ABSTRACT

NGC 1068 is a nearby Active Galactic Nucleus (AGN) of type 2, meaning that its accretion disk is hidden behind a large amount of foreground extinction. Observations at several wavelengths have revealed various disk-like structures around the nucleus, all possibly part of the putative torus responsible for the obscuration of the AGN. The paper presents results based on GRAVITY/VLTI interferometric observations in the near-infrared, which provide very high angular resolution, and gives insights into the geometry of the innermost region of the torus. The 3D orientation of the structure is surprising in several aspects, as it is misaligned with other disks present around the nucleus, and leaves a clear line of sight toward the central source.

Key words: NGC 1068 – Active Galactic Nuclei – GRAVITY – dust

1 Introduction

AGN are observed with various characteristics in terms of luminosity and spectral properties. A large amount of these differences can be explained by the Unified Model of AGN originally proposed by Antonucci (1993), which states that a structure surrounding the central source causes drastic extinction for some positions of the observer. This parsec-scale obscuring structure (commonly called the torus) is assumed to be located in the equatorial plane of the jet, and to be the continuation of the large-scale accretion flow.

The AGN of NGC 1068 is among the easiest to observe, as it is relatively close to us ($D_L = 14.4$ Mpc, with $1''$ corresponding to 70 pc), and is located in the center of a face-on spiral galaxy. As a consequence, the object has been observed by many instruments, and a wealth of information is available at various wavelengths and spatial scales. It is known to be a type 2 AGN, meaning that its central source is obscured by a large amount of foreground material. The following list presents some of the main structures present in the nucleus of NGC 1068; from large to small spatial scales:

- The Narrow Line Region, which is an ionized outflow observed and characterized through spatially resolved emission line Doppler shifts in the UV and IR (Das et al., 2006; Poncet et al., 2008), extends up to several hundred parsecs from the nucleus. It appears to have a hollow bicone shape with a revolution axis almost in the plane of the sky ($i \sim 5\,–\,10\,^\circ$) and oriented with PA $\sim 30\,^\circ$.
- An extended scattering structure, observed through polarimetric imaging with SPHERE and described by Gratadour et al. (2015). With dimensions of $20 \times 60$ pc, it appears to be seen edge-on, and is oriented with PA $\sim 120\,^\circ$.
- A molecular disk, observed through CO and HCN emission lines with ALMA (García-Burillo et al., 2016; Gallimore et al., 2016; Impellizzeri et al., 2019). With a typical spatial scale of $\sim 10$ pc, it is aligned along PA $\sim 110\,^\circ$ and seems to have an inclination comprised between 34 and 66$\,^\circ$. Interestingly, this disk is counter-rotating with respect to both the external regions of the galaxy and the inner maser disk (described below).
- An edge-on maser disk observed with the VLBA, with an inner radius $r_{in} \sim 0.65$ pc and an outer radius $r_{out} \sim 1.1$ pc, oriented along PA $\sim 135\,^\circ$ (Greenhill et al., 1996).

The different structures described above are good examples of the general cylindrical geometry assumed for AGN, with an outflow along the polar axis and cold, obscuring material in the equatorial plane. However, as one can notice in the $i$ and PA values given above, these structures are only approximately aligned with these two preferred directions.

The next section presents the geometrical properties of the hot dust located within the inner radius of the maser disk, based on the analysis of very high angular resolution observations obtained with GRAVITY, the near-infrared instrument of the VLTI. The orientation of this hot dust with respect to other components of the nucleus will be discussed in the following sections.

2 Observation and results

This study is based on a GRAVITY observation of NGC 1068, performed during the night of November 20, 2018 (Gravity Collaboration et al., 2017, ESO programmes IDS 0102.B-0667, 0102.C-0205 and 0102.C-0211). GRAV-
Gallimore et al. (2001) were then used to compute synthetic interferometric observables: the squared visibility (with wavelength dependence), closure phase in Fig. 1, and an optimal solution is found, which is in fair agreement with the observed K band magnitude. This result is supported by the fact that the luminosity of the central source is at the sublimation temperature, its radius matches well the previous estimate from independent measurements, ranging from a few $10^3$ W to a few $10^8$ W (Pier et al., 1994; Bland-Hawthorn et al., 1997; Kishimoto, 1999; Gallimore et al., 2001).

These two conclusions indicate that the inner edge of the dusty torus is not responsible for the extinction toward the central accretion disk, but is rather itself surrounded by a large amount of obscuring material.

### 4 Misalignments

The second remarkable feature of this hot dusty ring model is its misalignment with respect to the previously mentioned structures. Compared to the extended scattering torus, it is not seen edge-on, and the estimations of their PA differ by 30°. The inclination of the molecular torus could be compatible, but their PA differ even more. At last, our model is similar to the maser disk in terms of PA but greatly differs in terms of inclination, with the maser detection requiring a disk closely aligned to the line of sight.

Since these structures are also misaligned between each other, and that several methods used to model the GRAVITY
Fig. 2. Comparison of the model with observed quantities. Top panel: observed and modeled squared visibility. Bottom panel: observed and modeled closure phase.
observations gave similar geometrical parameters (geometric modeling in Vermot et al. (2021) and image reconstruction in Gravity Collaboration et al. (2020)), one can reasonably assume that this new misalignment is not an artifact resulting from the interpretation of the interferometric data.

Geometrically, these observations at different wavelengths could probe different radii of a warped large scale-disk. However, this wouldn’t explain the counter-rotation observed between the molecular and maser disks, and no sign of warping is present in the maser observations. Hence, it can be concluded that these different observations are not probing a unique structure, but several ring-like objects intricated around the nucleus. Such structures could result from the tidal disruption of molecular clouds surrounding the nucleus, as seen in the Milky Way.
