Abstract

An important component of plant evolution is the plethora of pathways producing more than 200,000 biochemically diverse specialized metabolites with pharmacological, nutritional and ecological significance. To unravel dynamics underlying metabolic diversification, it is critical to determine lineage-specific gene family expansion in a phylogenomics framework. However, robust functional annotation is often only available for core enzymes catalyzing committed reaction steps within few model systems. In a genome informatics approach, we extracted information from early-draft gene-space assemblies and non-redundant transcriptomes to identify protein families involved in isoprenoid biosynthesis. Isoprenoids comprise terpenoids with various roles in plant-environment interaction, such as pollinator attraction or pathogen defense. Combining lines of evidence provided by synteny, sequence homology and Hidden-Markov-Modelling, we screened 17 genomes including 12 major crops and found evidence for 1,904 proteins associated with terpenoid biosynthesis. Our terpenoid genes set contains evidence for 840 core terpene-synthases and 338 triterpene-specific synthases. We further identified 190 prenyltransferases, 39 isopentenyl-diphosphate isomerases as well as 278 and 219 proteins involved in mevalonate and meyerithrol pathways, respectively. Assessing the impact of gene and genome duplication to lineage-specific terpenoid pathway expansion, we illustrated key events underlying terpenoid metabolic diversification within 250 million years of flowering plant radiation. By quantifying Angiosperm-wide versatility and phylogenetic relationships of pleiotropic gene families in terpenoid modular pathways, our analysis offers significant insight into evolutionary dynamics underlying diversification of plant secondary metabolism. Furthermore, our data provide a blueprint for future efforts to identify and more rapidly clone terpenoid biosynthetic genes from any plant species.
Introduction

To elucidate the dynamics underlying metabolic diversification across multiple lineages, it is of paramount importance to identify and distinguish the complete set of orthologous and paralogous loci present within multiple genome annotations in a phylogenetic framework [1]. Two homologous genes are referred to as orthologs if they descend from one locus present in the common ancestor lineage and split due to speciation [2,3]. By definition, orthologous genes are embedded in chromosomal segments derived from the same ancestral genomic locus, thus sharing high inter-species synteny between closely related lineages [4]. In contrast, paralogous loci refer to homologs within one lineage and are due to, for example, tandem-, transposition- or whole genome duplications (WGDs) [5,6]. Large-scale synteny is not observed for paralogs derived from small-scale events like tandem- and transposition duplication. In contrast, paralogs derived from WGDs are located within intra-species syntenic genomic blocks, and can be referred to as ohnologs or syntelogs [7,8]. Supergene loci refer to clusters of genes in close genomic proximity, often causing linkage disequilibrium [9,10]. Tandem duplicates comprise arrays of paralog supergenes that are due to, for example, errors in meiosis like unequal crossing over and have been connected to metabolic diversification in plants [11–13].

Together with the continuous progress and use of next generation sequencing techniques, genome-wide analysis of syntelog distribution provided evidence for a history of ancient shared and/or lineage-specific polyploidy events for all flowering plant lineages [4]. For example, the lineage of the model plant Arabidopsis underwent at least five polyploidy events during evolution, two preceding and three following angiosperm evolution [14]. Among those, the most recent WGD event is commonly referred to as “At-α” and is shared by all other mustard family members, including the extant sister clade of the Aethionemeae [15,16]. The more ancient At-β WGD event is in turn shared by core species in the order Brassicales, and excepting early-branching lineages such as papaya [17,18] and therefore occurred after split of the Carica lineage. At-γ refers to an older whole genome triplication (WGT) event with evidence in all Asterids (including tomato) and Rosids, grape (Vitales) and basal clades such as Pachysandra terminalis (Buxales) and Gunnera manicata (Gunnerales) [19,20]. Crops like Brassica rapa (Br-α WGT), Solanum lycopersicum and Solanum tuberosum (Sol-α WGD/WGT) also show evidence of ancient genome multiplications [21,22]. As a consequence, the level of “genome multiplicity” expected from the successive WGDs/WGTs in B. rapa (defined as “syntenic depth”) is 36x when compared to the 1x eudicot ancestor (3x due to At-γ, 2x due to At-β, another 2x due to At-α as well as 3x due to Br-α, see above).

Evidence is now accumulating for significant impact of ancient and recent gene and genome duplication events to birth and diversification of key biological traits. Duplication was proposed to be a key factor in expansion of regulatory and enzymatic pathways involved in generation of >200,000 diverse biochemical secondary metabolites in the flowering plant lineage [23–25]. For example, a differential impact of various duplication modes has been revealed for plant resistance proteins [26]. Likewise, the last three polyploidy events of the Arabidopsis lineage (see above) likely contributed to shaping the genetic versatility of the glucosinolate pathway, a class of plant secondary metabolites with beneficial effects to human health and nutrition [25]. Similarly, polyploidy has been brought in connection to the origin of C4-photosynthesis in Cleomaceae [27].

Little is known about the impact of genome duplication to diversification of isoprenoid pathways. Isoprenoids form a highly diverse class of metabolites commonly found in all kingdoms of life [28]. In angiosperms, for example, phytol side-chain substitutes of chlorophyll and carotenoid pigments as well as phytohormones like gibberellin or brassinosteroids are well-characterized isoprenoids involved in basic metabolic processes that are essential for plant
growth and development [29–31]. To the knowledge of the authors, evidence for the connection of polyploidy to secondary metabolite pathway evolution is to date only available for glucosinolates biosynthesis in the mustard family [25]. Note that both glucosinolates and terpenoids are defined as specialized or secondary metabolites that play major roles in plant-insect interactions like, for example, attraction of beneficial organisms or defense against herbivores [32]. Boutanaev et al. investigated core terpene synthase (TPS) genes (which generate terpene scaffold diversity) and identified micro-syntenic clusters that have arisen within recent evolutionary history by gene duplication, acquisition of new function and genome reorganization [33]. Note that in concert with TPS genes, terpenoid biosynthesis depends on various independent pathways (referred to as modules hereafter). Here, we performed further extended comparative analysis of various independent terpenoid biosynthetic modules in context of gene- and genome duplication.

Briefly, a sequential combination of six distinct reaction modules acts in concert to convert primary metabolites to longer-chain compounds mediating designated biological function. Therefore, plant terpenoid biosynthesis displays “modular” organization, including (1) TPS genes, (2) IPP isomerases (IDI), (3) prenyltransferases (PTF), (4) genes from MVA and (5) MEP pathways as well as (6) triterpene-specific synthases (see Fig 1 for a comprehensive overview). Notably, genes involved in the latter three modules share a common evolutionary origin (i.e. genes are homologous) as previously described based on analyses of Solanaceae species [34]. All terpenoids are synthesized from two universal C5-isoprenoid building blocks (a) isopentenyl diphosphate (IPP) and (b) its isomer dimethylallyl diphosphate (DMAPP). In plants, IPP is synthesized independently by the mevalonate (MVA, shown in black in Fig 1) and methylerythritol phosphate (MEP, Shown in purple in Fig 1) pathways. In contrast, DMAPP is synthesized by enzymes of the MEP pathway only [35]. Both DMAPP and IPP compounds can be isomerized by enzymes of the IPP isomerase type (IDI, shown in turquoise in Fig 1) [36].
Due to the economic relevance of enzymes involved in MEP and MVA pathways as well as IPP isomerases, the underlying biochemistry has been thoroughly investigated. Note that both MVA and MEP pathways comprise sequential arrangements of consecutive reaction steps leading to formation of intermediate products [37]. Analysis of stoichiometry indicated dosage-dependent effects regarding both pathways in yeast [38]. Going beyond yeast, comparative network analysis of MVA and MEP pathways in prokaryotes and the model plant *A. thaliana* characterized dosage-dependent effects of enzymes in both pathways and elevations of corresponding metabolite concentrations in plants and humans. This indicates that enzymes involved in MVA and MEP pathways operate concentration-dependent across all kingdoms of life [37,39]. Similarly, genetic engineering of *Escherichia coli* in context of industrial terpenoid production revealed that enzymes of the IDI group function in a dosage-dependent manner [40]. This was confirmed by mechanistic investigations of IDI enzymes in *Thermus thermophilus* due to their relevance for a wide range of biotechnological applications [41]. Likewise, dosage-dependent effects have been revealed for plant-derived IDI enzymes. For example, the economic potential of *in vitro* production of caoutchouc led to cloning, heterologous expression and functional characterization (i.e. determination of biochemical function) of IDI loci from the rubber tree *Hevea brasiliensis* [42].

Enzymes of the prenyltransferase class (PTF, shown in green in Fig 1) subsequently catalyze formation of C10-prenyl diphosphate molecules. Moreover, they can mediate the (optional) elongation of the C10-backbone by the addition of further C5-isopentenyl diphosphate units necessary for formation of di- and sesquiterpenes including longer-chain (C25-C55) tetra- and polyprenylterpenes [43–45]. Terpene synthases (encoded by TPS genes, shown in red in Fig 1) catalyze conversion of specific C10-, C15 or C20 isoprenoid precursors to specialized monoterpenes (C10), sesquiterpenes (C15) and diterpenes (C20), building a module further downstream within terpenoid biosynthesis, respectively [29,46]. Specialized triterpene synthases catalyze formation of pentacyclic triterpenes (such as lupane and squalene) (C30, shown in blue in Fig 1) [47–49]. Note that those compounds can be further modified in distant branches of plant secondary metabolism, for example to triterpene alcohols (such as lanosterol and cycloarthenol) with various bioactivities [50,51]. Entry to the aforementioned MEP pathway was previously proposed to be catalyzed by two divergent 1-deoxy-D-xylulose 5-phosphate synthase isoforms in *S. lycopersicum* (SIDXS1 / SIDXS2) and *A. thaliana* (AtDXS1 / AtDXS2) [28,52–54]. In tomato, DXS1 is ubiquitously expressed whereas DXS2 transcripts are abundant in a few tissue types including glandular trichomes. Trichomes are hair-like structures present in the aerial parts of many plant species. They exhibit tremendous diversity but are of general interest to plant breeders since they are often responsible for the production of plant secondary metabolites with various bioactivities, including terpenoids [55–57]. Interestingly, knock-down of DXS2 led to a differential distribution of mono- and sesquiterpenes within tomato glandular trichomes as well as to a significant increase of trichome density, giving rise to economic and ecological potential to this small gene family [52].

The core-TPS gene family has been most intensively studied in the model plant *Arabidopsis thaliana*. The ecotype Col-0, that contains 32 full-length functional and 8 pseudogenes of the terpene synthase type, of which about a third have been annotated to a designated biochemical function by functional characterization [29,58–64]. Most of the Col-0 core-TPS genes are constitutively expressed in roots, flowers or leaves for production of mono-, di- or sesquiterpenes whereas some are up-regulated under presence of specific stress-related stimuli [58,64,65]. Notably, 27 of the 32 Col-0 core-TPS genes comprise supergene clusters organized in 16 tandem arrays [11], whereas two of them constitute an ohnolog duplicate gene pair due to the most recent At-α ancient whole genome duplication event (see above) [8]. Beyond *A. thaliana*, efforts to identify core-TPS genes have been published for tomato (*S. lycopersicum*) [66], orange (*C. nucifera*) [67], cucumber (*C. melo*), pear (*P. communis*), and grape (*V. vinifera*) [68,69].
sinensis) [67], eucalyptus (E. grandis) [68], grape (V. vinifera) [69], millet (S. bicolor), apple (M. domestica) [70] and the basal Angiosperm Amborella (A. trichopoda) [71]. However, functional characterization (i.e. distinct biochemical function) of all TPS genes present within a species are currently available for tomato and the model plant Arabidopsis only. The complete set of biosynthetic elements involved in both MEP and MVA pathways as well as other terpenoid-associated prenyltransferases including triterpene-specific synthases has to-date only been described in Arabidopsis with a total of 34 genes [35]. Among those, 15 possess prenyltransferase activity, whereas nine and eight belong to the MVA and MEP pathway, respectively. Furthermore, the A. thaliana genome contains two genes encoding proteins of the IPP isomerase (IDI) type with similar bioactivities [35,36]. In total, the gene count of all modules within the complete terpenoid biosynthetic pathway therefore rises to 66 including 32 functional core-TPS genes in Arabidopsis, with a 64% (42 / 66) fraction of tandem duplicate supergenes and 21% (14 / 66) comprising ohnolog duplicate gene pairs dating back to the At-α, At-γ or At-β ancient whole genome multiplication events (see above) [8,11,72].

In this study, we employed a meta-method by combining evidence provided by sequence homology (BLAST), HMM Modelling (interpro scan) and genomic context (SynMap) for robust annotation of genes involved in all modules of terpenoid biosynthesis on a uniquely broad phylogenomics framework. First, we infer novel annotation for loci previously not brought in connection to terpenoid biosynthesis within 17 genome assembly including twelve major crops, thereby providing insights to diversification of plant secondary metabolism during 250 MA of flowering plant evolution. Second, we assessed and compared key factors contributing to copy number variation across all terpenoid biosynthetic modules, thereby providing evidence for the impact of gene- and genome duplication to metabolic diversification in plants. Third, we established a novel clade of duplicate genes with pleiotropic effects in control of trichome density and terpenoid biosynthesis, thereby providing data that support the concept of functional divergence following gene and genome duplication. In summary, our data offer significant insight into evolutionary dynamics underlying diversification of plant secondary metabolism. Furthermore, we provide a blueprint for future efforts to identify and more rapidly modify terpenoid biosynthetic genes across all modules in any flowering plant species.

Materials and Methods

Software prerequisites

All employed Perl and Python scripts required perl (strawberry v5.18) and Python (v2.7) libraries including Bioperl (v1.6.910) and Biopython (v1.63) modules, respectively. The iprscan_urllib.py script for HMM-based domain annotation (see below) required SOAPy, NumPy and urlib Python modules. For BLAST screens, we employed the stand-alone command line version of NCBI BLAST 2.2.27+ (ftp://ftp.ncbi.nlm.nih.gov/blast/executables/blast+/LATEST/, last accessed on December 13th, 2014) [73]. Fisher’s exact test for count data was performed using the R package for statistical computing (www.r-project.org, last accessed on December 13th, 2014).

Genome annotations

In total, we analyzed 15 draft genomes as well as two gene-space assemblies represented by non-redundant transcriptomes. The complete sets of representative genes and proteins for 12 of these 17 datasets were downloaded using www.phytozome.net, last accessed on December 13th, 2014) [74] and the CoGe package for comparative genomics [4]. We included Amborella trichopoda EVM27 [71], Arabidopsis thaliana TAIR10 [75], Brassica rapa v1.1 [76], Carica papaya v0.5 [18], Citrus sinensis v1 [77], Eucalyptus grandis v1.1 [78], Glycine max Wm82.a2.v1
Sorghum bicolor v1.4 [80], Solanum tuberosum v3.2.10 [81], Solanum lycopersicum v2.40 (Potato Genome Consortium 2012), Vitis vinifera Genoscope.12X [20] and Zea mays 5a.59 [82]. Tarenaya hasslerania v5 [83] (Weber, Schranz et al, unpublished data), Cleome gynandra v2 (Weber, Schranz et al. 2014, unpublished data) and Nicotiana benthamiana v0.42 [84] genome annotations were made available by the authors. Non-redundant transcriptomes of Cannabis sativa ChemDawg (marijuana) [85] and Lactuca sativa (Mitchelmoore et al, unpublished data) early-draft gene-space assembly of were extracted from Genbank [86].

**De novo** protein annotation of early-draft gene-space assemblies

Non-redundant transcriptome data of Cannabis sativa ChemDawg (marijuana) and Lactuca sativa derive from unpublished early-draft gene-space assembly (see above) and therefore contain significant parts of non-coding sequences as well as putative sequencing errors. We therefore subjected both datasets to the translatedna.py script v1.75 (https://github.com/jenhantao/HiSeq/blob/master/translatedna.py, last accessed on December 13th, 2014). First, single mRNA sequences were translated in all six frames. Second, the peptide fragment encoded by the largest open reading frame was printed. All other parts were discarded. The output comprises an approximation on the non-redundant set of proteins for both species.

**Confirmation and expansion of multi-gene families associated with the terpenoid biosynthetic module in Arabidopsis thaliana (“run 1”)**

Functional annotation of target genes across all organisms was an interlaced approach consisting of 3 independent BLAST screens (run 1–3). For run 1 in A. thaliana, we obtained 32 core-TPS genes from [29] as well as 34 genes acting in modules further up- and downstream in terpenoid biosynthesis [35]. We queried all 66 sequences against the TAIR10 A. thaliana genome annotation in a BLAST screen without e-value threshold (forward run). We extracted all target sequences and queried them back against the A. thaliana TAIR10 genome annotation with an applied target sequence maximum threshold of 2 (under consideration of self-hits produced by Col-0 genes within this pool) (reverse run). After removal of self-hits, we scored loci as associated with the A. thaliana terpenoid specialized metabolism if they were part of the target sequence pool in the forward run, and aligned to a terpenoid biosynthetic gene as defined by [29,35] in the reverse run. We thereby created an extended set of A. thaliana TP-associated loci (85 genes).

**Species-wise determination of putative homologous gene anchors (“run 2”)**

In the next step for large-scale specialized terpenoid biosynthetic gene identification, run 2 determined unidirectional best BLAST hits for both (a) protein and (b) coding DNA sequences between A. thaliana Col-0 and all other 14 genome annotations in a screen without e-value thresholds (for early-draft gene-space assemblies, only protein data were used). Since terpenoid biosynthetic loci can comprise multiple domain types connected by partially conserved linkers, the BLAST approach can result in false positives due to short but highly conserved highest-scoring sequence pairs (HSPs) in functionally non-relevant (i.e. structural) parts of the protein. Therefore, we developed a python script to discard target sequences with a query/target sequence length ratio below 0.5 and above 2.0 as previously described to avoid false positive BLAST results due to short but highly conserved highest-scoring sequence pairs (HSPs) in functionally non-relevant (i.e. structural) parts of the protein [26]. We determined (c) additional, length-filtered HSP pairs (based on both CDS and proteins) for these loci within the
Syntelog / ohnolog determination

Calculation of pairwise syntenic blocks within and between genomes is based on integer programming [87] but implemented to an easy-to-use web interface termed CoGe package for comparative genomics (www.genomevolution.org, last accessed on December 13th, 2014) [4,88]. Within all genome assemblies, we determined genes sharing the same genomic context to counterparts in the *A. thaliana* Col-0 genome annotation (defined as syntelogs) using the DAGchainer [89] and Quota-Align [87] algorithms implemented to the “SynMap” function within CoGe. To mask noise generated by successive duplication(s) of ohnolog blocks including segmental duplications, we applied Quota-Align ratios for the “coverage depth”-parameter that are consistent with the syntenic depth (defined as the level of “genome multiplicity” expected from the multiplication of successive WGDs/WGTs) calculated for each genome annotation. For merging of adjacent syntenic blocks, we applied a threshold of n = 350 gene spacers. For within-species ohnolog counterparts of target genes, we applied the “Synfind” function within the CoGe package (https://genomeevolution.org/CoGe/SynFind.pl, last accessed on December 13th, 2014). To decrease false-positive scoring of recent segmental duplications, we set maximum threshold values of 1.5 for the Ks-value averages between duplicate gene copies. This facilitates selective scoring of ohnolog duplicate pairs within genomic blocks that are due to polyploidy as previously described [4]. Please note that we appended URLs to regenerate genome-wide ohnolog identification for 13 out of 17 genomes subjected to this analysis (see Results section).

Determination of tandem duplicate gene copies

Following a widely-used method for tandem duplicate identification, we queried the complete set of proteins encoded in the whole genome assembly against itself in a BLAST screen without any e-value threshold (this ensures the identification of most homologs including highly diverged ones) and filtered our final set of target sequences from above outside a window of n = 10 allowed gene spacers in both directions from the query sequences (this ensures the identification of adjacent duplicates organized in arrays among all homologs scored above) as previously described for the identification of tandem duplicates [11]. We acknowledged that determination of genome-wide tandem duplicate frequencies following this approach decreases in accuracy with increased degrees of assembly fragmentation (i.e. total number of scaffolds/contigs). This means that false-negatives singletons are more likely scored in genomes with many short scaffolds (“gene-space assemblies”) compared to annotations with few scaffolds in the size-range of chromosome pseudo-molecules which is due to the lack of information on the relative order of scaffolds. Similarly, it is not possible to score tandem duplicates based on non-redundant transcriptomes because those represent collections of single transcripts without information of the genomic context. As a result, our analysis of tandem duplicate fractions was restricted to 13 genome assemblies.

Scoring of putative gene transposition duplicate pairs among *Arabidopsis DXS*-like genes

Scoring of gene transposition duplicate pairs among *DXS* genes involved three steps. First, we obtained all tandem- and ohnolog duplicates present within the gene family as described above. Second, we queried CDS sequences of non-tandem/non-ohnolog duplicate target genes against the *Arabidopsis* genome in a BLAST screen without e-value threshold. Third, we
generated (B)LastZ two-way alignments of the genomic regions that harbor (a) query as well as (b) highest-scoring non-self target sequence within a 40 kb window (20 kb on each side). This was accomplished using the Gevo function from the CoGe comparative genomics package (http://genomevolution.org/CoGe/GEvo.pl, last accessed on December 13th, 2014) [4]. Graphical highlights of transposon-like sequences have been customized by choosing “show other features” in the “results visualization” tab. We scored DXS-like gene pairs as gene transposition duplicates if they comprise highest-scoring sequence pairs embedded in otherwise non-syntenic regions, while both loci showing evidence for adjacent fragments of transposable elements as previously described [25].

Determination of anchor paralogs and generation of extended multi-gene family pools across all analyzed species (“run 3”)

Since ortholog detection based on unidirectional or reciprocal best BLAST hits can miss many “real” orthologs in duplicate-rich species like animals or plants [90], a separate run was necessary to increase accuracy. For run 3, we defined the initial homologous genes set as the merged set consisting of five HSP partner groups (first group: based on length-filtered protein pairs; second group: based on non-length-filtered protein pairs; third group: based on non-length-filtered CDS pairs; fourth group: based on length-filtered CDS pairs; fifth group: based on syntelogs, see above for length filter criteria). We thereby created a set of putative homologous loci anchoring all A. thaliana gene families in all other analyzed genome annotations (“anchor pool”). In a next step, we performed a BLAST search without e-value thresholds to query all homologous anchor genes against all 17 genomes in a species-wise manner to determine putative paralogs of the anchor gene set (“run 3 forward”). We extracted all target sequences and queried them against the A. thaliana Col-0 TAIR10 genome annotation with a target sequence maximum threshold of 2 (“run 3 reverse”). After removal of self-hits, we scored loci as associated with terpenoid biosynthesis within their species if they align to any member of the extended terpenoid biosynthetic loci in A. thaliana (see above). We defined all members of this pool as homologous to the anchor pool if they were not present within the set of homologous anchor genes (see above).

Hidden Markov Modeling and prediction of protein domains

Since we included highest-scoring sequence partners based on BLAST as well as syntelogs, the above-mentioned extended multi-gene family pool of terpenoid biosynthetic genes is based on both sequence homology and genomic location of its members. However, we observed an erosion of synteny across lineages relative to their phylogenetic distance. Furthermore, DNA sequence homology decreases with phylogenetic distance due to wobble rules for the 3rd codon position. Likewise, the protein sequence homology between distant multi-gene family members can decrease due to synonymous substitutions of amino acids belonging to the same chemical class (i.e. aliphatic, aromatic, basic, cyclic). Therefore, we applied a final filtering step to remove false-positive loci from the extended terpenoid biosynthetic genes pool across all genomes (including the extended terpenoid biosynthetic genes pool in Arabidopsis, see above). Using the iprscan_urllib.py script provided by the European Molecular Biology Laboratory (EMBL, Heidelberg, Germany) (https://www.ebi.ac.uk/Tools/webservices/download_clients/python/urllib/iprscan_urllib2.py, last accessed on December 13th, 2014), we queried every member of the terpenoid biosynthetic genes pool (including the extended set determined for A. thaliana, see above) to 14 algorithms that apply Hidden Markov Models for (protein domain) signature recognition (BlastProDom, FPrintScan, HMMPiR, HMMPfam, HMMsmart, HMMTigr, ProfileScan, HAMAP, PatternScan, SuperFamily, SignalPHMM, TMHMM, HMMpanther and...
Gene3D) [91]. We overcame the one-sequence-at-a-time limitation of the EMBL server by writing batch wrappers for 25x-fold parallelization. As a result, we mapped all protein domains present in the putative multi-gene family pool onto their genes in less than a day, and discarded all false positive genes from the whole set (i.e. genes not encoding at least one domain common to at least one reaction module). Referencing of all identified genes to distinct terpenoid biosynthetic modules was based on presence of module-specific protein domains.

Multiple protein alignments
To generate multiple alignments of protein sequences, the stand-alone 64-bit version of MAFFT v7 was employed (http://mafft.cbrc.jp/alignment/software/, last accessed on December 13th, 2014) [92]. First, all terpenoid biosynthetic proteins were aligned species-wise using the command line {mafft.bat —anysymbol —thread 4 —threadit 0 —reorder —auto input > output} Mesquite v2.75 (http://mesquiteproject.org, last accessed on December 13th, 2014) was used with multi-core preferences to trim MAFFT multiple alignments down to gap-free sites. Trimmed blocks were re-aligned using MAFFT with the command line {mafft.bat —anysymbol —thread 4 —threadit 0 —reorder —maxiterate 1000 —retree 1 —localpair input > output}.

Microarray-based gene expression analysis in Arabidopsis
To test differential and trichome-specific expression of DXS-like genes in Arabidopsis, we have used a Col-0 wild type trichome-specific transcriptome dataset (available at the TrichOME database, http://www.planttrichome.org/, last accessed on December 13th, 2014) [93]. Normalized values of three independent experiments performed with the ATH1 microarray were generated and averaged as described [94]. For calculation of relative gene expression, we referenced the bHLH-motif containing house-keeping gene AT4G34720 [95].

Quantitative PCR-based gene expression analysis in tomato (S. lycopersicum)
Leaves, stems and roots were collected in triplicate from 4-week-old Solanum lycopersicum cultivar Moneymaker plants. Part of the stems were left intact and part were used for trichome isolation by shaking the stems in liquid nitrogen. Frozen isolated trichomes, stems that remained after trichome removal, intact stems, leaves and roots were ground to a fine powder and subjected to RNA isolation with Tri Reagent (Sigma) and DNase treatment (TURBO DNase, Ambion) according to the manufacturer’s instructions. cDNA was synthesized from 1 μg of total RNA using the RevertAid kit (Fermentas). RT-qPCR was used to study the expression of 1-deoxy-d-xylulose 5-phosphate synthase isoforms 1, 2 and 3 (DXS1, DXS2, and DXS3) in cDNA derived from different tissues. Gene specific primers were designed using Primer3-Plus (DXS1-F: 5’-ATTGGGATATGGCTCAGCAG-3’; DXS1-R: 5’-CAGTGGTTTGCACAGAAGCTTG-3’; DXS2-F: 5’-TTTACGGACCCGCAAACCATTAG-3’; DXS2-R: 5’-GTCCTTGAGGTCACATTTGC-3’; DXS3-F: 5’-AATGGAGCCCTCACCTCACC-3’; DXS3-R: 5’-ACCCAGCTGCAAATGTTACC-3’). Tomato RUB1 conjugating enzyme-encoding (RCE1) gene (Gen-Bank accession no. AY004247) (RCE-F: 5’-GATTCCCTCTCTCATCAATCTTCCAG-3’ and RCE-R 5’-GACGTTAAATGTGCACCCCTACA-3’) was used for normalization. PCR reactions were prepared in duplicate by mixing cDNA equivalents of 10 ng RNA with the SYBR Green Real-Time PCR master mix (Invitrogen) and 300 nM of each primer. Quantification of the transcript level was performed in an ABI 7500 Real-Time PCR System (Applied Biosystems) with the following cycling program: 2 min, 50°C, 15 min 95°C, 45 cycles of 15 sec at 95°C and 1 min at 60°C followed by a melting curve analysis. At the end of each run, amplified products were sequenced to verify their identity. Relative expression values were calculated using the
efficiency \( \delta \text{Ct} \) method as previously described [96]. All wet-lab expression analysis were performed in four independent biological and three technical replicates.

**Phylogenetic and similarity/identity analysis**

We performed Bayesian Markov chain Monte Carlo (MCMC) analysis using MrBayes version 3.2.2 (http://mrbayes.sourceforge.net/, last accessed on December 13th, 2014) [97] with the following parameters: Dirichlet model; uniform gamma shape parameter variation 0.00–200.00; 50 million generations; 2 independent runs, 4 chains each; temperature heating 0.2; sample taking every 5000 generations; burn-in time at 12500000 samples. Bayesian inference trees were constructed using the CIPRES package (http://www.phylo.org/sub_sections/portal/, last accessed on December 13th, 2014) [98]. Model convergence was checked in Tracer version 1.5 (http://tree.bio.ed.ac.uk/software/tracer/, last accessed on December 13th, 2014) [99]. FigTree v1.3.1 was used to generate and edit phylogenetic trees (http://tree.bio.ed.ac.uk/software/figtree/, last accessed on December 13th, 2014) [100]. Results were scored reliable once the effective sampling size of all parameters was above 100. Tree branches supported with posterior probabilities (PP) below 0.7 were considered weak and above 0.9 as strong. Protein sequence similarity analysis were performed using the Needle program from the EMBOSS software package (http://emboss.sourceforge.net/, last accessed on December 13th, 2014) [101].

**Results**

(Re)annotation of the *Arabidopsis* terpenoid biosynthetic inventory and expansion of genes associated with all reaction modules

As an initial step for identification of genes involved in all terpenoid biosynthetic modules, we reviewed current literature to pool all published *Arabidopsis* core-TPS genes with biosynthetic elements acting further up- and downstream in the pathway (Fig 1) [29,35,61]. As a result, we generated a list of 66 biosynthetic elements previously identified in the model plant (Table 1). This compilation represents a patchwork of information containing both genes found by functional studies as well as genes with computationally inferred association to terpenoid metabolism. Hence, uniform standards of gene identification have not been applied for curation of this initial list.

In a next step, we therefore screened for additional members of all involved gene families within the Col-0 genome that may have been missed in previous studies in an interlaced bioinformatics approach (see Materials & Methods section). Briefly, we combined layers of information based on sequence similarity, gene synteny and Hidden Markov Modelling. First, we queried all 66 genes against the Col-0 genome in a sensitive BLAST screen (no e-value cutoff). After removing self hits, we included every target sequence for further analysis if it formed a highest-scoring sequence pair with a distant member of the initial list. This included identification of ohnologs as well as annotation and mapping of protein domains. Interestingly, this led
Table 1. The published terpenoid biosynthetic module in *Arabidopsis*.

(Continued)
to evidence for 19 additional genes that produce highest-scoring sequence pairs (HSPs) with genes mentioned in Table 1. In essence, these genes comprise tandem-, transposition- as well as ohnolog duplicate copies of genes previously known to be associated with terpenoid metabolism (Table 2). Note that segmental duplications are excluded from this analysis due to technical reasons (see below). Interestingly, 18 of those 19 genes are annotated as triterpene-specific synthases. Thirteen of those have been functionally characterized in previous efforts [47–49, 102]. Five further ones lack functional data but have been assigned to three-letter code nomenclature in the Arabidopsis information resource based on computational inferences (i.e. sequence homology). Interestingly, all those loci include an encoded oxysqualene synthase domain (S1 Table). In contrast, one is a DXS-like gene with its closest homolog involved in the MEP pathway (Table 2). Note that the initial set of query genes applied to our first, above-mentioned BLAST analysis did not contain triterpene-specific synthases (Table 1). Therefore, our results indicate sequence homology of triterpene-specific synthases to genes of the core-TPS as well as the prenyltransferase class. Based on these findings, we hypothesize that all three groups go back to one common ancestral gene family with subsequent rounds of duplication

going hand in hand with functional diversification as previously described in many cases in-cluding proline-rich proteins [103].

To account for the whole range of sequence diversity found among Arabidopsis terpenoid biosynthetic genes, we merged Table 1A and 1B and obtained pool of 85 genes putatively involved in all Col-0 terpenoid biosynthetic modules ("extended set") (sum of all Col-0 gene entries in S2 Table). Initially, we dissected all members into three groups based on putative affiliation with a certain module (Fig 1): (a) prenyltransferases and triterpene-specific synthases, (b) core terpene synthases and (c) genes involved in MEP and MVA pathways including IPP isomerases, respectively. Visual comparison of duplicate fractions revealed striking differences between the subsets but also when comparing to the fraction of duplicates among all protein-coding genes (Fig 2). For the whole set of 85 genes, we found a 68%-fraction of tandem duplicate supergene clusters and a 15%-fraction of ohnolog duplicate pairs (Fig 2A, Table 3 and Table 4). For subgroup (a), we report a 70%-fraction of tandem duplicate supergenes and a 13%-fraction of ohnolog duplicate copies (Fig 2B). In contrast, 94% of subgroup (b) comprise members of tandem arrays, while the ohnologs fraction drops to 6% (Fig 2C, Table 3 and Table 4). Interestingly, subgroup (c) contains only 16% of tandem duplicate genes but a 27% fraction of genes retained after ancient polyploidy events (Fig 2D).

In summary, we found a connection to biosynthesis of mono-, di- and sesquiterpenes for 19 additional genes in Arabidopsis that are homologous to but absent from the published set of

terpenoid biosynthetic genes. Likewise, we showed an asymmetric distribution of duplicates among genes involved in different modules of terpenoid biosynthesis in *Arabidopsis*.
Protein domain annotation of extended genes set associated with all terpenoid biosynthetic modules in *Arabidopsis*

Increasing phylogenetic distance of plant species can lead to increased sequence diversity in homologs while the broad class of biological function remains unchanged [1,104]. For example, amino acid substitutions within the same chemical group (i.e. aliphatic, aromatic) may have little or no effects on protein function, but may result in decreased accuracy in orthologous and paralogous gene detection by sequence homology (such as BLAST) [90,105,106]. We therefore performed Hidden Markov Modelling (HMM)-driven protein motif searches and annotation among all subsets of genes involved in the extended set of Col-0 terpenoid biosynthetic genes in order to screen for additional homologs (see Materials & Methods section). Briefly, we submitted all 85 target sequences to the “Interpro5” algorithm that performs parallelized prediction of protein domains (see Materials & Methods section) [91,107–109]. This is based on machine learning for pattern recognition rather than direct sequence comparisons. As the “training” dataset for domain modelling for the submitted protein sequences, Interpro5 uses the HMM-generated profiles of all protein motif entries and associated sequences present within the pfam and various other databases [110]. Notably, benchmarking of profile HMMs and the BLAST algorithm previously revealed a higher sensitivity of HMM-based methods that is mirrored by an increased alignment quality [111].

doi:10.1371/journal.pone.0128808.t003
As a result of HMM-driven protein domain annotation, we obtained a collection of all motifs encoded by all genes present in the initial set (Table 5). First, we pooled all terpenoid pathway-associated genes from the extended set into (a) core-TPS proteins, (b) IPP isomerases, (c) genes involved in the MEP pathway, (d) MVA pathway-associated proteins, (e) prenyltransferases as well as (f) triterpene-specific synthases and subjected all six sets to the Interpro5 algorithm [91], thereby querying a total of 14 protein motif databases. Five among those recognized motifs shared by every single member of at least 2 pools and were selected for further analysis: Interpro, Pfam, Panther, Gene3D as well as Superfamily [107,110,112–114] (Table 5).

In a next step, we screened for protein motif entries within these 5 databases that are specific for any of the 6 aforementioned subsets of genes associated with all Col-0 terpenoid biosynthetic modules (S1 Table). Interestingly, our approach identified 38 domains associated with more than one subgroup due to accurate modelling of protein domain signatures (Table 5). Those were found either for both core-TPS proteins and prenyltransferases, or for both core-TPS genes and triterpene-specific synthases. Together with the sequence homology determined in the initial BLAST screen that formed the extended set of Col-0 target genes, this illustrates that those gene families are similar in terms of both sequence and domain structure as described above and hence might share a common evolutionary origin and function (S1 Table). As a
result, it is not possible to affiliate one distinct homologous genes to one of these three subsets based on domain composition in every case without functional data at hand, also when utilizing specific combinations of two or more domains. In summary, we performed in-depth investigation of protein domains among all enzymes involved in every Arabidopsis terpenoid biosynthetic module, thereby curating a set of all detectable domains involved in the terpenoid biosynthetic pathway within the Arabidopsis model plant.

Annotation of genes in all terpenoid biosynthetic modules across 17 target species based on both sequence homology and protein domain composition

We obtained a list of 1,904 protein-coding genes with putative annotation to a terpenoid biosynthetic module. To cross-reference every member to one of the six designated functional modules (Fig 1), we mapped all aforementioned protein motifs onto all target genes. For genes with ambiguous domain composition (i.e. presence of 38 domains without clear referencing to one functional module within the terpenoid biosynthesis, see above), we used the annotation of its highest-scoring target sequence alignment in Arabidopsis. Depending on sequence homology as well as on presence/absence of the aforementioned module-specific protein domains (S1 Table), we describe a total of 840 core terpene synthases genes (shown red in Fig 1), 190 prenyltransferases (shown in green in Fig 1), 338 triterpene-specific synthases (shown in blue in Fig 1) as well as 219 and 278 genes associated with the MEP (shown in purple in Fig 1) and MVA pathways (shown in black in Fig 1), respectively. Likewise, we found a total of 39 IPP isomerases (shown in turquoise in Fig 1), summing up to 1,904 target genes in total (Fig 3). Please note that all sequence identifiers are appended in S2 Table.

Compared to the total number of protein-coding genes present in the genome, V. vinifera (grapevine) possesses the most expanded inventory of terpenoid biosynthetic genes including all modules, but also for individual modules like core terpene synthases, triterpene-specific synthases and both MEP and MVA pathways. In contrast, the highest number of prenyltransferases relative to the total number of protein-coding genes is encoded by the C4-species C. gynandra. The small gene family of IPP isomerases is most abundant (i.e. target gene count compared to number of all genes per genome) in B. rapa. Note that the B. rapa genome possesses the highest syntenic depth level among all species analyzed in this study (S3 Table).

In contrast, the basal Angiosperm A. trichopoda possesses the leanest inventory relative to the number of all protein-coding genes when looking at all terpenoid biosynthetic modules. Same counts for triterpene-specific synthases and for genes associated with the MVA pathway. For core-TPS genes, the G. max (soybean) genome encodes the smaller relative number of

### Table 5. Overview of protein domain annotation for the extended set of Arabidopsis terpenoid biosynthetic genes^A^.

doi:10.1371/journal.pone.0128808.t005
proteins. For prenyltransferases, we found that the *L. sativa* genome encodes the smallest relative number. In contrast, the MEP pathway in *S. tuberosum* (potato) recruits the lowest number of genes compared to all of its protein-coding genes. Finally, we found the lowest relative number of IPP isomerases within the *C. papaya* genome (*S3 Table*). In summary, we provide evidence for annotation of 1,904 genes to every major module of terpenoid biosynthesis within 17 target genomes, many of which have not been connected to this trait so far. Similar to functional annotation of the *Arabidopsis* genome, computational inferences of gene function comprise an important step for the future collection of functional data in wet-lab experiments [75].

### General and subset-specific cross-referencing of supergene clusters and ohnolog duplicates to terpenoid biosynthetic elements among all species

After curating a set of 1,904 target genes across 17 species, we first scored supergenes organized in tandem arrays as well as ohnolog duplicates due to polyploidy events. Second, we compared the obtained duplicate fractions between all six modules of terpenoid biosynthesis. For
detection of potential enrichment or depletion of duplicate frequencies within these subsets, a species-wise comparison to the genome-wide average of tandem/ohnolog duplicates fraction was necessary. Due to technical reasons, these genome-wide fractions can’t be accurately determined for C. gynandra, N. benthamiana, C. sativa and L. sativa (for Cannabis and Lactuca, non-redundant RNAseq data are available only whereas the C. gynandra and N. benthamiana assemblies are highly fragmented, leading to a highly error-prone determination of genome-wide duplicates fractions, see Materials & Methods section). Therefore, our genome-wide analysis of duplicates fractions was restricted to 13 genome assemblies.

On average, 46% of all curated genes associated with terpenoid biosynthesis comprise supergenes with duplicates organized in tandem arrays. Compared to the 32% average observed for the genome-wide tandem duplicate fraction determined across the 13 genome assemblies subjected to this part of our analysis, our results highlight a significant enrichment of supergene clusters for terpenoid biosynthetic genes according to statistical analysis based on Fisher’s exact test on count data (Table 3, S4 Table). Next, we investigated the species-wise fractions of tandem duplicates among all identified terpenoid biosynthetic genes across all analyzed genomes, the significant enrichment for supergene clusters holds up for all organisms except C. sinensis, G. max, Z. mays and A. trichopoda (Table 3). However, comparison of duplicate frequencies within different functional modules of terpenoid biosynthesis across the 13 genomes subjected to tandem duplicate analysis did reveal certain subsets that are enriched for duplicates (five genomes were not applicable to this analysis due to technical reasons, see above). For example, triterpene-specific synthases are significantly enriched for tandem arrayed supergenes compared to the genome-wide background in G. max. Similarly, core-TPS genes are enriched for tandem duplicates compared to genome-wide average in the basal angiosperm A. trichopoda (Table 3). We have found that only Citrus and maize lack significant enrichment for tandem duplicates among all subsets of genes involved in terpenoid biosynthesis. Based on the enriched fraction of tandem duplicates specific for certain terpenoid biosynthetic modules, we deducted a general pattern. Both core-TPS genes and triterpene-specific synthases were found to be significantly more enriched for tandem duplicates across most of the analyzed species, whereas MEP and MVA pathways as well as IPP isomerase functions retained few or no supergene clusters within most analyzed species (Table 3, S4 Table).

In a next step, we determined the cumulative fraction of duplicate genes retained after ancient polyploidy events (ohnologs). Similar to the analysis of tandem duplicates, ohnolog identification relies on gene contextual information and is hence not applicable to highly fragmented gene-space assemblies or translated transcriptome datasets (see above) [4,89]. Please note that we appended URLs for online-regeneration of ohnolog identification in 13 genomes out of 17 genomes (Table 4). We again measured genome-wide averages wherever possible and compared them to the fractions among all subsets as described above for tandem duplicate supergenes (Table 4). On average, 18% of all genes associated with all modules of terpenoid biosynthesis comprise ohnolog duplicate gene copies. Compared to the 28% fraction of genome-wide ohnolog merged across all analyzed species, Fisher’s exact test on count data indicates absence of significant ohnolog enrichment for this set (S5 Table). In contrast, species-wise analysis revealed a significant enrichment of ohnologs among all terpenoid biosynthetic genes identified in Z. mays (Table 4). Moreover, analysis of species-specific ohnolog distributions among different terpenoid biosynthetic modules highlighted differential trends. In essence, we revealed patterns of above-average ohnolog retention opposite to those described for tandem duplicates. For example, dosage-independent modules like core-TPS synthases and triterpene-specific synthases contain below-average ohnolog fractions in all analyzed species (Table 4), while recruiting highest fractions of supergene clusters as shown above (Table 3).
Strikingly, genes associated with dosage-dependent modules like the MVA pathway and IPP isomerases show the highest fractions of ohnolog duplicates merged across all genomes (Table 4). In contrast, both subsets include low fractions of tandem duplicates compared to other subsets (Table 3).

However, ohnolog fractions of dosage-dependent modules vary greatly between different species in many cases. The small gene family of IPP isomerases, for example, consists of 100% ohnolog duplicates within Arabidopsis, Brassica, Tarenaya as well as Glycine. In contrast, we did not detect retained ohnologs within this gene families within Carica, Citrus, Eucalyptus, Vitis, all analyzed Solanaceae as well as Sorghum based on the applied preferences. This is likely due to technical reasons (see Materials & Methods section). Briefly, the scoring method of SynMap depends on presence of long colinear regions and hence the N50 value indicating the “fragmentation” of the assembly. This means that false-negatives are more likely scored in genomes with many short scaffolds compared to few in the size-range of chromosome pseudomolecules, due to the lack of information on the relative order of scaffolds.

In summary, we showed above-average fractions of ohnologs combined with below-average fractions of supergene clusters recruited by two dosage-dependent terpenoid biosynthetic modules (IPP isomerases and genes involved in the MVA pathway) (Table 3, Table 4). In addition, we revealed a below-average rate of ohnolog retention combined with a significantly increased rate of tandem duplicates for stoichiometrically insensitive genes (i.e. genes that are not acting in a dosage-dependent way) like core-terpene synthases as well as triterpene-specific synthases.

Identification and phylogenetic analysis of key genes controlling isoprenoid profiles and trichome density

The aforementioned biosynthetic inventory of all plant terpenoid biosynthetic modules is necessary and sufficient for production of related compounds with designated biochemical function. However, some terpenoids are autotoxic and can only be produced in high amounts in specialized hair-like aerial structures termed glandular trichomes [56,115] where they are stored or secreted to the surface in order to facilitate ecological interactions (i.e. repelling herbivores or attracting beneficial organisms). Biogenesis and distribution of trichomes is controlled by various biosynthetic and regulatory processes, often mediated by pleiotropic genes [116,117]. In this context, it has recently become evident that trichome density on the leaf surface is amongst other factors influenced by a class of pleiotropic genes that also catalyzes the entry step to the MEP pathway [35]. In tomato, two deoxy-xylulose phosphate synthase genes (DXS) have previously been identified. Interestingly, differential and tissue-specific expression was observed: While DXS1 is ubiquitously expressed, DXS2 was found to be abundant in only a few tissues including trichomes. Reduction of DXS2 expression in cultivated tomato led to an increase in glandular trichome density [52]. To identify additional DXS-like homologs, we screened our curated genes set and found evidence for 79 encoded proteins within all genomes subjected to our analysis (Fig 4, S5 Table). In addition, we included four DXS-like genes that were previously identified in the moss Physcomitrella patens to reconstruct the evolutionary history of all 83 target genes during Angiosperm radiation [53,118].

As previously reported, the Physcomitrella DXS-like genes form a monophyletic clade that groups distant to all other analyzed Angiosperm target genes. Strikingly, we have identified multiple gene family members that remained un-characterized within all other analyzed annotations except maize. Within the Angiosperm clades, we found that DXS-like genes always group in three distinct clades that form monophyletic groups rooted by basal members present in the Amborella genome (Fig 4), which is commonly placed at or near the base of the flowering plant lineage [71,119]. Within those clades, we observed grouping of closely related species.
consistent with the evident phylogenetic relationships of these species as a whole (Fig 4). However, our analysis also revealed clade-specific differences. First, we did not detect any proteins grouping to clade three within the non-redundant *Cannabis* transcriptome (*S5 Table*). Second, whereas most organisms encode at least one member of every clade, Brassicaceae and Cleomaceae have lost DXS-like genes belonging to clade two (Fig 4, *S5 Table*). Interestingly, the model plant *Arabidopsis* contains one highly diverged member of clade two that groups closer to clade one than to any other clade two homologs (marked by black arrow).

**Fig 4. Phylogenetic relationships among 83 DXS-like proteins.** Brassicaceae and Cleomaceae are marked in blue. Solanaceae are marked in red. Proteins encoded in the basal Angiosperm Amborella are marked in green. The moss *Physcomitrella* comprises the outgroup and is marked in yellow. DXS-like genes group in three distinct clades since the origin of Angiosperms. Notably, all analyzed Brassicaceae have lost DXS2-like genes. However, the model plant *Arabidopsis* contains one highly diverged member of clade two that groups closer to clade one than to any other clade two homologs (marked by black arrow).

doi:10.1371/journal.pone.0128808.g004
Next, we assessed the contribution of gene and genome duplication to DXS-like gene family composition among four further genome annotations with most accurate determination of ohnolog blocks (Table 6). To our knowledge, the contribution of genome duplication to DXS-like family evolution has previously not been assessed to that extent. For *A. thaliana*, *B. rapa*, *T. hasslerania* and *G. max*, we found 24 DXS-like genes in total, organized in eight duplicate groups (defined as set of genes comprising descendants from one distinct ancestral singleton due to one or more rounds of duplication) and distributed across all three DXS-like clades.

### Table 6. Overview of gene and genome duplication responsible for DXS-like cluster extension; shown are all target genes for four genomes•.

| Species      | Gene Identifier | Clade | Origin of Duplication | Duplicate Group | Similarity\(^{B}\) to Duplicate copy | Identity\(^{B}\) to Duplicate copy |

- Analysis restricted to Genomes with most accurate identification of ohnologs due to technical limitation.
- Based on encoded protein sequence.
- Origin of GTD Duplicate based on lowest blastp e-value for alignment to other family members.
- Embedded in most fractionated subgenome; similarity and identity scores shown relative to ohnologs in both other subgenomes.
- Note significant length difference of both genes in this array; low similarity and identity scores indicate annotation error dividing one ORF into two neighboring genes. Both values are excluded for calculation of average.
- Gene scored as Segmental Duplicate due to high synteny score of harbouring region while other members of duplicate group are sufficient to cover the synthenic depth of this genome (i.e. no WGT evident).

\(^{A}\) doi:10.1371/journal.pone.0128808.T006
Strikingly, 100% of those are due to ancient polyploidy events, either directly when forming pairs (WGD) or triplets (WGT) of ohnolog copies or indirectly when forming tandem- or transposition duplicates (GTD) of ohnolog group members (Table 6). In A. thaliana, for example, DXS1 (AT4G15560) and DXS2 (AT3G21500) form the ohnolog duplicate gene pair A15N013, dating back to the At-α WGD event [8,72] (Table 1A and 1B). The encoded proteins share 78.8% of protein sequence similarity (Table 6). Likewise, the corresponding genes are differentially expressed and pleiotropic (see introduction section; i.e. involved in terpenoid biosynthesis, plastid development and trichome formation [35,53,54,120,121]). Further analysis of DXS3 (AT5G11380) indicated its putative origin due to gene transposition duplication of DXS1. First, both genes form a highest-scoring sequence pair based on our BLAST analysis after removal of self-hits in Arabidopsis (see Materials & Methods section). Second, both genes are embedded in a non-syntenic genomic regions that contain remnants of transposon-like sequences (Fig 5). Considering the increased phylogenetic distance between this pair of genes and its reduced degree of protein sequence similarity (Table 6) compared to the pair of DXS1/DXS2 (Fig 4), this illustrates that genetic versatility within the Arabidopsis DXS family was further leveraged by a gene transposition duplication (GTD). Taken together, these results give rise to the onset of functional diversification of the A15N013 ohnolog pair following the At-α WGD event in Brassicaceae (see Discussion section). Similarly, short sequence duplication may have contributed to functional diversification of DXS-like genes. Based on those results, we further assessed the impact of various duplication modes to all other identified DXS-like genes in all analyzed genome assemblies including analysis of expression and sequence diversity.

Initially, we assessed divergence levels among both pairs of DXS-like protein sequences and compared those following various modes of duplication by testing for differential and tissue-specific expression of all three DXS-like genes in Arabidopsis. Please note that glandular trichomes are absent in the model plant [122]. Notably, DXS1 is the only member of its gene family that is annotated to “trichome specific up-regulation” in the plant ontology database (PO:0000282) [123–125]. However, we confirmed expression of all three loci in Arabidopsis non-glandular trichomes (and various other tissue types) based on publically available microarray data [94]. Furthermore, we uncovered consistent patterns of differential expression across several tissue types. Compared to housekeeping gene expression, DXS1 transcript are most abundant in all analyzed tissues. The ohnolog duplicate DXS2 shows lowest expression levels, whereas the transposed duplicate DXS3 forms an intermediate across all analyzed tissues (Fig 6).
To assess and compare DXS-like gene family divergence in further species, we have performed two separate approaches. First, we performed DXS-like gene expression analysis. Second, we assessed and compared the protein sequence identities of DXS-like duplicate groups due to different duplication events.

Gene duplication can result in transposition of the novel duplicate copy to a distant genomic location, leading to the presence of other cis-acting elements including promoters or enhancers that influence gene expression [126,127]. This results in sub-functionalization of segregants on the expression level. To extend the aforementioned findings concerning sub-functionalization of DXS genes in A. thaliana, we have tested expression of S. lycopersicum target genes in every clade. In addition to increased expression of DXS2 in trichomes and global expression of DXS1 that was previously made evident [52] (Fig 7), we have uncovered that transcript levels of DXS3 are almost 2-fold higher in trichomes compared to any other analyzed tissue type (Fig 8).

In addition to frequent changes in gene expression, recent analysis revealed an accelerated rate of amino acid changes when comparing ohnolog duplicates to their paralogs [128]. High rates of amino acid substitutions lead to decreased levels of protein sequence identities when comparing gene copies due to different duplication modes. For example, polyploidy facilitated rapid diversification of protein sequences and sub-functionalization on a biochemical level in several cases, including glucosinolate biosynthesis, resistance proteins of the NB-LRR type as well as L-type lectin receptor-like kinases [25,26,129]. In all three cases, functional diversification among certain duplicate pairs correlates with differentially decreased protein sequence identities when comparing “novel” gene copies due to certain duplication events. Therefore, we assessed protein sequence similarity/identity among all other seven DXS-like duplicate groups (i.e. sets of genes due to duplication of one distinct ancestral singleton), thereby screening for indications of putative sub- or neo-functionalization (Table 6). Values for protein sequence similarity (identity) range from 45.4% (44.8%) (G. max, duplicate group 7) to 96.8% (94.1%) (G. max, duplicate group 8). In summary, DXS-like proteins share an average of 77.6% (73.4%) for sequence similarity (identity) among all groups, thereby reaching a cumulative divergence
level similar to that observed in *A. thaliana*, for which data on differential target gene expression following gene and genome duplication are available (see above).

In summary, we have analyzed three clades of DXS-like genes present in every analyzed genome annotation. We have assessed differential and tissue-specific expression for two distant lineages, thereby collecting indications for putative sub-functionalization following gene and genome duplication within this group of target genes. To further support this hypothesis, more sequence and expression data are necessary from basal angiosperms in order to facilitate comparison of the observed profiles in a more ancestral state.

Discussion

A combination of synteny, sequence similarity and protein domain modelling facilitates large-scale gene identification and novel annotations in all modules of terpenoid biosynthesis

In a genome informatics approach, we combined a novel and easy-to-follow meta-method for gene and supergene cluster identification with a custom pipeline for de novo protein annotation for large-scale identification of biosynthetic elements associated with plant secondary metabolism. The method provided in this article is novel because it integrates information provided by the genomic location of target genes to information on sequence homology and to the information on encoded protein domain composition. Our method can be applied to a collection of final stage genome annotations, early-stage gene-space assemblies as well as non-redundant transcriptomes, thereby facilitating uniform standards for gene identification. In this context, we analyzed various datasets of different quality for a flowering-plant wide comparative survey of genes building up a major pathway of plant specialized metabolism. In summary, we curated a set of genes associated with all modules of terpenoid biosynthesis and determined key factors shaping metabolic diversification in an Angiosperm-wide scale.

First, we investigated 17 species including twelve major crops. During this initial part of our analysis, we discovered previously uncharacterized genes of the (a) TERPENE SYNTHASE- as well as the (b) DXS-like types in all species except Arabidopsis and Eucalyptus. These gene families have often been subjected to species-specific analysis in the past because they are involved in (a) generating a diverse set of terpenoid compounds and (b) in control of trichome density on the leaf surface, thereby providing significant economic and ecologic potential. The provided data on novel annotations of target genes in most species elucidated the power of our approach in a proof-of-concept and may act as a blueprint for future efforts to more rapidly find and clone functional core-TPS and DXS-like genes from any flowering plant in context of plant breeding and biotechnology.

Second, we identified various genes that have previously not been associated with a distinct function and established computational inferences to encoded prenyltransferases and triterpene-specific synthases across all lineages. These enzymes are commonly associated with the biosynthesis of di-, sesqui-, tri-, tetra- and polyterpenes. Assessing similarities to core-TPS genes in both coding sequence on the DNA level and protein domain composition, we provided indications for the common evolutionary origin shared among all three gene families. Furthermore, we monitored the underlying variation of gene copy number in a phylogenomics framework and thereby described a framework that increased genetic versatility to create the necessary basis for metabolic diversification within a timeframe of 250 MA corresponding to flowering plant radiation.

Third, our approach identified homologs of all genes currently annotated to MVA and MEP pathways including DXS-like genes in Arabidopsis across all analyzed genomes. Large-scale annotation of genes employed by those pathways has to date not yet been made available for every analyzed species except Arabidopsis, tomato and potato. In this context, our study provides and important prerequisite for future efforts aiming at metabolic engineering within any of the analyzed crop lineages.

Both gene- and genome duplication mediated a dramatic increase of genetic versatility underlying modular terpenoid biosynthesis in all species

In the next part of our analysis, we screened for gene and genome duplication events that affected copy number of all loci involved in distant modules of terpenoid biosynthesis across all
investigated species. In this context, genetic versatility is defined as the number of homologs within one gene family. Including novel annotations of previously un-identified genes to all six modules (see above), we described a 376%-increase of terpenoid biosynthetic gene copy number (“genetic versatility”) ranging from the leanest state found in the basal Angiosperm Amborella (50 genes) up to most versatile genotypes found for Vitis that has been subjected to extensive human domestication (188 genes). Merging the genetic inventory associated with all six modules, we revealed that this increase is driven by a combination of gene and genome duplication across 250 MA corresponding with the radiation time of flowering plants. However, individual differences apply when considering single terpenoid biosynthetic modules separately. To our knowledge, this is the to-date most intensive and systematic study of plant gene family expansion that influenced metabolic diversification in a phylogenomics framework.

Please note that segmental duplications are excluded from our analysis. In this context, we acknowledged an error rate due to false-positive scoring as ohnolog duplicates affecting ancient segmental duplications of large genomic regions. Briefly: It is currently not possible to accurately distinguish large segmental duplications from fractionated blocks due to genome multiplications in all cases. Likewise, very short segmental duplications with high degree of fractionation may be accidentally scored as a series of distant gene transposition duplication. This is mainly due to technical reasons, because the SynMap algorithm controls scoring of synteny merely based on a function of collinear genes in a certain density as previously described[4,87,88]. However, most segmental duplications that did not emerge roughly at the same time than any of the investigated genome duplications will display significantly different averages for ka/ks values, and are therefore excluded from synteny analysis due to the cut-offs thresholds applied in the SynMap preferences (see Materials & Methods section).

Enzymes catalyzing the committed step of end product biosynthesis are more often encoded by supergene clusters due to tandem duplication

We highlighted a consistently asymmetric distribution of supergene clusters across all terpenoid biosynthetic modules. Generally, core terpene synthases as well as triterpene-specific synthases comprise enzymes catalyzing the committed step for biosynthesis of designated end products (mono-, di-, sesqui-, and triterpenes). We revealed that those are most enriched for tandem duplicate copies across all analyzed genomes. Please note that in alignment with this these findings, the role of syntenic core-TPS supergene clusters that include adjacent loci involved in different modules was recently made evident for diversification of terpenoid pathway assembly during radiation of various Angiosperm clades (see below) [33]. Moreover, it has become evident that single-featured polymorphisms affecting those genes are sufficient to alter, amongst others, herbivore behavior in otherwise isogenic lines [130–132]. In the opinion of the authors, such processes may have correlated with human efforts of plant domestication and crop breeding in multiple cases. It seems possible that sub-functionalization following tandem duplication of target genes influenced key traits (i.e. scent, taste), making the plant more suitable for further selection. This hypothesis is supported by the high target gene count for highly domesticated species with high content of terpenoids (like Vitis, Cannabis and Lactuca). Although Eucalyptus possesses the highest terpenoid biosynthetic gene count among all species analyzed in this study, it did not undergo major processes of human domestication [78]. However, several herbivores are known to respond differently to Eucalyptus inter- and intraspecific variation of secondary metabolite profiles with potential effects on target gene evolution [133]. Please also note that intensive domestication may also lead to a low TPS gene count in some cases, for example as a result of selection towards different key traits negatively influenced by genes in linkage disequilibrium to TPS genes [134].
Dosage-dependent enzymes in modules mediating intermediate reaction steps are more often encoded by ohnolog duplicates—Introducing a two-step model for rapid plant pathway diversification

Compared to the above-mentioned asymmetric distribution of tandem duplicate copies across all subsets of genes involved in terpenoid biosynthesis, we reported opposite tendencies for retained ohnologs. We made evident that multi-gene family members involved in the MVA pathway as well as IPP isomerases more often tend to originate from whole genome multiplication events. For the MVA pathway, ohnolog fractions greatly outreach genome-wide averages for all genome annotations except papaya. IPP isomerases comprise 100% of retained ohnologs in Brassicaceae, Cleomaceae as well as Glycine. These groups of gene copies are due to duplication of a distinct ancestral singleton (“duplicate groups”) but encode enzymes involved in different terpenoid functional modules, working together by catalyzing neighboring reactions and isomerization of intermediate products (IPP or MVA/MEP modules). According to the gene balance hypothesis, duplicate loci are preferentially retained when functioning together in a dosage-dependent way [6,135]. In this context, we showed an asymmetric ohnologs distribution among the modules acting up- and downstream of core terpene scaffold synthesis.

Based on those findings, we hypothesize a two-step mechanism for the rapid plant pathway- and trait diversification observed in nature. This proposed mechanism depends on both gene- and genome duplication and affects different groups of genes at different times. In a first step, ancient polyploidy plays a paramount role by mediating the described expansion of certain genetic networks involved in plant primary metabolism (like MEP/MVA and IDI loci, see Fig 1), thereby creating a certain degree of “pathway redundancy”. Due to stoichiometric effects, the following post-polyploidy rate of plant survival depends on parallel retention of most (if not all) duplicated genes present in affected metabolic modules. Both functional diversification of ohnolog duplicates and/or incomplete module retention may lead to detrimental effects due to altered fractions of primary metabolite concentrations, as previously hypothesized and backed up by gene network analysis in context of mustard family evolution [135,136]. In a second step, more recent, short sequence duplications (including tandem and gene transposition duplication) creates an extended pool of trans-acting elements (like, for example, additional core-TPS or DXS genes). Since increased copy number of those genes does not lead to detrimental effects due to stoichiometry as described above, functional diversification may create extended capabilities to catalyze biosynthesis of extended product ranges (novel functions). The aforementioned polyploidy-induced primary module duplication created a superabundance of primary metabolites, thereby providing a “playground” for the evolution of novel functions catalyzed by novel gene copies due to short sequence duplicates.

In a nutshell, our results provided evidence for a partial polyploidy-driven expansion of plant secondary metabolism and strongly supported the gene-balance hypothesis for the dosage-dependent subset of involved key genes. Such trends have often been suggested for plants [14,23,137], but solid evidence on a genetic level was to-date only available for glucosinolates and plant resistance proteins of the NB-LRR type [25,26].

Duplicate gene copies of ancestral singletons diversified in metabolic function following gene and genome duplication: the case of DXS-like genes

Recent analysis strongly support the concept of functional specialization following gene duplication as the evolutionary fate explaining retention of the duplicated gene pair DXS1/DXS2 in Arabidopsis [53]. Based on this approach, we performed follow-up analysis of DXS-like gene family evolution on a broader phylogenomics scale. In summary, we showed that certain sets
of duplicate gene copies that descend from duplication of one ancestral singleton (i.e. duplicate groups) contain genes encoding different enzymes for the same pathway in *Arabidopsis* and tomato. Some of those convey pleiotropic effects due to published annotation to different traits (i.e. control of trichome density and terpenoid biosynthesis). Additionally, we identified common protein motifs present (a) within and (b) across different modules of terpenoid biosynthesis. We conclude an expansion of isoprenoid pathways by gene family diversification following gene and genome duplication, thereby resulting in the complex, modular architecture of terpenoid biosynthesis and the plethora of produced compounds observed across the Angiosperm clade. Because supergene clusters tend to be younger than genes preferentially retained after ancient polyploidy events [11,138], ohnologs are likely prone to acquire additional roles over time as previously described (sub- and neo-functionalization) [135,139,140].

Moreover, we have found evidence for the preferential (i.e. above-average) retention of IPP genes following various independent, successive polyploidy events for the Brassicaceae-Cleomaceae sister group system [83]. Similar to DXS-like proteins, IPP isomerases convey pleiotropic functions because they are relevant for the biosynthesis of other isoprenoid compounds beyond plant terpenoid biosynthesis. They also have been brought in connection with plant development in *Arabidopsis*, thereby mediating a check-point for primary metabolism (e.g. hormones) and different branches of specialized metabolism [141–143]. The observed trend of IDI over-retention is consistent for species-specific WGT events (Th-α for *Tarenaya* and Br-α for *Brassica*) as well as for the more ancient At-α WGD event shared by all Brassicaceae [8,17,72,144]. Similarly, we observed a rising IDI gene counts following soybean polyploidy. We concluded a preferential retention of this gene family following polyploidy that might be due to reported dosage-sensitivity (see Introduction section) and is likely visible especially in the aforementioned genomes due to their high levels of syntenic depth (i.e. high levels of genome multiplicity due to more successive WGDs/WGTs compared to other genomes). However, the case of *Arabidopsis* provides an exception which might be due to its reductive genome state that has been previously reported for the genus of the model plant [145].

Furthermore, our results further support the concept of sub-functionalization among DXS-like genes on a broader phylogenomics scale than previously reported [53]. In addition, we assessed and compared the differential impact of various duplication modes (i.e. WGD and short sequence duplication) to functional diversification of DXS-like genes, thereby uncovering novel aspects shaping target gene family evolution. Similar to IDI loci, DXS-like genes have been associated with more than one trait. Two among three DXS-like genes in *Arabidopsis* comprise the retained ohnolog pair A15N013, dating back to the At-α that is shared by all Brassicaceae. While both DXS1 (AT4G15560) and DXS2 (AT3G21500) are annotated to the MEP pathway, DXS1 is also involved in plastid development [8,52,72,120,121]. In addition to the reported control of isoprenoid profiles, functional evidence for control of trichome density on the leaf surface has been made evident [52]. Initially, we discovered a whole new clade of DXS-like genes with members in Solanaceae and Brassicaceae including *Arabidopsis*. Next, we scored the contribution of ohnolog retention to the set of target loci identified the Brassicaceae-Cleomaceae sister group system as well as the legume *G. max*. We showed that all target genes within the aforementioned four genome annotations date back to ancient polyploidy events, either directly by comprising ohnolog duplicate groups or indirectly by comprising tandem- or transposition copies of ohnologs. Furthermore, we unraveled phylogenetic relationships within the target gene family that groups to three clades of encoded DXS-like proteins. We brought those clades in connection with a expression polymorphisms following gene- and genome duplication in tomato and the model plant *Arabidopsis*, thereby elucidating another case of putative sub-functionalization following duplication.
Modified terpenes: Future work or going beyond the plant terpenoid biosynthetic module

Recently, Boutanaev et al. published a very conclusive investigation of core-TPS gene diversification across an evolutionary timeframe similar to the scope of our study (see introduction) [33]. The authors defined an (incomplete) “terpenome” that merely consists of (some, but not all present) core-TPS genes and supergene clusters that consist of both core-TPS and CYP-like genes. CYP-like genes encode cytochrome P450 enzymes that catalyze downstream modifications of various secondary metabolite core structures including alkaloids, glucosinolates and terpene post-modification reactions [146–148]. The authors infer an important role of (micro) synteny and TPS/CYP-locus linkage disequilibrium for terpenoid pathway assembly in plants, and suggest a differential mechanism of trait diversification in monocots and dicots [33]. However, terpenoid biosynthesis in plants is modular because it consists of more than just the core-TPS gene family (Fig 1). Likewise, CYP-like genes are not the only family mediating terpene post-modification reactions [35]. Due to our large-scale annotation of terpenoid biosynthetic genes across all pathway modules within 17 representative genomes, our results provide a valuable basis for future efforts to further investigate the role of synteny and genetic linkage disequilibrium in context of a more complete “terpenome”. This includes the possibility to better elucidate the effects of genetic co-segregation with many other gene families that convey terpene downstream modifications, similar to the aforementioned case study published by Boutanaev et al. [33]. Such gene families may include, for example, UDP glucuronosyltransferases and many other pleiotropic genes involved in biosynthesis of terpenoids and, beyond that, various other plant secondary metabolites [149]. Ultimately, the data provided in our study will facilitate a better understanding of plant secondary metabolite pathway assembly in Angiosperms with various implications for plant breeding and metabolic engineering in context of medicine, flavor, fragrance and pigment production.

Supporting Information

S1 Table. HMM-driven protein domain prediction among the extended set of Arabidopsis terpenoid biosynthetic genes.
(XLS)

S2 Table. Cross-referencing of 1,904 target genes among 17 genomes to a specific subset of genes acting in the terpenoid biosynthetic module.
(XLS)

S3 Table. Species-specific relative size of terpenoid biosynthetic modules. Numbers are quotients of the module-wise gene count of terpenoid biosynthetic pathways and the number of all protein-coding genes within the whole genome. Species with highest and lowest relative pathway size among all analyzed species are color-coded as indicated in the legend.
(XLS)

S4 Table. Species-wise distribution of DXS-like genes among three subgroups.
(XLS)

S5 Table. Comparison of genome-wide numbers of tandem/ohnolog duplicates to numbers among subsets of the terpenoid biosynthetic module, including p-values from Fisher’s exact test on count data. Red indicates absence of tandem/ohnolog duplicates. Green indicates significant enrichment among terpenoid biosynthetic genes compared to background with threshold of 0.01.
