Abstract—As machine learning (ML) has seen increasing adoption in safety-critical domains (e.g., autonomous vehicles), the reliability of ML systems has also grown in importance. While prior studies have proposed techniques to enable efficient error-resilience techniques (e.g., selective instruction duplication), a fundamental requirement for realizing these techniques is a detailed understanding of the application’s resilience. In this work, we present TensorFI, a high-level fault injection (FI) framework for TensorFlow-based applications. TensorFI is able to inject both hardware and software faults in general TensorFlow programs. TensorFI is a configurable FI tool that is flexible, easy to use, and portable. It can be integrated into existing TensorFlow programs to assess their resilience for different fault types (e.g., faults in particular operators). We use TensorFI to evaluate the resilience of 12 ML programs, including DNNs used in the autonomous vehicle domain. Our tool is publicly available at https://github.com/DependableSystemsLab/TensorFI.

I. INTRODUCTION

In the past decade, Machine Learning (ML) has become ubiquitous in many applications. ML is also being increasingly deployed in safety-critical applications such as Autonomous Vehicles (AVs)2 and aircraft control3. In these domains, it is critical to ensure the reliability of the ML algorithm and its implementation as faults can lead to loss of life and property. Moreover, there are often safety standards in these domains that prescribe the allowable failure rate. For example, in the AV domain, the ISO 26262 standard mandates that the FIT rate (Failures in Time) of the system be no more than 10, i.e., at most 10 failures in a billion hours of operation4, in order to achieve ASIL-D levels of certification. Therefore, there is a compelling need to build efficient tools to (1) test and improve the reliability of ML systems, and (2) evaluate their failure rates in the presence of different fault types.

The traditional way to experimentally assess the reliability of a system is fault injection (FI). FI can be implemented at the hardware or software level. Software-Implemented FI (also known as SWiFI) has lower costs, is more controllable, and easier for developers to deploy5. Therefore, SWiFI has become the dominant method to assess a system’s resilience to both hardware and software faults.

There has been a plethora of SWiFI tools such as NF-Tape6, Xception7, GOOFI8, LFI9, LLFI10, PINFI11. These tools operate at different levels of the system stack, from the assembly code level to the application’s source code level. In general, the higher the level of abstraction of the FI tool, the easier it is for developers to work with, and use the results from the FI experiments5.

Due to the increase in popularity of ML applications, there have been many frameworks developed for writing them. One of the most popular frameworks is TensorFlow12, which was released by Google in 2017. Other examples are PyTorch13 and Keras14. Unlike traditional applications, these frameworks allow the developer to “compose” their application as a sequence of operations, which are connected together in the form of a graph. The connections represent the data-flow and control dependencies among the operations. While the underlying implementation of these frameworks is in C++ or assembly code for performance reasons, the developer writes their code using high-level languages (e.g., Python).

In this paper, we introduce a SWiFI tool called TensorFI which injects faults into the data-flow graph used in TensorFlow applications. TensorFI performs interface-level FI15,16. We focus on TensorFlow as it is the most popular framework used today for ML applications17, though our technique is not restricted to TensorFlow. TensorFI can be used to inject both hardware and software faults in the outputs of TensorFlow operators, and study the effects of the faults on the ML application. The main advantage of TensorFI over traditional SWiFI frameworks is that it directly operates on the TensorFlow operators and graph, and hence its results are readily accessible to developers.

Building a FI tool for TensorFlow applications is challenging due to three reasons. First, because TensorFlow operators are implemented in C++ or assembly code and optimized for different platforms (i.e., different processors and operating systems), it is not practical to modify the implementation of these operators as doing so will hurt both portability and performance. However, in order to inject faults at the level of TensorFlow operators and the graph, one needs to intercept the operators at runtime to modify their execution results. Unfortunately, TensorFlow does not expose the operators once the graph has been constructed, and most of the execution...
occurs “behind the scenes” in the low-level code. Therefore, it is not possible to intercept these operators. Secondly, the speed of execution of the TensorFlow graph should not be adversely affected when no faults are injected, as otherwise developers will avoid using the framework. Finally, there are many external libraries that are used by TensorFlow developers. These often rely on the structure and semantics of the TensorFlow graph, and hence these should not be modified.

TensorFI addresses the above challenges by first duplicating the TensorFlow graph and creating a FI graph that parallels the original one. The operators in the FI graph mirror the functionality of the original TensorFlow operators, except that they have the capability to inject faults based on the configuration parameters specified. These operators are implemented by us in Python, thereby ensuring their portability. Moreover, the FI graph is only invoked during fault injection, and hence the performance of the original TensorFlow graph is not affected (when faults are not injected). Finally, because we do not modify the TensorFlow graph other than to add the FI graph, external libraries that depend on the graph’s structure and semantics can continue to work.

We make the following contributions in this paper.

- Propose a generic FI technique to inject faults at the level of the TensorFlow graph, without hurting portability and performance,
- Implement the FI technique in TensorFI, a flexible tool, which allows easy configuration of FI parameters.
- Evaluate TensorFI on 12 ML applications in TensorFlow, including deep neural network (DNN) applications used in AVs, across a wide range of FI configurations (e.g., fault types, error rates). We find that there are significant differences due to both individual ML applications, as well as due to different configurations. We also evaluate the performance of TensorFI.

II. BACKGROUND AND FAULT MODEL

We start by explaining the general structure of ML applications, followed by related work in the area of ML reliability. We then introduce the fault model we assume in this paper.

A. Machine Learning Applications

An ML model takes an input that contains specific features to make a prediction. Prediction tasks can be divided into classification and regression. The former is used to classify the input into categorical outputs (e.g., image classification). The latter is used to predict dependent variable values based on the input. ML models can be either supervised or unsupervised. In the supervised setting, the training samples are assigned with known labels (e.g., linear regression, neural network), while in an unsupervised setting there are no known labels for the training data (e.g., k-means, kernel density estimation).

An ML model typically goes through two phases: 1) training phase where the model is trained to learn a particular task; 2) inference phase where the model is used for making predictions on test data. The parameters of the ML model are learned from the training data, and the trained model will be evaluated on the test data, which represents the unseen data and will not be used in the training phase.

B. Related Work

Several studies have attempted to evaluate the error resilience of ML applications through fault injections [18], [19]. However, such FI techniques are limited to the specific application being studied, unlike TensorFI that is able to perform FI on generic ML applications.

More recent studies investigate the resilience of deep neural networks (DNN) by building fault injectors [20]–[23]. Li et al. build a fault injector by using the tiny-CNN framework [20]. Reagen et al design a generic framework for quantifying the error resilience of ML applications [21]. Sabbagh et. al develop a framework to study the fault resilience of compressed DNNs [23]. However, their study focuses only on DNNs and hardware faults, and hence is not applicable to other ML algorithms. Chen et al. introduce a technique to efficiently prune the hardware FI space by analyzing the underlying property of ML models [22]. In contrast to the above studies, TensorFI targets a broad range of ML applications, and can be used to inject both software and hardware faults.

C. TensorFlow

TensorFlow is an open-source framework for modeling large data-flow graphs and widely used for building ML programs. TensorFlow allows programmers to represent the program in the form of a TensorFlow graph (see below). TensorFlow is flexible and can be better optimized as it exposes the underlying graph to the developer. Thus, TensorFlow is considered a low level framework. Many high level frameworks like Keras use TensorFlow as their backend for implementation.

To use TensorFlow, programmers use the built-in operators to construct the data-flow graph of the ML algorithm during the training phase. Once the graph is built, it is not allowed to be modified. During the inference phase, data is fed into the graph through the use of placeholder operators, and the outputs of the graph correspond to the outputs of the ML algorithm. In this phase, the graph is typically executed directly in the optimized form on the target platform using custom libraries.

TensorFlow also provides a convenient Python language interface for programmers to construct and manipulate the data-flow graphs. Though other languages are also supported, the dominant use of TensorFlow is through its Python interface. Note however that the majority of the ML operators and algorithms are implemented as C/C++ code, and have optimized versions for different platforms. The Python interface simply provides a wrapper around these C/C++ implementations.

D. Fault Model

In this work, we consider two types of faults, hardware faults and software faults that occur during the execution of the TensorFlow program. As TensorFI operates at the level of TensorFlow operators, we abstract the faults to the operators’ interfaces. Thus, we assume that a hardware or software fault that arises within the TensorFlow operators, ends up
corrupting (only) the outputs of the operators. We do not make assumptions on the nature of the output’s corruption. For example, we consider that the output corruption could be manifested as a random value replacement (e.g., mutation testing \cite{24}) or a single bit-flip \cite{20–23}. We also assume that the faults do not modify the structure of the TensorFlow graph, and that the inputs provided into the program are correct, because such faults are extraneous to TensorFlow and are outside our scope. Finally, we assume that the faults occur neither in the ML algorithms, nor in the parameters of the ML model. This assumption is needed for us to compare the output of the FI runs with the golden runs, in order to determine if a Silent Data Corruption (SDC) has occurred.

We only consider faults during the inference phase of the ML program. Because training is usually a one-time process and the results of the trained model can be checked. Inference, however, is executed repeatedly with different inputs, and is hence likely to experience faults. This fault model is in line with other work in this area \cite{20–23}.

III. METHODOLOGY

We start this section by articulating the design constraints of TensorFI. We then present the design of TensorFI, and an example of its operation. Finally, we present its implementation and explain how to configure it.

A. Design Constraints

We follow 3 constraints in the design of TensorFI.

- **Ease of Use and Compatibility:** The injector should be easy-to-use and require minimal modifications to the application code. We also need to ensure compatibility with third-party libraries that may construct the TensorFlow graph using custom APIs.

- **Portability:** Because TensorFlow may be pre-installed on the system, and each individual system may have its own installation of TensorFlow, we should not assume the programmer is able to make any modifications to TensorFlow or its libraries.

- **Minimal Interference:** First, the injection process should not interfere with the normal execution of the TensorFlow graph when no faults are injected. Further, it should not make the main graph incapable of being executed on GPUs or parallelized due to the modifications it makes. Finally, the fault injection process should be reasonably fast, when faults are injected.

We also make two assumptions in TensorFI. First, we assume that faults occur only during the execution of the TensorFlow operators, and that the faults are transient in nature. In other words, if we reexecute the same operator, the fault will not reappear. This is because studies have shown that the kinds of faults that are prevalent in mature software are often transient faults \cite{25}. Second, we assume that the effect of a fault propagates to the outputs of the TensorFlow operators only, and not to any other state. In other words, there is no error propagation to the permanent state, which is not visible at TensorFlow graph level. Again, this is due to the structure of TensorFlow graphs, and our fault model (Section II).

B. Design of TensorFI

To satisfy the design constraints outlined earlier, TensorFI operates directly on TensorFlow graphs. The main idea is to create a replica of the original TensorFlow graph but with new operators. The new operators are capable of injecting faults during the execution of the operators and can be controlled by an external configuration file. Further, when no faults are being injected, the operators emulate the behavior of the original TensorFlow operators they replace. Because TensorFlow does not allow the dataflow graph to be modified once it is constructed, we need to create a copy of the entire graph, and not just the operators we aim to inject faults into. The new graph mirrors the original one, and takes the same inputs as it. However, it does not directly modify any of the nodes or edges of the original graph and hence does not affect its operation. At runtime, a decision is made as to whether to invoke the original TensorFlow graph or the duplicated one for each invocation of the ML algorithm. Once the graph is chosen, it is executed to completion at runtime.

TensorFI works in two phases. The first phase instruments the graph, and creates a duplicate of each node for fault injection purposes. The second phase executes the graph to inject faults at runtime, and returns the corresponding output. Note that the first phase is performed only once for the entire graph, while the second phase is performed each time the graph is executed (and faults are injected). We explain below how this satisfies the design constraints.

- **Ease of Use and Compatibility:** To use TensorFI, the programmer change a single line in the Python code. Everything else is automatic, namely the graph copying and duplication. Because we duplicate the TensorFlow graph, our method is compatible with external libraries.

- **Portability:** We do not make any modifications to the TensorFlow code or the internal C++ implementation of the TensorFlow operators, which are platform specific. Therefore our implementation is portable. We do however require the interfaces of the TensorFlow operators are consistent across TensorFlow versions.

- **Minimal Interference:** TensorFI does not interfere with the operation of the main TensorFlow graph. Further, the original TensorFlow operators are not modified in any way, and hence they can be optimized or parallelized for specific platforms. The only overhead introduced by TensorFI is the check at runtime on whether to call the original graph or the duplicated graph, but this incurs minimal overhead.

C. Example of TensorFI’s Operation

We consider an example of TensorFI’s operation on a small TensorFlow program. Because our goal is to illustrate the operation of TensorFI, we consider a simple computation rather than an ML algorithm. The example is shown in Figure [1]. The nodes in blue represent the original TensorFlow graph,
while those in red represent the duplicated nodes created by TensorFI.

In the original TensorFlow graph, there are two operators, an ADD operator which adds two constant node “a” and “b”, and a MUL operator, which multiplies the resulting value with that from a place-holder node. A place-holder node is used to feed data from an external source such as a file into a TensorFlow graph, and as such represents an input to the system. A constant node represents a constant value. TensorFI duplicates both the ADD and MUL operators in parallel to the main TensorFlow graph, and feeds them with the values of the constant nodes as well as the place-holder node. Note however that there is no flow of values back from the duplicated graph to the original graph, and hence the fault injection nodes do not interfere with the original computation performed by the graph. The outputs `orig` and `faulty` represent the original and fault-injected values respectively. The graph is created before the fault injection process is launched after the training phase.

At runtime, a dynamic decision is made as to whether we want to compute the `orig` output or the `faulty` output. If the `orig` output is demanded, then the graph nodes corresponding to the original TensorFlow graph are executed. Otherwise, the nodes inserted by TensorFI are executed and these emulate the behavior of the original nodes, except that they inject faults. For example, assume that we want to inject a fault into the ADD operator. Every other node inserted by TensorFI would behave exactly like the original nodes in the TensorFlow graph, with the exception of the ADD operator which would inject faults as per the configuration (Section III-E).

D. Implementation

TensorFI supports the following features:

- Comparing each FI result with the golden run
- Launching multiple FI runs in parallel (multi-threading)
- Support for visualizing the modified TensorFlow graphs
- Ability to specify fault type etc. in a configuration file
- Automated logging of fault injection runs
- Support for statistics collection and analysis

Our implementation consists of about 2500 lines of heavily commented Python code, and is split into 5 modules. We have made TensorFI publicly available under a MIT license on Github (https://github.com/DependableSystemsLab/TensorFI), along with extensive documentation.

E. Configurations

TensorFI allows the user to configure it through a YAML interface. Figure 2 shows a sample file for configuring TensorFI in YAML format. This is loaded at program initialization, and is fixed for the entire fault injection campaign. The config file consists of the following fields:

- **Seed**: The random seed used in the fault injection experiments, for reproducibility purposes (this is optional).
- **ScalarFaultType**: The fault type to inject for scalar values (full list of types in Table I). We set this to `bitflip-Element`.
- **TensorFaultType**: The fault type to inject for tensor values (full list of types in Table I). We set this to `bitflip-Element`.
- **InjectMode**: The mode of injection (list of modes in Table II). We set this to `errorRate`.
- **Ops**: This is a list of the TensorFlow operators that need to be injected, and the probability for injecting a fault into each operator when the mode is `errorRate`. Probability values can range from 0 (never inject) to 1 (always inject). We choose `ALL`, which represents all operators.
- **SkipCount**: This is an optional parameter for skipping the first ‘n’ invocations of an operator before injection, where ‘n’ can be any integer value, greater than 0.

IV. EVALUATION

Our goal is to study how resilient are different ML applications (and datasets) to different fault configurations of TensorFI, thereby demonstrating its utility. We first describe

| Mode               | Meaning                                      |
|--------------------|----------------------------------------------|
| errorRate          | Specify the error rate for different operator instances |
| dynamicInstance    | Perform random injection on a randomly chosen instance of each operation |
| oneFaultPerRun     | Choose a single instance among all the operators at random so that only one fault is injected in the entire execution |

### Table I: List of fault types supported by TensorFI

| Type               | Explanation                                      |
|--------------------|--------------------------------------------------|
| None               | Do not inject a fault                             |
| Zero               | Change output of the target operator into all zeros |
| Rand               | Shuffle all data items in the output of the target operator into random values |
| Rand-element       | Shuffle one data item in the output of the target operator into a random value |
| bitFlip-element    | Single bit-flip in one data item in the output of the target operator |
| bitFlip-tensor     | Single bit-flip in all data items in the output of the target operator |

### Table II: List of injection modes supported by TensorFI

| Mode               | Meaning                                      |
|--------------------|----------------------------------------------|
| errorRate          | Specify the error rate for different operator instances |
| dynamicInstance    | Perform random injection on a randomly chosen instance of each operation |
| oneFaultPerRun     | Choose a single instance among all the operators at random so that only one fault is injected in the entire execution |
our experimental setup, followed by the research questions we ask in this study. We then present our results.

A. Experimental Setup

**ML applications:** We choose a total of 12 ML applications, 12 of which are supervised learning applications (e.g., and deep neural networks like ResNet, VGGNet) that are commonly used in existing studies. In addition, we also choose an ML application used in the AV domain, i.e., comma.ai driving model. Table I lists the applications.

In addition to supervised models, TensorFI can be used to inject faults into unsupervised models that use clustering, decision trees etc. We use one such application Generative Adversarial Networks (GAN) to show the effects of the injected faults visually. Because GANs do not have an expected output label, we do not consider it as part of the other experiments.

**ML datasets:** We use 4 public ML datasets that are commonly used in ML studies. MNIST dataset is a handwritten digits dataset (with 10 different digits). GTSRB dataset is a dataset consisting of 43 different types of traffic signs. ImageNet is a large image dataset with more than 14 million images in 1000 classes. In addition, we use a real-world driving dataset that is labeled with steering angles.

For models that use the ImageNet dataset (ResNet-18 and SqueezeNet), we use the pre-trained model from since it is commonly used in ML studies. In addition, we also choose an ML application used in the AV domain, i.e., comma.ai driving frame as metrics to evaluate the model's accuracy - these are commonly used in ML studies in the AV domain.

**Metrics:** We consider SDC rate as the metric for evaluating the resilience of ML applications. An SDC is a wrong output that deviates from the expected output of the program. SDC rate is the fraction of the injected faults that result in SDCs. For classifier applications, an SDC is any misclassification. However, the steering model comma.ai produces a continuous value as output. For this model, we use different threshold values for the deviations of steering angles to identify SDCs: 15, 30, 60 and 120 degrees. For the steering model, we use RMSE (root mean square error) and average deviation per frame as metrics to evaluate the model's accuracy - these are commonly used in ML studies in the AV domain.

**Experiments:** For each benchmark, we perform 1000 random FI experiments per fault configuration and input. We choose 10 inputs for each application, and hence perform a total of 10,000 fault injections per configuration and we use 14 different fault configurations. We also calculate the error bars at the 95% confidence interval for each experiment.

Fig. 3 shows examples of some of the SDCs observed in our experiments for both the steering model and classification applications. These may result in safety violations in AVs if they are not mitigated. With that said, we do not specifically distinguish safety-critical outcomes in SDCs.

B. Research Questions

We use different configurations of TensorFI (shown in Table I and Table II) for answering the following Research Questions (RQs):

| ML model | Dataset | Dataset Description | Accuracy |
|----------|---------|---------------------|----------|
| Neural Net | MNIST | Hand-written digits | 85.42% |
| Fully Connected Net | MNIST | Hand-written digits | 97.54% |
| LeNet | MNIST | Hand-written digits | 99% |
| AlexNet | MNIST | Hand-written digits | 94% |
| CNN | MNIST | Hand-written digits | 95.74% |
| Highway CNN | MNIST | Hand-written digits | 97.92% |
| Recurrent NN | MNIST | Hand-written digits | 98.40% |
| VGG11 | GTSRB | Real-world traffic sign | 99.74% |
| ResNet-18 | ImageNet | General images | 62.66% (top-1) |
| SqueezeNet | ImageNet | General images | 52.936% (top-1) |
| comma.ai model [28] | Driving | Real-world driving frame | 24.12 (RMSE) |

| Error Rate | SDC Rate | ML model | Dataset | Dataset Description | Accuracy |
|------------|----------|----------|---------|---------------------|----------|
| oneFaultPerRun | 0.01 | Neural Net | MNIST | Hand-written digits | 85.42% |
| dynamicInstance | 0.01 | Fully Connected Net | MNIST | Hand-written digits | 97.54% |
| oneFaultPerRun | 0.01 | LeNet | MNIST | Hand-written digits | 99% |
| dynamicInstance | 0.01 | AlexNet | MNIST | Hand-written digits | 94% |
| oneFaultPerRun | 0.01 | CNN | MNIST | Hand-written digits | 95.74% |
| dynamicInstance | 0.01 | Highway CNN | MNIST | Hand-written digits | 97.92% |
| oneFaultPerRun | 0.01 | Recurrent NN | MNIST | Hand-written digits | 98.40% |
| dynamicInstance | 0.01 | VGG11 | GTSRB | Real-world traffic sign | 99.74% |
| oneFaultPerRun | 0.01 | ResNet-18 | ImageNet | General images | 62.66% (top-1) |
| dynamicInstance | 0.01 | SqueezeNet | ImageNet | General images | 52.936% (top-1) |
| oneFaultPerRun | 0.01 | comma.ai model [28] | Driving | Real-world driving frame | 24.12 (RMSE) |

RQ1: What are the SDC rates of different applications under the oneFaultPerRun and dynamicInstance error modes?

RQ2: For the errorRate mode, how do the SDC rates vary for different error rates?

RQ3: How do the SDC rates vary for faults in different TensorFlow operations in the same ML application?

RQ4: What is the performance overhead of TensorFI?

C. Results

We organize the results for the 11 ML models listed in Table II by each RQ, and then show the results of the FI experiments for GANs. For RQ1 and RQ2, we choose all the operations in the data-flow graph during the inference phase, which is a subset of operations in the TensorFlow graph. This is because many of the operations in the TensorFlow graph are for training, and are not executed during the inference phase (thus we do not inject faults into these operations). We also do not inject faults into those operations that are related to the input (e.g., reading the input, data preprocessing), as we assume that the inputs are correct as per our fault model.

1) RQ1: Error resilience for different error modes: In this RQ, we study the effects of two different error modes, namely oneFaultPerRun and dynamicInstance. We choose single bit flip faults as the fault type for this experiment. Fig. 3 shows the SDC rates obtained across applications. We can see that different ML applications exhibit different SDC rates, and there is considerable variation.

We can also observe that there are differences between the two fault modes. For the dynamic instance injection mode, the SDC rates for all the applications are higher than those in the one fault per run mode. This is because in the dynamic instance mode, each type of operation will be injected at least...
once, while in the one fault per run mode, only one operator is injected in the entire application. Thus the applications present higher SDC rates for the former.

We also observe significant differences between applications within the one fault per run mode. For example, the comma.ai driving model has a higher SDC rate than the classifier applications. This is because the output of the classifier applications are not dependent on the absolute values (instead classification probability is used). Thus, the applications are still able to generate correct output despite the fault occurrence, and hence have higher resilience. However, the comma.ai model predicts the steering angle, which is more sensitive to value deviations. For example, a deviation of 30 due to fault in the classification model will not cause an SDC as long as the predicted label is correct; whereas the deviation would constitute an SDC in the comma.ai model if we use the threshold=15 or 30.

In the one fault per run mode, we find that RNN exhibits the highest resilience (less than 1% SDC rate). This is because unlike feed-forward neural networks, RNN calculates the output not only using the input from the previous layer, but also the internal states from other cells. Under the single fault mode, the other internal states remain intact when the fault occurs at the output of the previous layer. Therefore, faults that occur in the feed-forward NNs are more likely to cause SDCs in this mode. However, under the dynamic instance injection mode, more than one fault will be injected. As a result, some of the internal states are also corrupted, thus making the results prone to SDCs (e.g., RNN has around 38% SDC rate).

We also find that AlexNet exhibits high resilience in the one-fault-per-run and dynamic instance injection modes. This is because AlexNet has many operations such as ADD, MUL, which are more resilient to faults (see Fig. 7). Therefore, the proportion of operations that are more prone to SDCs (e.g., convolution operations, activation function) is not as high as that in other models such as VGG11.

2) RQ2: Error resilience under different error rates: In this RQ, we explore the resilience of different models for the errorRate injection mode. This mode allows us to vary the probability of error injection on a per-operator basis. We choose 2 different fault types for studying the effects of the error rate, namely bitFlip-element and Rand-element.

Fig. 5 and Fig. 6 show the variation SDC rates with error rates under both fault types. As expected, we can observe that larger error rates result in higher SDC rates in all the applications, as more operations are injected. However, compared with the results from the bit-flip FI, random value replacement results in lower SDC rates. This is likely because the random value causes lesser value deviation than the bit-flip fault type (in our implementation, we use the random number generator function from numpy library). Thus, a lower value deviation in this mode leads to lower SDC rates [20], [22].

Fig. 5 shows the variations of SDC rates of different ML applications with error rate under the bit-flip fault type. While we note that the SDC rates of all the applications grow along with the increase of error rates, we observe different applications have different rates of growth of SDCs. In particular, we find that there are four outliers in the results for the bit-flip fault model (Fig. 5). RNN, HCNN, ResNet and FCN, which exhibit significantly higher SDC rates than their counterparts. We find that the main reason is that these models have a significantly higher number of operations, thereby increasing the number of injected operators and resulting in higher SDC rates.

Likewise, in the case of the random replacement we find that the SqueezeNet applications exhibit nearly flat growth in SDC rates with error rates, and that the SDC rates are consistently low. This is because faults need to cause large deviation in order to cause SDCs, which rarely occurs with the random replacement fault type.

3) RQ3: SDC rates across different operations: In this RQ, we study the SDC rates on different operations in the CNN model. The SDC rates are shown in Fig. 7. It can be seen that faults in the convolution layer usually have higher SDC rates, compared with other operations (e.g., Sub).

Moreover, we can see that operations such as SoftMax, ArgMax, Equal exhibit the highest SDC rates. In fact, the SDC rates on the ArgMax and Equal operations are nearly 100%. This is because these operations are directly associated with the output, and thus faults in these operations are more
likely to cause SDCs. On the other hand, operators such as Sub, MatMul have low SDC rates because faults in these operations are unlikely to propagate much. For example, faults at the convolution layer are likely to propagate through the complex convolution operations, in which faults can quickly propagate and amplify. However, faults at operations such as add and multiply might be masked before propagating to the convolution layer, or occur after the convolution layer. Therefore, due to the limited fault amplification effect, faults in these operations are less likely to cause SDCs.

4) **RQ4: Overhead.** In this question, we measure the execution time for the TensorFlow programs as a baseline for 50 predictions. Then we measure the time taken for 50 predictions after the TensorFI instrumentation phase, but with fault injections disabled. These measurements are detailed in the Disable FI column of the Table IV. We then measure the time taken for 50 predictions with a single bit flip fault injected per run, and report this time in the Enable FI column. The first subcolumn ‘Inst.’ in Overheads, is the instrumentation overhead (difference between Disable FI and Baseline over the Baseline) and the second subcolumn ‘FI’ gives the overhead incurred by fault injection alone (difference between Enable and Disable FI over Disable FI).

As can be observed, the instrumentation overheads are relatively small, and range from 0.1x to 6.9x across applications. The fault injection overheads are much higher, ranging from 21x to 131x. This is because we are emulating the TensorFlow operators during fault injections in Python, and cannot benefit from the optimizations and low-level implementation of TensorFlow. However, the instrumentation phase itself incurs only modest overheads, with an average of 1.5x, when faults are not injected, in keeping with our minimal interference goal - this overhead is due to the runtime check for choosing which version of the operator to invoke (Section III-D).

While the overheads may seem high, we report the actual time taken by the FI experiments to put this number in perspective. In our experiments, the most time-consuming experiment is on the ResNet and Highway CNN models, which took less than 16 hours to complete. However, on average, most of our experiments took 3-4 hours to complete for injecting 10,000 faults, which is reasonable.

5) **GAN FI results.** As mentioned, we show the GAN results separately as generated images do not have a labelled reference output, and we choose to not measure their SDC rates with another level of indirection from the discriminator.

The set of images in the top row, (ii) to (vi), are generated from setting the fault type to Rand-element. (ii) and (iii) are for one fault per run, and dynamic instance respectively. (iv) to (vi) are generated from the errorRate mode. (iv) is from setting the error rate to 25%. We can see the fault progression clearly as the image becomes more difficult to decipher as the error rate increases. The second row shows images obtained from similar configurations as the first row, with the only difference being that the fault type chosen is single bit flip. We observe that with bit flip in the operators, the resulting faults in images (vii) to (xi) tend to be more bipolar (i.e., have more black and white pixels than shades of grey). This is likely because with bit flips, the tensor values that store the image data are toggled between being present (1) at a pixel or being absent (0). As this error propagates into more operators, the computations performed amplify this effect and the resultant end images have strong activated regions of black or white. In the random replacement mode, the injected operations are replaced with random values and consequently the generated pixels to also exhibit any values within the range.
V. CONCLUSION

We present TensorFI, a generic fault injection tool for ML applications written using the TensorFlow framework. TensorFI is a configurable tool that can be easily integrated into existing ML applications. TensorFI is portable, configurable, and fast. Further, it is also compatible with third party libraries that use TensorFlow. We use TensorFI to study the resilience of 12 TensorFlow ML applications under different fault configurations, including one used in AVs. Our evaluation demonstrates the utility of TensorFI in evaluating ML applications’ resilience.
