(Dated: February 1, 2008)

We study the production of heavy quarkonium in association with an additional heavy pair. We argue that important contributions may come from phase space regions where three heavy fermions are separated by relative velocities much lower than the speed of light, and to which standard effective field theories do not apply. In this region, infrared sensitive color exchange is specific to the presence of the unpaired (anti)quark. This effect vanishes as the motion of the additional particle becomes relativistic with respect to the pair, and is completely absent for massless quarks and gluons in the final state.

In heavy-quarkonium production, the formation of the heavy-quark pair can be perturbative. The subsequent evolution of the quark pair is conventionally treated in the language of effective theories, most notably non-relativistic QCD (NRQCD) \cite{Collins:1998rz}. In NRQCD, non-perturbative dynamics is organized through a factorization characterized by a joint expansion in the strong coupling, $\alpha_s$ and $v$, the relative velocity. This expansion is well-justified for heavy-quarkonium decays, although it still lacks a compelling proof for production processes. It is clear, however, that NRQCD cannot apply directly to reactions in which three heavy particles, two quarks and an antiquark for example, are produced close together in phase space, simply because there is no unique choice of relative velocity $v$.

Although the application of NRQCD to production processes has had many successes \cite{Brambilla:2008bi}, \cite{Beneke:2005kh}, there remain well-known data anomalies, particularly in connection with the polarization observations at the Tevatron \cite{Abazov:2007ku} and the size of the associated production cross section for $J/\psi$ with $c\bar{c}$ pairs, as seen by the BELLE and Babar collaborations \cite{Kou:2005zk}. Regarding the latter, the rate for $J/\psi$ associated production is unexpectedly large compared to $J/\psi$ with light hadrons. The importance of associated production within the formalism of NRQCD has recently been explored at leading order (LO) for hadroproduction in Ref. \cite{Kosower:2007pj} and at next-to-leading order (NLO) for $e^+e^-$ annihilation in Ref. \cite{Atwood:2007zb}. We will see, however, that NRQCD may not be the complete story for these processes.

Associated pair production for $J/\psi$ and related quarkonium states provides access to a novel kinematic region, where the heavy quarkonium is produced close in phase space to open heavy flavor. The presence of the additional quark, itself a source of color, could influence hadronization. In addition, studying this configuration sheds light on NRQCD factorization \cite{Atwood:2007zb} for processes without associated heavy quark pairs, and we will make contact with our previous work on that important question \cite{Kosower:2007pj}. We begin with a discussion of matching and infrared poles in dimensional regularization for NLO corrections to associated production of heavy quarks $Q$, of mass $m$, in $e^+e^-$ annihilation.

![FIG. 1: Representative lowest order diagrams for a virtual photon decaying into two heavy quark pairs, for fixed quark momentum $P_1$ and antiquark momentum $P_2$. The pair $P_1$ and $P_2$ will be associated with a bound state.](image-url)

Diagrams for $e^+e^- \rightarrow Q\bar{Q} + Q\bar{Q}$ are shown in Fig. \ref{fig:diagram}. Because we will study final states with two pairs, we will find it useful to refer to the pair that forms the bound state as the “active” pair. To be specific, we will denote the quark and antiquark momenta of the active pair as $P_1$ and $P_2$, respectively, with total and relative momenta and rest-frame relative velocity given by

$$P_1 = \frac{P}{2} + q, \quad P_2 = \frac{P}{2} - q, \quad v^2 = \frac{q^2}{E^2 - 2} = 1 - \frac{4m^2}{P^2}, \quad (1)$$

where $2E^*$ is the total center of mass energy of the active pair, and where in the second expression for $v^2$ we give the invariant form. In the diagrams of Fig. \ref{fig:diagram} we refer to the additional heavy particle that is closest in phase space to the active pair as the “spectator” quark (or antiquark).

The LO NRQCD cross sections for the amplitudes of Fig. \ref{fig:diagram} are given by

$$d\sigma_{e^+e^- \rightarrow H + X}(p_H) = \sum_n d\tilde{\sigma}_{e^+e^- \rightarrow Q\bar{Q}[n] + X}(p_H) \langle O_n^H \rangle,$$  \hspace{1cm} (2)

where $d\tilde{\sigma}_{e^+e^- \rightarrow Q\bar{Q}[n] + X}(p_H)$ is an NRQCD coefficient function, projected onto heavy quark pair state $Q\bar{Q}[n]$. 

\[\text{[arXiv:0707.2973v2  [hep-ph]]} \]
The corresponding NRQCD operators are of the form

$$O^{H}_{\mu}(0) = \sum_{N} \chi^\dagger(0) \kappa_{n} \psi(0) \{N, H\} \langle N, H | \psi^\dagger(0) \kappa'_{n} \chi(0) \rangle,$$

with $\kappa_{n}$ and $\kappa'_{n}$ projections for color (octet or singlet) and spin, and where we suppress gauge links [9]. At LO, NRQCD singlet configurations are present only in diagrams where the active quark and antiquark arise from different lines, as in the first graph on the right-hand side of Fig. 1. In the second graph, the active pair is purely octet, and is expected to contribute at a much lower level than the singlet NRQCD cross section [7], and all corrections to the singlet NRQCD cross section [7], and all infrared safe at higher orders. Not only infrared singularities but also singular dependence in any of the relative velocities must be absorbed into the long-distance matrix elements of the effective theory, a process referred to as matching. At LO, all gluons are off-shell by at least a multiple of $m$, and the full LO amplitudes may be absorbed into coefficient functions. Nontrivial issues of factorization and matching first arise at NLO.

For NRQCD factorization to be predictive, it is necessary that the coefficient function, $d\hat{\sigma}_{e^+e^-\rightarrow Q\bar{Q}[n]+X(P_H)}$ be infrared safe at higher orders. Not only infrared singularities, but also singular dependence in any of the relative velocities must be absorbed into the long-distance matrix elements of the effective theory, a process referred to as matching. At LO, all gluons are off-shell by at least a multiple of $m$, and the full LO amplitudes may be absorbed into coefficient functions. Nontrivial issues of factorization and matching first arise at NLO.

As noted above, when more than two relative velocities are small, the standard NRQCD power counting does not apply directly, simply because there are now three dimensionless scales, $\beta_{ij} \equiv \sqrt{1 - 4m^2/(P_i + P_j)^2}$, $i \neq j = 1, 2, 3$, instead of the single $v = \beta_{12}$ defined by the active pair. Thus, where there was once one “soft” region $mv$ and one “ultrasoft” region $mv^2$, there are now three of each. Let us see how these considerations emerge in the NLO diagrams of Fig. 2.

We stress that the region of small relative velocity for three of the four particles in double heavy-pair production is leading-power in the overall center-of-mass energy, $\sqrt{s}$. For example, the two diagrams on the right-hand side of Fig. 1 contribute to the fragmentation of a heavy quark into the quark plus a pair. Such contributions also occur as part of the high-$p_T$ cross section for associated production in hadronic collisions, as studied in Ref. [2].

![FIG. 2: Diagrams for one-loop virtual infrared corrections, where the blob represents a complete set of lowest order Feynman diagrams, as shown in Fig. 1.](image)

When $\beta_{ij} \ll 1$, the infrared pole behavior of any of the exchanges shown in Fig. 2 is given up to a sign by

\[
-i \frac{g^2}{2 \pi} \int \frac{d^D k}{(2\pi)^D} \frac{4P_i \cdot P_j}{[2P_i \cdot k + k^2 + i\epsilon][-2P_j \cdot k + k^2 + i\epsilon][k^2 + i\epsilon]} = \frac{\alpha_s}{2\pi} \left[ -\frac{1}{2\epsilon} \left( \frac{1}{\beta_{ij}} + \beta_{ij} \right) (2\beta_{ij} - i\pi) + \ldots \right].
\]

with corrections that are finite as $\epsilon = 2 - D/2 \rightarrow 0$ or that vanish as higher powers of $\beta_{ij}$. We will concentrate on the
imaginary term, which is singular for both vanishing $\beta$ and $\epsilon$. Consider now the imaginary contributions of Eq. (4) to the NLO amplitude $A_{\beta}$, traversed over the colors of the active pair to enforce a singlet configuration in the final state. Denoting by $A_{\beta}$ the amplitude with an exchange between $P_{1}$ and $P_{2}$, we have, suppressing common color factors in the quark and antiquark couplings,

$$\text{Im} \left[ A_{13} + A_{23} \right] = \frac{\alpha_{s}}{4\epsilon} A^{(0)}(P) \left[ \frac{1 + \beta_{13}^{2}}{\beta_{13}} - \frac{1 + \beta_{3}^{2}}{\beta_{23}} \right] \quad (5)$$

where $A^{(0)}$ represents the LO amplitude. From this soft gluon correction, the third and fourth diagrams in Fig. 2 inherit color singlet configurations for the pair $P_{1}, P_{2}$ in the final state at NLO. We should mention that this contribution is subleading in the number of colors $N_{c}$. Indeed, it constitutes an alternative mechanism to the “preconfinement” scenario, identified long ago in Ref. [11], and built into most hadronization models in event generators [12].

The essential feature of Eq. (4) is the presence of poles in the relative velocities $\beta_{13}$ and $\beta_{3}$. These poles cancel identically for $P_{1} \cdot P_{3} = P_{2} \cdot P_{3}$ or for $P_{3}^{2} = 0$. In the former case, the relative velocity of the spectator quark and the active quark equals the relative velocity of the spectator and the active antiquark. Here, soft gluons emitted by the spectator cannot resolve the charges of the active quark (of momentum $P_{3}$) and $P/2$ [13],

$$\beta_{S} = \sqrt{\frac{-q_{S}^{2}}{m^{2} - q_{S}^{2}}}, \quad P_{S}^{\mu} = \frac{P_{S}^{\mu}}{2} \sqrt{1 - \frac{q_{S}^{2}}{m^{2}} + q_{S}^{\mu}} \quad (6)$$

with $P_{0}^{\mu} = (2m, 0)$ and $q_{S} \cdot P_{0} = 0$. Expanding in the relative momentum of the active pair in the spirit of NRQCD, we find

$$\frac{1}{\beta_{13}} - \frac{1}{\beta_{23}} \sim -\frac{4}{\beta_{3}^{2}} \frac{q_{S} \cdot q}{m^{2}} \sim \frac{4}{\beta_{S}} v \cos \phi_{S}, \quad (7)$$

where in the second relation $\phi_{S}$ is the angle between the vectors $q_{S}$ and $q$. The presence of the cosine, which is odd under the interchange of the members of the active pair, is an expression of the dipole nature of this contribution to the amplitude.

Although the expansion in Eq. (7) is applicable in only a limited region of phase space, it is a region in which the active pair and spectator quark form a system of invariant mass of order $(3m)^{2}$. In this kinematic region, the squares of NLO corrections to LO diagrams like those on the right-hand side of Fig. 1 contribute to the cross section at leading power in the overall center-of-mass energy. At NNLO, the squares of the imaginary poles of Eq. (1) produce $\alpha_{s}^{4}(1/\epsilon^{2})$ corrections to the cross section. All other diagrams contribute only at the single-pole level [13]. We note again, that in accordance with the results of Ref. [9], this contribution vanishes in the limit $m \rightarrow 0$, and so is consistent with NRQCD factorization at large $p_{T}$.

In summary, we have identified a new, leading-power “color-transfer” infrared-divergent contribution to the formation of color-singlet pairs, which is specific to associated production. This contribution must be added to that of the familiar color-octet mechanism [1]. The infrared divergence signals that color transfer cannot be absorbed into a coefficient function, while its dependence on $\beta_{S}$ signals that it cannot be absorbed into matrix elements in an effective field theory based on the dynamics of a single pair. This mechanism is non-leading in the number of colors, although that by itself should not eliminate it from consideration.

It is natural to try and estimate the magnitude of this new effect. A plausible estimate can be given by elaborating on the analogy just observed between the normal color octet mechanism and color transfer. In both cases, an S-wave pair is transformed to P-wave by the gluonic field strength contracted with the pair’s color dipole. In the octet mechanism, the field couples to the polarization of an emitted gluon, while in color transfer it is coupled to the Coulomb field of the spectator. To return to an S-wave state, we will assume a $\beta_{S}$-independent $v^{2}$ suppression, following NRQCD power counting [1, 2]. At fixed $\beta_{S}$, let us assume that the nonperturbative formation of quarkonium state, $H$ is similar for these two transitions. We then square the $\beta_{S}$-dependent kinematic factor of Eq. (7), and replace the $v$-dependence by the NRQCD matrix element $\langle 3S_{0}^{H} \rangle$. In the total cross section at fixed $\beta_{S}$, such
that is, the standard color singlet, plus a color-octet contribution enhanced by the factor $1/\beta_S^4$, with $\beta_S$ the velocity of the closest heavy spectator, $Q' = Q, \bar{Q}$. By numerical evaluation, we have verified [13] that the short-distance cross section, $d\sigma_{e^+e^-\rightarrow Q\bar{Q}S_1+Q'(\beta_S)}(p_H)$ is also larger than the corresponding singlet contribution. With $\beta_S \sim 0.3$, our estimate of color transfer would then become competitive with the color singlet cross section at the same $\beta_S$. Of course, for $\beta_S < v$ an expansion in $v/\beta_S$ loses meaning, and we do not offer Eq. (8) as a realistic estimate, especially for $J/\psi$, with $v \sim 0.5$. We do present it, however, as an indication of the possible importance of the new mechanism.

A signature of the color-transfer process would clearly be an enhancement in any open heavy flavor at low relative velocity to quarkonia, in hadronic scattering as well as leptonic annihilation. Another signal could be in studies of polarization. As observed in Ref. [6] in the context of LO NRQCD, associated production leads to a more complex polarization structure than that expected from a pure octet mechanism. Although color transfer does not fall cleanly into the analysis of NRQCD, we might expect much the same spin symmetry to apply, so that a study of polarization effects can also help characterize this mechanism.

To develop an effective theory that incorporates color transfer, we shall have to add new operators. As already found in Ref. [6] in the context of NRQCD factorization, the long-distance transition from octet to color singlet states can be associated with a nonlocal operator of the form $\int_0^\infty d\lambda' \lambda' \left[ P^\mu q' F_{\nu\mu,a}(\lambda' P) \right]$, with $P$ and $q$ as in Eq. (1). Noting that $\lambda q$ can be interpreted as the configuration-space separation of a pair, we see that this is the same operator that represents the singlet-octet transition in the potential NRQCD Hamiltonian [14, 15], here extended to production. It is clear, however, that this correspondence holds only in the region where we can strongly order the velocities. More generally, we shall have to introduce products of three fields, as $\psi_i^\dagger P_1 \bar{\chi} P_2 \psi_j^\dagger$, whose interactions with the soft gluon field will be labeled by momenta (as in NRQCD) according to heavy quark effective theory. In general the nonperturbative dynamics of these operators will overlap with those of NRQCD, as well as those of potential NRQCD. It will require some care to avoid double counting and to develop a formalism that can be matched to the phenomenology of associated production.

We thank Geoff Bodwin for many useful discussions on factorization.
