by the supervised model. Therefore, many interesting and informative comments will be discouraged or neglected, because they are not paired with the articles in the training set.

**Semantic Gap** There is a semantic gap between articles and comments. In machine translation and text summarization, the target output mainly shares the same points with the source input. However, in article commenting, the comments often have some external information, or even tell an opposite opinion from the articles. Therefore, it is difficult to automatically mine the relationship between articles and comments.

**Solutions**

Facing the above challenges, we provide three solutions to the problems.
### Retrieval Model

Given a large set of candidate comments, the retrieval model can select some comments by matching articles with comments. Compared with the generative model, the retrieval model can achieve more promising performance. First, the retrieval model is less likely to suffer from the mode collapse problem. Second, the generated comments are more predictable and controllable (by changing the candidate set). Third, the retrieval model can be combined with the generative model to produce new comments (by adding the outputs of generative models to the candidate set).

### Unsupervised Learning

The unsupervised learning method is also important for machine commenting to alleviate the problems described above. Unsupervised learning allows the model to learn more complex patterns of commenting and improves the generalization of the model. Many comments provide some unique opinions, but they do not have paired articles. For example, many interesting comments on social media (e.g. Twitter) are about recent news, but require redundant work to match these comments with the corresponding news articles. With the help of the unsupervised learning method, the model can also learn to generate these interesting comments. Additionally, the unsupervised learning method does not require negative samples in the training stage, so that it can alleviate the negative sampling bias.

### Modeling Topic

Although there is semantic gap between the articles and the comments, we find that most articles and comments share the same topics. Therefore, it is possible to bridge the semantic gap by modeling the topics of both articles and comments. It is also similar to how humans generate comments. Humans do not need to go through the whole article but are capable of making a comment after capturing the general topics.

### Proposed Approach

We now introduce our proposed approach as an implementation of the solutions above. Then, we define the retrieval-based commenting framework. After that, a neural variational topic model is introduced to model the topics of the comments and the articles. Finally, semi-supervised training is used to combine the advantage of both supervised and unsupervised learning.

### Retrieval-based Commenting

Given an article, the retrieval-based method aims to retrieve a comment from a large pool of candidate comments. The article consists of a title $t$ and a body $b$. The comment pool is formed from a large scale of candidate comments $[c_1, c_2, \ldots, c_N]$, where $N$ is the number of the unique comments in the pool. In this work, we have 4.5 million human comments in the candidate set, and the comments are various, covering different topics from pets to sports.

The retrieval-based model should score the matching between the upcoming article and each comments, and return the comments which is matched with the articles the most. Therefore, there are two main challenges in retrieval-based commenting. One is how to evaluate the matching of the articles and comments. The other is how to efficiently compute the matching scores because the number of comments in the pool is large.

To address both problems, we select the “dot-product” operation to compute matching scores. More specifically, the model first computes the representations of the article $h_a$ and the comments $h_c$. Then the score between article $a$ and comment $c$ is computed with the “dot-product” operation:

$$s(a, c) = h_a^T h_c$$  \hspace{1cm} (1)

The dot-product scoring method has proven a successful in a matching model (Henderson et al. 2017). The problem of finding datapoints with the largest dot-product values is called Maximum Inner Product Search (MIPS), and there are lots of solutions to improve the efficiency of solving this problem. Therefore, even when the number of candidate comments is very large, the model can still find comments with the highest efficiency. However, the study of the MIPS is out of the discussion in this work. We refer the readers to relevant articles for more details about the MIPS (Shrivastava and Li 2014; Auvolat and Vincent 2015; Shen et al. 2015; Guo et al. 2016). Another advantage of the dot-product scoring method is that it does not require any extra parameters, so it is more suitable as a part of the unsupervised model.

### Neural Variational Topic Model

We obtain the representations of articles $h_a$ and comments $h_c$ with a neural variational topic model. The neural variational topic model is based on the variational autoencoder framework, so it can be trained in an unsupervised manner. The model encodes the source text into a representation, from which it reconstructs the text.

We concatenate the title and the body to represent the article. In our model, the representations of the article and the comment are obtained in the same way. For simplicity, we denote both the article and the comment as “document”. Since the articles are often very long (more than 200 words), we represent the documents into bag-of-words, for saving both the time and memory cost. We denote the bag-of-words representation as $X \in \mathbb{R}^{|V|}$, where $x_i \in \mathbb{R}^{|V|}$ is the one-hot representation of the word at $i^{th}$ position, and $|V|$ is the number of words in the vocabulary. The encoder $q(h|X)$ compresses the bag-of-words representations $X$ into topic representations $h \in \mathbb{R}^K$:

$$z = \text{tanh} (W_1 X + b_1)$$  \hspace{1cm} (2)

$$q(h|X) = \text{tanh} (W_2 z + b_2)$$  \hspace{1cm} (3)

where $W_1, W_2, b_1$, and $b_2$ are the trainable parameters. Then the decoder $p(X|h)$ reconstructs the documents by independently generating each words in the bag-of-words:

$$p(X|h) = \prod_{i=1}^{N} p(x_i|h)$$  \hspace{1cm} (4)
\[ p(x_i|h) = \text{softmax}(h^T M x_i) \] (5)

where \( N \) is the number of words in the bag-of-words, and \( M \in \mathbb{R}^{K \times |V|} \) is a trainable matrix to map the topic representation into the word distribution.

In order to model the topic information, we use a Dirichlet prior rather than the standard Gaussian prior. However, it is difficult to develop an effective reparameterization function for the Dirichlet prior to train VAE. Therefore, following (Srivastava and Sutton 2017), we use the Laplace approximation (Hennig et al. 2012) to Dirichlet prior \( p(h) = LN(h|\mu_0, \sigma_0) \):

\[ \mu_{oi} = \log \alpha_i - \frac{1}{K} \sum_{j=1}^{K} \log \alpha_j \] (6)

\[ \sigma_{oi} = \frac{1}{\alpha_i} (1 - \frac{2}{K}) + \frac{1}{K^2} \sum_{j=1}^{K} \frac{1}{\alpha_j} \] (7)

where \( LN \) denotes the logistic normal distribution, \( K \) is the number of topics, and \( \alpha \) is a parameter vector. Then, the variational lower bound is written as:

\[ L = -\frac{1}{2} \left( \sigma^T \sigma_0^{-1} + (\mu_0 - \mu)^T \text{diag}(\sigma_0^{-1})(\mu_0 - \mu) \right) \]
\[ - K + \log |\sigma|_0 \] + \( \sum_{i=1}^{N} \log p(x_i|\theta) \] (8)

where the first term is the KL-divergence loss and the second term is the reconstruction loss. The mean \( \mu \) and the variance \( \sigma \) are computed as follows:

\[ \mu = W_3 h + b_3 \] (9)

\[ \sigma = W_4 h + b_4 \] (10)

We use the \( \mu \) and \( \sigma \) to generate the samples \( \theta = \mu + \sigma^{1/2} \epsilon \) by sampling \( \epsilon \sim N(0, 1) \), from which we reconstruct the input \( X \).

At the training stage, we train the neural variational topic model with the Eq. [8]. At the testing stage, we use \( q(h|X) \) to compute the topic representations of the article \( h_a \) and the comment \( h_c \).

Training

In addition to the unsupervised training, we explore a semi-supervised training framework to combine the proposed unsupervised model and the supervised model. In this scenario we have a paired dataset that contains article-comment parallel contents \( (s, c) \in \mathbb{L} \), and an unpaired dataset that contains the documents (articles or comments) \( d \in \mathbb{U} \). The supervised model is trained on \( \mathbb{L} \) so that we can learn the matching or mapping between articles and comments. By sharing the encoder of the supervised model and the unsupervised model, we can jointly train both the models with a joint objective function:

\[ L = L_{\text{unsuper}} + \lambda L_{\text{super}} \] (11)

where \( L_{\text{unsuper}} \) is the loss function of the unsupervised learning (Eq. refloss), \( L_{\text{super}} \) is the loss function of the supervised learning (e.g. the cross-entropy loss of Seq2Seq model), and \( \lambda \) is a hyper-parameter to balance two parts of the loss function. Hence, the model is trained on both unpaired data \( \mathbb{U} \), and paired data \( \mathbb{L} \).

Experiments

Datasets

We select a large-scale Chinese dataset (Qin et al. 2018) with millions of real comments and a human-annotated test set to evaluate our model. The dataset is collected from Tencent News which is one of the most popular Chinese websites for news and opinion articles. The dataset consists of 198,112 news articles. Each piece of news contains a title, the content of the article, and a list of the users’ comments. Following the previous work (Qin et al. 2018), we tokenize all text with the popular python package jieba and filter out short articles with less than 30 words in content and those with less than 20 comments. The dataset is split into training/validation/test sets, and they contain 191,502/5,000/1,610 pieces of news, respectively. The whole dataset has a vocabulary size of 1,858,452. The average lengths of the article titles and content are 15 and 554 Chinese words. The average comment length is 17 words.

Implementation Details

The hidden size of the model is 512, and the batch size is 64. The number of topics \( K \) is 100. The weight \( \lambda \) in Eq. [11] is 1.0 under the semi-supervised setting. We prune the vocabulary, and only leave 30,000 most frequent words in the vocabulary. We train the model for 20 epochs with the Adam optimizing algorithms (Kingma and Ba 2014). In order to alleviate the KL vanishing problem, we set the initial learning to 5^{-5}, and use batch normalization (Ioffe and Szegedy 2015) in each layer. We also gradually increase the KL term from 0 to 1 after each epoch.

Baselines

We compare our model with several unsupervised models and supervised models.

Unsupervised baseline models are as follows:

- **TF-IDF (Lexical, Non-Neural)** is an important unsupervised baseline. We use the concatenation of the title and the body as the query to retrieve the candidate comment set by means of the similarity of the tf-idf value. The model is trained on unpaired articles and comments, which is the same as our proposed model.

- **LDA (Topic, Non-Neural)** is a popular unsupervised topic model, which discovers the abstract “topics” that occur in a collection of documents. We train the LDA with the articles and comments in the training set. The model retrieves the comments by the similarity of the topic representations.

- **NVDNM (Lexical, Neural)** is a VAE-based approach for document modeling (Miao, Yu, and Blunsom 2016). We compare our model with this baseline to demonstrate the effect of modeling topic.

The supervised baseline models are:

- **S2S (Generative)** (Sutskever, Vinyals, and Le 2014) is a supervised generative model based on the seq- uence-to-sequence network with the attention mechanism (Bahdanau, Cho, and Bengio 2014). The model uses the titles and the bodies of the articles as the encoder input, and generates the comments with the decoder.
- **IR (Retrieval)** (Qin et al. 2018) is a supervised retrieval-based model, which trains a convolutional neural network (CNN) to take the articles and a comment as inputs, and output the relevance score. The positive instances for training are the pairs in the training set, and the negative instances are randomly sampled using the negative sampling technique (Mikolov et al. 2013).

**Retrieval Evaluation**

For text generation, automatically evaluate the quality of the generated text is an open problem. In particular, the comment of a piece of news can be various, so it is intractable to find out all the possible references to be compared with the model outputs.

Inspired by the evaluation methods of dialogue models, we formulate the evaluation as a ranking problem. Given a piece of news and a set of candidate comments, the comment model should return the rank of the candidate comments. The candidate comment set consists of the following parts:

- **Correct**: The ground-truth comments of the corresponding news provided by the human.
- **Plausible**: The 50 most similar comments to the news. We use the news as the query to retrieve the comments that appear in the training set based on the cosine similarity of their tf-idf values. We select the top 50 comments that are not the correct comments as the plausible comments.
- **Popular**: The 50 most popular comments from the dataset. We count the frequency of each comments in the training set, and select the 50 most frequent comments to form the popular comment set. The popular comments are the general and meaningless comments, such as “Yes”, “Great”, “That’s right’, and “Make Sense”. These comments are dull and do not carry any information, so they are regarded as incorrect comments.
- **Random**: After selecting the correct, plausible, and popular comments, we fill the candidate set with randomly selected comments from the training set so that there are 200 unique comments in the candidate set.

Following previous work, we measure the rank in terms of the following metrics:

- **Recall@k**: The proportion of human comments found in
the top-k recommendations.

**Mean Rank (MR):** The mean rank of the human comments.

**Mean Reciprocal Rank (MRR):** The mean reciprocal rank of the human comments.

The evaluation protocol is compatible with both retrieval models and generative models. The retrieval model can directly rank the comments by assigning a score for each comment, while the generative model can rank the candidates by the model’s log-likelihood score.

**Results** Table 2 shows the performance of our models and the baselines in retrieval evaluation. We first compare our proposed model with other popular unsupervised methods, including TF-IDF, LDA, and NVDM. TF-IDF retrieves the comments by similarity of words rather than the semantic meaning, so it achieves low scores on all the retrieval metrics. The neural variational document model is based on the neural VAE framework. It can capture the semantic information, so it has better performance than the TF-IDF model. LDA models the topic information, and captures the deeper relationship between the article and comments, so it achieves improvement in all relevance metrics. Finally, our proposed model outperforms all these unsupervised methods, mainly because the proposed model learns both the semantics and the topic information.

We also evaluate two popular supervised models, i.e. seq2seq and IR. Since the articles are very long, we find either RNN-based or CNN-based encoders cannot hold all the words in the articles, so it requires limiting the length of the input articles. Therefore, we use an MLP-based encoder, which is the same as our model, to encode the full length of articles. In our preliminary experiments, the MLP-based encoder with full length articles achieves better scores than the RNN/CNN-based encoder with limited length articles. It shows that the seq2seq model gets low scores on all relevant metrics, mainly because of the mode collapse problem as described in Section Challenges. Unlike seq2seq, IR is based on a retrieval framework, so it achieves much better performance.

**Generative Evaluation**

Following previous work (Qin et al. 2018), we evaluate the models under the generative evaluation setting. The retrieval-based models generate the comments by selecting a comment from the candidate set. The candidate set contains the comments in the training set. Unlike the retrieval evaluation, the reference comments may not appear in the candidate set, which is closer to real-world settings. Generative-based models directly generate comments without a candidate set. We compare the generated comments of either the retrieval-based models or the generative models with the five reference comments. We select four popular metrics in text generation to compare the model outputs with the references: BLEU (Papineni et al. 2002), METEOR (Banerjee and Lavie 2005), ROUGE (Lin and Hovy 2003), CIDEr (Vedantam, Zitnick, and Parikh 2015).

**Result** Table 3 shows the performance for our models and the baselines in generative evaluation. Similar to the retrieval evaluation, our proposed model outperforms the other unsupervised methods, which are TF-IDF, NVDM, and LDA, in generative evaluation. Still, the supervised IR achieves better scores than the seq2seq model. With the help of our proposed model, both IR and S2S achieve an improvement under the semi-supervised scenarios.

**Analysis and Discussion**

We analyze the performance of the proposed method under the semi-supervised setting. We train the supervised IR model with different numbers of paired data. Figure 1 shows the curve (blue) of the recall@1 score. As expected, the performance grows as the paired dataset becomes larger. We further combine the supervised IR with our unsupervised model, which is trained with full unpaired data (4.8M) and different number of paired data (from 50K to 4.8M). It
shows that IR+Proposed can outperform the supervised IR model given the same paired dataset. It concludes that the proposed model can exploit the unpaired data to further improve the performance of the supervised model.

Although our proposed model can achieve better performance than previous models, there are still remaining two questions: why our model can outperform them, and how to further improve the performance. To address these queries, we perform error analysis to analyze the error types of our model and the baseline models. We select TF-IDF, S2S, and IR as the representative baseline models. We provide 200 unique comments as the candidate sets, which consists of four types of comments as described in the above retrieval evaluation setting: Correct, Plausible, Popular, and Random. We rank the candidate comment set with four models (TF-IDF, S2S, IR, and Proposed+IR), and record the types of top-1 comments.

Figure 2 shows the percentage of different types of top-1 comments generated by each model. It shows that TF-IDF prefers to rank the plausible comments as the top-1 comments, mainly because it matches articles with the comments based on the similarity of the lexicon. Therefore, the plausible comments, which are more similar in the lexicon, are more likely to achieve higher scores than the correct comments. It also shows that the S2S model is more likely to rank popular comments as the top-1 comments. The reason is the S2S model suffers from the mode collapse problem and data sparsity, so it prefers short and general comments like “Great” or “That’s right”, which appear frequently in the training set. The correct comments often contain new information and different language models from the training set, so they do not obtain a high score from S2S.

IR achieves better performance than TF-IDF and S2S. However, it still suffers from the discrimination between the plausible comments and correct comments. This is mainly because IR does not explicitly model the underlying topics. Therefore, the correct comments which are more relevant in topic with the articles get lower scores than the plausible comments which are more literally relevant with the articles. With the help of our proposed model, proposed+IR achieves the best performance, and achieves a better accuracy to discriminate the plausible comments and the correct comments. Our proposed model incorporates the topic information, so the correct comments which are more similar to the articles in topic obtain higher scores than the other types of comments. According to the analysis of the error types of our model, we still need to focus on avoiding predicting the plausible comments.

Conclusion

We explore a novel way to train a machine commenting model in an unsupervised manner. According to the properties of the task, we propose using the topics to bridge the semantic gap between articles and comments. We introduce a variation topic model to represent the topics, and match the articles and comments by the similarity of their topics. Experiments show that our topic-based approach significantly outperforms previous lexicon-based models. The model can also profit from paired corpora and achieves state-of-the-art performance under semi-supervised scenarios.
