Abstract

Given a random $n \times n$ symmetric matrix $W$ drawn from the Gaussian orthogonal ensemble (GOE), we consider the problem of certifying an upper bound on the maximum value of the quadratic form $x^\top W x$ over all vectors $x$ in a constraint set $S \subset \mathbb{R}^n$. For a certain class of normalized constraint sets $S$ we show that, conditional on certain complexity-theoretic assumptions, there is no polynomial-time algorithm certifying a better upper bound than the largest eigenvalue of $W$. A notable special case included in our results is the hypercube $S = \{\pm 1/\sqrt{n}\}^n$, which corresponds to the problem of certifying bounds on the Hamiltonian of the Sherrington-Kirkpatrick spin glass model from statistical physics.

Our proof proceeds in two steps. First, we give a reduction from the detection problem in the negatively-spiked Wishart model to the above certification problem. We then give evidence that this Wishart detection problem is computationally hard below the classical spectral threshold, by showing that no low-degree polynomial can (in expectation) distinguish the spiked and unspiked models. This method for identifying computational thresholds was proposed in a sequence of recent works on the sum-of-squares hierarchy, and is believed to be correct for a large class of problems. Our proof can be seen as constructing a distribution over symmetric matrices that appears computationally indistinguishable from the GOE, yet is supported on matrices whose maximum quadratic form over $x \in S$ is much larger than that of a GOE matrix.
1 Introduction

An important phenomenon in the study of the computational characteristics of random problems is the appearance of \textit{statistical-to-computational gaps}, wherein a problem may be solved by an inefficient algorithm—typically a brute-force search—but empirical evidence, heuristic formal calculations, and negative results for classes of powerful algorithms all suggest that the same problem cannot be solved by any algorithm running in polynomial time. Many examples of this phenomenon arise from Bayesian estimation tasks, in which the goal is to recover a signal from noisy observations. Bayesian problems exhibiting statistical-to-computational gaps in certain regimes include graph problems such as community detection [DKMZ11], estimation for models of structured matrices and tensors [LKZ15, ISS15], statistical problems arising from imaging and microscopy tasks [PWBM18a, BBLS18], and many others. A different family of examples comes from random optimization problems that are \textit{signal-free}, where there is no “planted” structure to recover; rather, the task is simply to optimize a random objective function as effectively as possible. Notable instances of problems of this kind that exhibit statistical-to-computational gaps include finding a large clique in a random graph [Jer92], finding a large submatrix of a random matrix [GL18], or finding an approximate solution to a random constraint satisfaction problem [AC08].

In this paper, we study a problem from the latter class, the problem of maximizing a quadratic form $x^T W x$ over a constraint set $x \in S \subseteq \mathbb{R}^n$, where $W$ is a random matrix drawn from the Gaussian orthogonal ensemble $W \sim \text{GOE}(n)$. Unlike previous works that have studied whether an efficient algorithm can optimize and find $x = x(W)$ that achieves a large objective value, we study whether an efficient algorithm can certify an upper bound on the objective over all $x \in S$. In the notable case of the Sherrington-Kirkpatrick (SK) Hamiltonian [SK75, Pan13], where $S = \{ \pm 1/\sqrt{n} \}^n$, while there is an efficient algorithm believed to optimize arbitrarily close to the true maximum [Mon18], we show that, conditional on the correctness of the \textit{low-degree likelihood ratio method} recently developed in the sum-of-squares literature [BHK+16, HS17, HKP+17, Hop18] (which we explain in Section 2.4), there is no efficient algorithm to certify an upper bound that improves on a simple spectral certificate. Thus, the certification task for this problem exhibits a statistical-to-computational gap, while the optimization task does not.

\textbf{Signal-free random optimization problems.} The general task we will be concerned with is the optimization of a random function,

\begin{align}
\text{maximize} & \quad f_\omega(x) \\
\text{subject to} & \quad x \in S \\
\text{where} & \quad \omega \sim \mathcal{P}.
\end{align}

Sometimes, such a task arises in statistical estimation as a likelihood maximization, where the random function $f_\omega(x)$ is the likelihood of an observed dataset $\omega$ for a given parameter value $x$. But the same formal task, stripped of this statistical origin, is still common: in statistical physics, random functions arise in models of magnetism in disordered media; in optimization, random functions encode uncertainty in the parameters of a problem; and in theoretical computer science, random instances of algorithmic tasks describe the average-case rather than worst-case computational characteristics of a problem. Below, we review a well-studied example showing the connection between a prominent statistical estimation problem and a related signal-free random optimization problem.

\footnote{Gaussian orthogonal ensemble (GOE): $W$ is symmetric with $W_{ij} = W_{ji} \sim \mathcal{N}(0, 1/n)$ for $i \neq j$ and $W_{ii} \sim \mathcal{N}(0, 2/n)$ independently.}
Example 1.1. Consider the Rademacher-spiked Wigner model, a family of probability distributions $P_{\lambda,x}$ indexed by $x \in \{\pm 1/\sqrt{n}\}^n$ and $\lambda > 0$. Letting $W \sim \text{GOE}(n)$, $P_{\lambda,x}$ is the law of the random matrix $\lambda xx^\top + W$. For $\lambda$ fixed, the log-likelihood of $x$ for some observed data $Y \in \mathbb{R}^{n \times n}$ is

$$\log P_{\lambda,x}[Y] = -\frac{n}{4}||Y - \lambda xx^\top||_F^2 = c_Y + \frac{\lambda n}{2}x^\top Yx,$$

where $c_Y$ depends on $Y$ but not on $x$.

Thus, drawing $Y \sim P_{\lambda,x^*}$ and maximizing the likelihood gives a random optimization problem,

$$\begin{align*}
\text{maximize} & \quad x^\top Yx \\
\text{subject to} & \quad x \in \{\pm 1/\sqrt{n}\}^n \\
\text{where} & \quad Y \sim P_{\lambda,x^*}. 
\end{align*}$$

(2)

Success in the associated estimation problem corresponds to recovering $x^*$ as the solution to this problem; the “overlap” $\langle x, x^* \rangle$ is often used as a quantitative measure of success in this task.

A natural “signal-free” version of this problem arises by setting $\lambda = 0$. In this case, note that $P_{0,x^*} = P_0$ does not actually depend on $x^*$, leaving us with the optimization

$$\begin{align*}
\text{maximize} & \quad x^\top Wx \\
\text{subject to} & \quad x \in \{\pm 1/\sqrt{n}\}^n \\
\text{where} & \quad W \sim \text{GOE}(n). 
\end{align*}$$

(3)

Up to scaling and a change of sign, this task is the same as that of identifying the ground state configuration or energy in the Sherrington-Kirkpatrick (SK) spin glass model $[\text{SK75}], [\text{Pan13}]$. For this reason we refer to (3) as the SK problem. Note that there is no “planted” solution $x^*$ with respect to which we may measure an algorithm’s performance; rather, the quality of the $x$ an algorithm obtains is measured only by the value of $x^\top Wx$.

Computational tasks: optimization vs. certification. Let us contrast two computational tasks of interest for a given optimization problem. The first, most obvious task is that of optimization, producing an algorithm computing $\text{alg}_{\text{opt}} : \Omega \to \mathcal{S}$ such that $f_\omega(\text{alg}_{\text{opt}}(\omega))$ is as large as possible (say, in expectation, or with high probability as the size of the problem diverges).

Another task is that of certification, producing instead an algorithm computing a number $\text{alg}_{\text{cert}} : \Omega \to \mathbb{R}$, such that for all $\omega \in \Omega$ and all $x \in \mathcal{S}$ we have $f_\omega(x) \leq \text{alg}_{\text{cert}}(\omega)$. The main additional challenge of certification over optimization is that $\text{alg}_{\text{cert}}$ must produce a valid upper bound on $f_\omega$ for every possible value of the data $\omega \in \Omega$, no matter how unlikely $\omega$ is to occur under $P$. Subject to this requirement, we seek to minimize $\text{alg}_{\text{cert}}(\omega)$ (again, in a suitable probabilistic sense when $\omega \sim \mathcal{P}$). Convex relaxations are a common approach to certification, where $\mathcal{S}$ is relaxed to a convex superset $\mathcal{S}' \supset \mathcal{S}$ admitting a sufficiently simple description that it is possible to optimize exactly over $\mathcal{S}'$ using convex optimization.

If $x^* = x^*(\omega)$ is the true maximizer of $f_\omega$, then for any pair of optimization and certification algorithms as above, we have

$$f_\omega(\text{alg}_{\text{opt}}(\omega)) \leq f_\omega(x^*) \leq \text{alg}_{\text{cert}}(\omega).$$

(4)

Thus, in the case of a maximization problem, optimization algorithms approximate the true value $f_\omega(x^*)$ from below, while certification algorithms approximate it from above. We are then interested in how tight either inequality for random problems in growing dimension. Of course, we can achieve “perfect” optimization and certification by exhaustive search over all $x \in \mathcal{S}$, but we are interested only in computationally efficient algorithms.
To make these definitions concrete, we review an instance of each type of algorithm for the problem of Example 1.1.

Example 1.1 (Continued). In the SK problem \(^{(3)}\), two related spectral algorithms give simple examples of algorithms for both optimization and certification.

For certification, writing \(\lambda_{\text{max}}\) for the largest eigenvalue of \(W\), we may use the bound

\[
x^\top W x \leq \lambda_{\text{max}} \cdot \|x\|^2 = \lambda_{\text{max}} \approx 2
\]

for all \(x \in \{\pm 1/\sqrt{n}\}^n\), whereby \(\lambda_{\text{max}}\) is a certifiable upper bound on \(\text{(3)}\). From classical random matrix theory (see, e.g., [AGZ10]), it is known that \(\lambda_{\text{max}} \approx 2\) as \(n \to \infty\).

For optimization, for \(v_{\text{max}}\) the eigenvector of \(\lambda_{\text{max}}\), we may take \(x = x(W) := \text{sgn}(v_{\text{max}}) / \sqrt{n}\) where \(\text{sgn}\) denotes the \(\{\pm 1\}\)-valued sign function, applied entrywise. The vector \(v_{\text{max}}\) is distributed as an isotropically random unit vector in \(\mathbb{R}^n\), so the quality of this solution may be computed as

\[
x^\top W x = \lambda_{\text{max}} \cdot (x, v_{\text{max}})^2 + O \left(\frac{1}{\sqrt{n}}\right) = \lambda_{\text{max}} \cdot \frac{\|v_{\text{max}}\|^2}{n} + O \left(\frac{1}{\sqrt{n}}\right) \approx \frac{4}{\pi} \approx 1.2732
\]

with high probability as \(n \to \infty\). (The error in the first equation is obtained as \(\sum_i \lambda_i (v_i, x)^2 \approx \frac{1}{n} \text{Tr}(W)(1 - (v_{\text{max}}, x)^2)\), where the sum is over all eigenvectors \(v_i\) except \(v_{\text{max}}\). This analysis appeared in [ALR87], an early rigorous mathematical work on the SK model.)

On the other hand, deep results of statistical physics imply that the true optimal value approaches

\[
x^* x^* \approx 2 \mathcal{P}_* \approx 1.5264
\]

as \(n \to \infty\), where the constant \(\mathcal{P}_*\) is expressed via the celebrated Parisi formula for the free energy of the SK model [Par79, Pan13, Tal06]. The approximate value we give above was estimated with numerical experiments in previous works (see, e.g., [Par80, CR02]).

The recent result of [Mon18] implies, assuming a widely-believed conjecture from statistical physics, that for any \(\varepsilon > 0\) there exists a polynomial-time optimization algorithm achieving with high probability a value of \(2 \mathcal{P}_* - \varepsilon\) on the SK problem. This work builds on that of [ABM18, Sub18], and these works taken together formalize the heuristic idea from statistical physics that optimization is tractable for certain optimization problems exhibiting full replica symmetry breaking. On the other hand, there are few results addressing the SK certification problem. The only previous work we are aware of in this direction is [MS15], where a simple semidefinite programming relaxation is shown to achieve the same value as the spectral certificate \(\text{(5)}\).

Our contributions. The main result of this paper, which we now state informally, shows that for the SK certification problem, the simple spectral certificate \(\text{(5)}\) is optimal. See Corollary 3.9 for the formal statement.

Theorem 1.2 (Informal). Conditional on the correctness of the low-degree likelihood ratio method (see Section 2.4), for any \(\varepsilon > 0\), there is no polynomial-time algorithm that certifies the upper bound \(2 - \varepsilon\) on the SK problem \(\text{(3)}\) with probability \(1 - o(1)\) as \(n \to \infty\).

Theorem 1.2 reveals a striking gap between optimization and certification: it is possible to efficiently give a tight lower bound on the maximum objective value by exhibiting a solution \(x\), but impossible to efficiently give a tight upper bound. In other words, an algorithm can efficiently find a near-optimal solution, but cannot be sure that it has done so. The same result also holds for a wide variety of constraints other than \(x \in \{\pm 1/\sqrt{n}\}^n\) (see Corollary 3.9). Due to the high-dimensional...
setting of the problem, we expect the value of a certification algorithm to concentrate tightly; thus we also expect Theorem 1.2 to still hold if $1 - o(1)$ is replaced by any positive constant.

Our result has important consequences for convex programming. A natural approach for optimizing the SK problem would be to use a convex programming relaxation such as a semidefinite program based on the sum-of-squares hierarchy \cite{Sho87,Par00,Las01}. Such a method would relax the constraints of the SK problem to weaker ones for which the associated optimization problem can be solved efficiently. One can either hope that the relaxation is tight and gives a valid solution $x \in \{\pm 1/\sqrt{n}\}^n$ (with high probability), or use a rounding procedure to extract a valid solution from the relaxation. The optimal value of any convex relaxation of (3) provides an upper bound on the optimal value of (3) and therefore gives a certification algorithm. Thus Theorem 1.2 implies that (conditional on the correctness of the low-degree likelihood ratio method) no polynomial-time convex relaxation of (3) can have value $\leq 2 - \varepsilon$ (resolving a question posed by \cite{JKR18}) and in particular cannot be tight. As a result, we expect that natural relax-and-round approaches for optimization should fail to find a solution of value close to $2P^\ast$. This would suggest a fundamental weakness of convex programs: even the most powerful convex programs (such as sum-of-squares relaxations) seem to fail to optimize (3), even though other methods succeed (namely, the message-passing algorithm of \cite{Mon18}).

An explanation for this suboptimality is that convex relaxations are actually solving a fundamentally harder problem: certification.

Related work. The SK problem is not the first known instance of a problem where perfect optimization is tractable but perfect certification appears to be hard. One example comes from random constraint satisfaction problems (CSPs).

Example 1.3. In random MAX-3SAT, we draw a uniformly random $n$-variable $m$-clause 3-CNF formula and maximize $s_C(x)$, the number of satisfied clauses, over $x \in \{0, 1\}^n$.

If $m/n \to \infty$ as $n \to \infty$, the optimal value $\max_x s_C(x)$ is $(7/8 + o(1))m$ with probability $1 - o(1)$ \cite{CGL04}. This is achieved by the trivial optimization algorithm that chooses a uniformly random assignment $x$. On the other hand, sum-of-squares lower bounds suggest that it is hard to certify even $s_C(x) < m$ unless $m \gg n^{3/2}$ \cite{KMOW17}.

Prior work has used sum-of-squares lower bounds to argue for hardness of certification in problems such as random CSPs \cite{KMOW17}, planted clique \cite{DM15,MPW15,BHK16}, tensor injective norm \cite{HSS15,HKP17,Hop18}, graph coloring \cite{BKM17}, community detection in hypergraphs \cite{KBG17}, and others. These results prove that the sum-of-squares hierarchy (at some degree) fails to certify. If sum-of-squares fails at every constant degree (e.g., \cite{BHK16,KMOW17,HKP17}), this suggests that all polynomial-time algorithms should also fail. In our case, it appears difficult to prove sum-of-squares lower bounds for the SK problem, so we instead take a new approach based on a related heuristic for computational hardness, which we explain in the next section.

Overview of techniques. The proof of Theorem 1.2 has two parts. First, we give a reduction from hypothesis testing in the negatively-spiked Wishart model \cite{Joh01,BBP05,BS06,PWBM18} to the SK certification problem. We then use a method introduced in the sum-of-squares literature based on the low-degree likelihood ratio \cite{HS17,HKP17,Hop18} to give evidence that detection in the negatively-spiked Wishart model is computationally hard (in the relevant parameter regime).

In the spiked Wishart model, we observe either $N$ i.i.d. samples $y_1, \ldots, y_N \sim \mathcal{N}(0, I_n)$, or $N$ i.i.d. samples $y_1, \ldots, y_N \sim \mathcal{N}(0, I_n + \beta xx^\top)$ where the “spike” $x \in \{\pm 1/\sqrt{n}\}^n$ is a uniformly
random hypercube vector, and $\beta \in (-1, \infty)$. The goal is to distinguish between these two cases with probability $1 - o(1)$ as $n \to \infty$. In the negatively-spiked ($\beta < 0$) case with $\beta \approx -1$, this task amounts to deciding whether there is a hypercube vector $x \in \{\pm 1/\sqrt{n}\}^n$ that is nearly orthogonal to all of the samples $y_i$. When $N = \Theta(n)$, a simple spectral method succeeds when $\beta^2 > n/N$ [BBP05, BS06], and we expect the problem to be computationally hard when $\beta^2 < n/N$.

Let us now intuitively explain the relation between the negatively-spiked Wishart model and the SK certification problem. Suppose we want to certify that

$$SK(W) := \max_{x \in \{\pm 1/\sqrt{n}\}^n} x^\top W x \leq 2 - \varepsilon$$

where $W \sim \text{GOE}(n)$, for some small constant $\varepsilon > 0$. Since the eigenvalues of $W$ follow the semicircle distribution on $[-2, 2]$ [Wig93], we need to certify that the top $\delta n$-dimensional eigenspace of $W$ does not (approximately) contain a hypercube vector, for some small $\delta > 0$ depending on $\varepsilon$. In particular, we need to distinguish a uniformly random $\delta n$-dimensional subspace (the distribution of the actual top eigenspace of $W \sim \text{GOE}(n)$) from a $\delta n$-dimensional subspace that contains a hypercube vector. Equivalently, taking orthogonal complements, we need to distinguish a uniformly random $(1 - \delta)n$-dimensional subspace from a $(1 - \delta)n$-dimensional subspace that is orthogonal to a hypercube vector. This is essentially the problem of detection in the negatively-spiked Wishart model with $\beta \approx -1$ and $N = (1 - \delta)n$, and these parameters lie in the “hard regime” $\beta^2 < n/N$.

Formally, we construct a distribution $D(n)$ over $n \times n$ symmetric matrices with $SK(W) \geq 2 - \varepsilon/2$ when $W \sim D(n)$. This $D(n)$ also has the property that, conditional on the hardnes of the above detection problem, it is computationally hard to distinguish $W \sim D(n)$ from $W \sim \text{GOE}(n)$. The existence of such $D(n)$ implies hardness of certification for the SK problem, because if an algorithm could certify that $SK(W) \leq 2 - \varepsilon$ when $W \sim \text{GOE}(n)$, then it could distinguish $D(n)$ from GOE($n$).

The idea of “planting” a hidden solution (in our case, a hypercube vector $x$) in such a way that it is difficult to detect is referred to as quiet planting [ZK08, ZK11]. Our quiet planting scheme $D(n)$ draws $W \sim \text{GOE}(n)$ and then rotates the top eigenspace of $W$ to align with a random hypercube vector $x$, while leaving the eigenvalues of $W$ unchanged. (The more straightforward planting scheme, $W + (2 - \varepsilon/2)xx^\top$ with $W \sim \text{GOE}(n)$, is not quiet because it changes the largest eigenvalue of $W$ [PP07].) The question of how to design optimal quiet planting schemes in general remains an interesting open problem.

The final ingredient in our proof is to argue that detection in the spiked Wishart model is computationally hard below the spectral threshold. We do this through a calculation involving the projection of the likelihood ratio between the “null” and “planted” distributions of this model onto the subspace of low-degree polynomials. This method may be viewed as an implementation of the intuitive idea that the correct strategy for quiet planting is to match the low-degree moments of the distributions $D(n)$ and GOE($n$). We discuss the details of this method further in Section 2.4.

Our results on hardness in the spiked Wishart model may be of independent interest: our calculations indicate that, for a large class of spike priors, no polynomial-time algorithm can successfully distinguish the spiked and unspiked models below the classical spectral threshold [BBP05, BS06], both in the negatively-spiked and positively-spiked regimes.

## 2 Background

### 2.1 Probability Theory

All our asymptotic notation (e.g., $O(\cdot), o(\cdot)$) pertains to the limit $n \to \infty$. We consider parameters of the problem (e.g., $\beta, \gamma, \mathcal{X}, \mathcal{S}$) to be held fixed as $n \to \infty$. Thus, the constants hidden by $O(\cdot)$
and $o(\cdot)$ do not depend on $n$ but may depend on the other parameters.

**Definition 2.1.** If $(\Omega_n, F_n, P_n)$ is a sequence of probability spaces, and $A = (A_n)_{n \in \mathbb{N}}$ is a sequence of events with $A_n \in F_n$, then we say $A$ holds with high probability if $\lim_{n \to \infty} P_n[A_n] = 1$.

**Definition 2.2.** A real-valued random variable $\pi$ with $E[\pi] = 0$ is subgaussian if there exists $\sigma^2$ (the variance proxy) such that, for all $t \in \mathbb{R}$, $M(t) := E[\exp(t\pi)] \leq \exp(\sigma^2 t^2/2)$.

The name subgaussian refers to the fact that if $\pi \sim \mathcal{N}(0, \sigma^2)$, then $M(t) = \exp(\sigma^2 t^2/2)$. A random variable with law $\mathcal{N}(0, \sigma^2)$ is therefore subgaussian. Any bounded centered random variable is also subgaussian: if $\pi \in [a, b]$ almost surely, then $\pi$ is subgaussian with $\sigma^2 = \frac{1}{4}(b-a)^2$ (see, e.g., [RHS13]).

We next give some background facts from random matrix theory (see, e.g., [AGZ10]).

**Definition 2.3.** The Gaussian orthogonal ensemble $\text{GOE}(n)$ is a probability distribution over symmetric matrices $W \in \mathbb{R}^{n \times n}$, under which $W_{ii} \sim \mathcal{N}(0, 2/n)$ and $W_{ij} \sim \mathcal{N}(0, 1/n)$ when $i \neq j$, where the entries $W_{ij}$ are independent for distinct pairs $(i, j)$ with $i < j$.

The choice of variances ensures the following crucial invariance property of $\text{GOE}(n)$.

**Proposition 2.4.** For any $Q \in \mathcal{O}(n)$, if $W \sim \text{GOE}(n)$, then the law of $QWQ^\top$ is also $\text{GOE}(n)$.

Our scaling of the entries of $\text{GOE}(n)$ is chosen to ensure a spectrum of constant width.

**Proposition 2.5.** Let $W_n \sim \text{GOE}(n)$. Then, almost surely, $\lambda_{\min}(W_n) \to -2$ and $\lambda_{\max}(W_n) \to 2$ as $n \to \infty$. In particular, for any $\varepsilon > 0$, $\|W_n\| \leq 2 + \varepsilon$ with high probability.

Furthermore, by Wigner’s semicircle law [Wig93], the empirical distribution of eigenvalues of $W_n$ converges weakly to a semicircle distribution supported on $[-2, 2]$.

### 2.2 Constrained PCA

**Definition 2.6.** A constraint set is a sequence $\mathcal{S} = (\mathcal{S}_n)_{n \in \mathbb{N}}$ where $\mathcal{S}_n \subseteq \mathbb{R}^n$. The constrained principal component analysis (PCA) problem with constraint set $\mathcal{S}$, denoted $\text{PCA}(\mathcal{S})$, is

$$\begin{align*}
\text{maximize} & \quad x^\top W x \\
\text{subject to} & \quad x \in \mathcal{S}_n \\
\text{where} & \quad W \sim \text{GOE}(n).
\end{align*}$$

We will work only with constraint sets supported on vectors of approximately unit norm.

**Example 2.7.** Problems that may be described in the constrained PCA framework include:

- the Sherrington-Kirkpatrick (SK) spin glass model: $\mathcal{S}_n = \{\pm 1/\sqrt{n}\}^n$ [SK75, Pan13],
- the sparse PCA null model: $\mathcal{S}_n = \{x \in \mathbb{R}^n : \|x\| = 1, \|x\|_0 \leq \rho\}$ [DM14a, KXZ16],
- the spherical $2p$-spin spin glass model: $\mathcal{S}_{pm} = \{x^\otimes p : x \in \mathbb{R}^n, \|x\| = 1\}$ [CS92, CHS93],
- the positive PCA null model: $\mathcal{S}_n = \{x \in \mathbb{R}^n : x_i \geq 0, \|x\| = 1\}$ [MR10].

Our results apply to the first two examples: the SK model, and sparse PCA when $\rho = \Theta(n)$.

**Definition 2.8.** Let $f$ be a (randomized) algorithm that takes a square matrix $W$ as input and outputs a number $f(W) \in \mathbb{R}$. We say that $f$ certifies a value $B$ on $\text{PCA}(\mathcal{S})$ if

1. for any symmetric matrix $W \in \mathbb{R}^{n \times n}$, $\max_{x \in \mathcal{S}_n} x^\top W x \leq f(W)$, and
2. if $W_n \sim \text{GOE}(n)$ then $f(W_n) \leq B + o(1)$ with high probability.

We allow $f$ to be randomized (i.e., it may use randomness in its computations, but the output $B$ must be an upper bound almost surely). We do not expect certification algorithms to require randomness, but it may be convenient, e.g., to randomly initialize an iterative optimization procedure.
2.3 Spiked Wishart Models

**Definition 2.9.** A normalized spike prior is a sequence $\mathcal{X} = (\mathcal{X}_n)_{n \in \mathbb{N}}$ where $\mathcal{X}_n$ is a probability distribution over $\mathbb{R}^n$, such that if $x \sim \mathcal{X}_n$ then $\|x\| \to 1$ in probability as $n \to \infty$.

**Definition 2.10 (Spiked Wishart model).** Let $\mathcal{X}$ be a normalized spike prior, let $\gamma > 0$, and let $\beta \in [-1, \infty)$. Let $N = \lfloor n/\gamma \rfloor$. We define two probability distributions over $(\mathbb{R}^n)^N$:

1. Under $\mathbb{Q}$, the null model, draw $y_i \sim \mathcal{N}(0, I_n)$ independently for $i \in [N]$.

2. Under $\mathbb{P}$, the planted model, draw $x \sim \mathcal{X}_n$. If $\beta \|x\|^2 \geq -1$, then draw $y_i \sim \mathcal{N}(0, I_n + \beta xx^\top)$ independently for $i \in [N]$. Otherwise, draw $y_i \sim \mathcal{N}(0, I_n)$ independently for $i \in [N]$.

Taken together, $\mathbb{P}$ and $\mathbb{Q}$ form the spiked Wishart model $(\mathbb{P}, \mathbb{Q}) =: \text{Wishart}(n, \gamma, \beta, \mathcal{X})$. For fixed $\gamma$ and $\beta$ we denote the sequence $(\text{Wishart}(n, \gamma, \beta, \mathcal{X}))_{n \in \mathbb{N}}$ by $\text{Wishart}(\gamma, \beta, \mathcal{X})$.

Several remarks on this definition are in order. First, we make the explicit choice $N = \lfloor n/\gamma \rfloor$ for concreteness, but our results apply to any choice of $N = N(n)$ for which $n/N \to \gamma$ as $n \to \infty$.

Second, often the Wishart model is described in terms of the distribution of the sample covariance matrix $\frac{1}{n} \sum_{i=1}^N y_i y_i^\top$. We instead work directly with the samples $y_i$ so as not to restrict ourselves to algorithms that only use the sample covariance matrix. (This modification only makes our results on computational hardness of detection more general.)

Finally, the definition of $\mathbb{P}$ has two cases to ensure that the covariance matrix $I_n + \beta xx^\top$ is positive semidefinite. We will work in the setting $\beta > -1$ where the first case ($\beta \|x\|^2 \geq -1$) occurs with high probability. Priors for which this case occurs almost surely will be especially important, so we define the following terminology for this situation.

**Definition 2.11.** Let $\beta \in (-1, \infty)$ and let $\mathcal{X}$ be a normalized spike prior. We say that $\mathcal{X}$ is $\beta$-good if when $x \sim \mathcal{X}_n$ then $\beta \|x\|^2 > -1$ almost surely.

We will often consider spike priors having i.i.d. entries, and will sometimes need to slightly modify the spike prior to ensure that it is $\beta$-good and has bounded norm.

**Definition 2.12.** Let $\pi$ be a probability distribution over $\mathbb{R}$ such that $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Let $\text{iid} (\pi/\sqrt{n})$ denote the normalized spike prior $\mathcal{X} = (\mathcal{X}_n)$ that draws each entry of $x$ independently from $\text{iid} \frac{\pi}{\sqrt{n}}$. (We do not allow $\pi$ to depend on $n$.)

**Definition 2.13.** For a normalized spike prior $\mathcal{X}$, let the $\beta$-truncation $\text{trunc}_\beta(\mathcal{X})$ of $\mathcal{X}$ denote the following normalized spike prior. To sample $x$ from (\text{trunc}_\beta(\mathcal{X}))_n$, first sample $x' \sim \mathcal{X}_n$. Then, let $x = x'$ if $\beta \|x'\|^2 > -1$ and $\|x'\|^2 \leq 2$, and let $x = 0$ otherwise.

If $\beta > -1$ then since $\mathcal{X}$ is normalized ($\|x\| \to 1$ in probability), the first case of Definition 2.13 occurs with high probability. The upper bound $\|x'\| \leq 2$ is for technical convenience, and the constant 2 is not essential. Note also that the $\beta$-truncation of an i.i.d. prior is no longer i.i.d. We consider the algorithmic task of distinguishing between $\mathbb{P}$ and $\mathbb{Q}$ in the following sense.

**Definition 2.14.** For sequences of distributions $\mathbb{P} = (\mathbb{P}_n)_{n \in \mathbb{N}}$ and $\mathbb{Q} = (\mathbb{Q}_n)_{n \in \mathbb{N}}$ over measurable spaces $(\Omega_n, \mathcal{F}_n)_{n \in \mathbb{N}}$, an algorithm $f_n : \Omega_n \to \{0, 1\}$ achieves strong detection between $\mathbb{P}$ and $\mathbb{Q}$ if

$$\mathbb{Q}_n[f_n(y) = 0] = 1 - o(1) \quad \text{and} \quad \mathbb{P}_n[f_n(y) = 1] = 1 - o(1).$$

The celebrated BBP transition \cite{BBP05} implies a spectral algorithm for strong detection in the spiked Wishart model whenever $\beta^2 > \gamma$. 

8
The algorithm computes the largest eigenvalue (if \( \beta > 0 \)) or smallest eigenvalue (if \( \beta < 0 \)) of the sample covariance matrix \( \frac{1}{N} \sum_{i=1}^{N} y_i y_i^\top \). This eigenvalue converges almost surely to a limiting value which is different under \( P \) and \( Q \).

We will argue (see Corollary 3.3) that if \( X = \text{id}(\pi/\sqrt{n}) \) with \( \pi \) subgaussian, then no polynomial-time algorithm achieves strong detection below the BBP threshold (when \( \beta^2 < 2 \)). For some priors, exponential-time strong detection is possible below the BBP threshold [PWBM18b]. Very sparse Wishart distributions on some domain \( \Omega \) induce an inner product on \( \mathbb{R} \) given by \( \langle f, g \rangle_{L^2(\Omega)} = \mathbb{E}_{y \sim \Omega} [f(y)g(y)] \), and a norm \( \|f\|_{L^2(\Omega)}^2 = \langle f, f \rangle_{L^2(\Omega)} \). For \( D \in \mathbb{N} \), let \( \mathbb{R}[y]_{\leq D} \) denote the polynomials \( \Omega_n \to \mathbb{R} \) of degree at most \( D \). For \( f : \Omega_n \to \mathbb{R} \), let \( f_{\leq D} \) denote the orthogonal projection (with respect to \( \langle \cdot, \cdot \rangle_{L^2(\Omega)} \)) of \( f \) onto \( \mathbb{R}[y]_{\leq D} \). The following relates the distinguishing power of low-degree polynomials to the \textit{low-degree likelihood ratio}.

**Theorem 2.15** ([BBP05] [BS06]). Let \( X \) be any normalized spike prior. If \( \beta^2 > \gamma \) then there exists a polynomial-time algorithm for strong detection in \( \text{Wishart}(\gamma, \beta, X) \).

2.4 The Low-Degree Likelihood Ratio

Inspired by the sum-of-squares hierarchy (e.g., [Sho87] [Par00] [Las01]) and in particular the pseudo-calibration approach [BHK+16], recent works [HST17] [HKP+17] [Hop18] have proposed a strikingly simple method for predicting computational hardness of Bayesian inference problems. This method recovers widely-conjectured computational thresholds for high-dimensional inference problems such as planted clique, densest-k-subgraph, random constraint satisfaction, community detection, and sparse PCA (see [Hop18]). We now give an overview of this method.

Consider the problem of distinguishing two simple hypotheses \( P_n \) and \( Q_n \) which are probability distributions on some domain \( \Omega_n = \mathbb{R}^d(n) \) (where typically the dimension \( d(n) \) grows with \( n \)). One example is the spiked Wishart model \( \text{Wishart}(\gamma, \beta, X) \) for some fixed choice of the parameters \( \beta, \gamma, X \). The idea is to take low-degree polynomials as a proxy for polynomial-time algorithms and consider whether there are low-degree polynomials \( f_n : \Omega_n \to \mathbb{R} \) that can distinguish \( P_n \) from \( Q_n \).

We view \( Q_n \) as the “null” distribution, which is often i.i.d. Gaussian (as in the Wishart model) or i.i.d. Rademacher (\pm-valued). \( Q_n \) induces an inner product on \( L^2 \) functions \( f : \Omega_n \to \mathbb{R} \) given by \( \langle f, g \rangle_{L^2(Q_n)} = \mathbb{E}_{y \sim Q_n} [f(y)g(y)] \), and a norm \( \|f\|_{L^2(Q_n)}^2 = \langle f, f \rangle_{L^2(Q_n)} \). For \( D \in \mathbb{N} \), let \( \mathbb{R}[y]_{\leq D} \) denote the polynomials \( \Omega_n \to \mathbb{R} \) of degree at most \( D \). For \( f : \Omega_n \to \mathbb{R} \), let \( f_{\leq D} \) denote the orthogonal projection (with respect to \( \langle \cdot, \cdot \rangle_{L^2(\Omega)} \)) of \( f \) onto \( \mathbb{R}[y]_{\leq D} \). The following relates the distinguishing power of low-degree polynomials to the \textit{low-degree likelihood ratio}.

**Theorem 2.16** ([HST17]). Let \( P_n \) and \( Q_n \) be probability distributions on \( \Omega_n \) for each \( n \in \mathbb{N} \). Suppose \( P_n \) is absolutely continuous with respect to \( Q_n \), so that the likelihood ratio \( L_n = \frac{dP_n}{dQ_n} \) is defined. Then

\[
\max_{f \in \mathbb{R}[y]_{\leq D} \setminus \{0\}} \frac{\mathbb{E}_{y \sim P_n} f(y)}{\sqrt{\mathbb{E}_{y \sim Q_n} f(y)^2}} = \|L_n^{\leq D}\|_{L^2(Q_n)}. \tag{8}
\]

**Proof.** The left-hand side can be rewritten as

\[
\max_{f \in \mathbb{R}[y]_{\leq D} \setminus \{0\}} \frac{\langle f, L_n \rangle_{L^2(Q_n)}}{\|f\|_{L^2(Q_n)}},
\]

so by basic Hilbert space theory, the maximum is attained by taking \( f = L_n^{\leq D} \).

The left-hand side of (8) heuristically measures whether any degree-\( D \) polynomial can distinguish \( P_n \) from \( Q_n \). Thus we expect \( \|L_n^{\leq D}\|_{L^2(Q_n)} = \omega(1) \) if some degree-\( D \) polynomial that achieves strong detection, and \( \|L_n^{\leq D}\|_{L^2(Q_n)} = O(1) \) otherwise.
We take $O(\log n)$-degree polynomials $\Omega_n \to \mathbb{R}$ as a proxy for functions computable in polynomial-time. One justification for this is that many polynomial-time algorithms compute the leading eigenvalue of a matrix $M$ whose entries are constant-degree polynomials in the data; in fact, there is formal evidence that such low-degree spectral methods are as powerful as the sum-of-squares hierarchy \cite{HKP+17}. Typically, $O(\log n)$ rounds of power iteration are sufficient to compute the leading eigenvalue accurately, which amounts to evaluating the $O(\log n)$-degree polynomial $\text{Tr}(M^D)$ for some $q = O(\log n)$. This motivates the following informal conjecture.

**Conjecture 2.17** (Informal \cite{HS17 HKP+17 Hop18}). For “nice” distributions $P_n$ and $Q_n$, if $\|L_n^D\|_{L^2(Q_n)} = O(1)$ for some $D = \log^{1+\Omega(1)}(n)$, then there is no randomized polynomial-time algorithm for strong detection between $P$ and $Q$.

This conjecture is useful because the norm of the low-degree likelihood ratio, $\|L_n^D\|_{L^2(Q_n)}$, can be computed (or at least bounded) for various distributions such as the stochastic block model \cite{HS17} and the spiked tensor model \cite{HKP+17 Hop18}.

**Remark 2.18.** We do not expect the converse of Conjecture 2.17 to hold. If $\|L_n^D\|_{L^2(Q_n)} = \omega(1)$ for some $D = O(\log n)$ then we expect an $n^{O(\log n)}$-time algorithm but not necessarily a polynomial-time algorithm, because not every $O(\log n)$-degree polynomial can be evaluated in polynomial time.

Conjecture 2.17 is informal in that we do not specify what is meant by “nice” distributions. See \cite{Hop18} for a precise variant of Conjecture 2.17; however, this variant uses the more refined notion of coordinate degree and so does not apply to the calculations we will perform. Roughly speaking, “nice” distributions $P$ and $Q$ should satisfy the following:

1. $Q$ should be a product distribution, e.g., i.i.d. Gaussian or i.i.d. Rademacher;
2. $P$ should be sufficiently symmetric with respect to permutations of its coordinates; and
3. we should be able to add a small amount of noise to $P$, ruling out distributions with brittle algebraic structure (such as random satisfiable instances of XOR-SAT, which can be identified using Gaussian elimination \cite{CD99}).

We refer the reader to \cite{HS17 Hop18} for further details and evidence in favor of Conjecture 2.17.

## 3 Main Results

### 3.1 Spiked Wishart Models

We expect that Conjecture 2.17 applies to the spiked Wishart model. The following states this assumption formally.

**Conjecture 3.1.** Fix $\gamma > 0$, $\beta > -1$ and a normalized spike prior $\mathcal{X}$. Let $P_n$ and $Q_n$ be the planted and null models, respectively, of $\text{Wishart}(\gamma, \beta, \mathcal{X})$. Define the likelihood ratio $L_n = L_{n,\gamma,\beta,\mathcal{X}} = \frac{dP_n}{dQ_n}$.

If there exists some $D = D(n) = \log^{1+\Omega(1)}(n)$ such that $\|L_n^D\|_{L^2(Q_n)} = O(1)$, then there is no randomized polynomial-time algorithm for strong detection in $\text{Wishart}(\gamma, \beta, \mathcal{X})$.

We now give bounds on $\|L_{n,\gamma,\beta,\mathcal{X}}^D\|_{L^2(Q_n)}$.

**Theorem 3.2.** Fix constants $\gamma > 0$ and $\beta > -1$.

1. Suppose $\beta^2 < \gamma$. Let $\mathcal{X} = \text{trunc}_\beta(\text{iid}((\pi/\sqrt{n}))$ where $\pi$ is subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Then, for any $D = o(n/\log n)$, we have $\|L_{n,\gamma,\beta,\mathcal{X}}^D\|_{L^2(Q_n)} = O(1)$.
2. Suppose $\beta^2 > \gamma$. Let $X \sim \text{id}(\pi/\sqrt{n})$ be $\beta$-good with $\pi$ symmetric about zero, $\mathbb{E}[\pi] = 0$, and $\mathbb{E}[\pi^2] = 1$. Then, for any $D = \omega(1)$, we have $\|L_{n,\gamma,\beta,\lambda}^{D}\|_{L_{2}(Q_{n})} = \omega(1)$.

We prove Theorem 3.2 in Section 5. Part 1 of Theorem 3.2 combined with Conjecture 3.1 implies that for i.i.d. subgaussian priors, strong detection is computationally hard below the BBP threshold.

**Corollary 3.3.** Suppose Conjecture 3.1 holds. Fix constants $\gamma > 0$ and $\beta > -1$. Let $\pi$ be subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Let $X$ be either $\text{id}(\pi/\sqrt{n})$ or $\text{trunc}_{\beta}(\text{id}(\pi/\sqrt{n}))$. If $\beta^2 < \gamma$, then there is no randomized polynomial-time algorithm for strong detection in Wishart$(\gamma, \beta, X)$. 

**Proof.** The case $X = \text{trunc}_{\beta}(\text{id}(\pi/\sqrt{n}))$ follows immediately from Part 1 of Theorem 3.2. If strong detection is impossible for $X = \text{trunc}_{\beta}(\text{id}(\pi/\sqrt{n}))$, then strong detection is also impossible for $X = \text{id}(\pi/\sqrt{n})$, as these two spike priors differ with probability $o(1)$ (under the natural coupling). $\square$

A number of technical remarks on the content of Theorem 3.2 and Corollary 3.3 are in order.

**Remark 3.4.** Even if Conjecture 3.1 does not hold, note that Theorem 3.2 still implies unconditional lower bounds against low-degree polynomials in the sense of $[8]$. 

**Remark 3.5.** Part 2 of Theorem 3.2 serves only to check that we do not predict computational hardness when $\beta^2 > \gamma$ (as polynomial-time strong detection is possible in this regime; see Theorem 2.15). The assumption that $\pi$ is symmetric about zero should not be essential.

**Remark 3.6.** In Part 1 of Theorem 3.2 and in Corollary 3.3, the requirement that $X$ be a $\beta$-truncated i.i.d. prior can be relaxed. We only require that $X$ is the $\beta$-truncation of a normalized prior admitting a local Chernoff bound (see Definition 5.11).

**Remark 3.7.** Part 1 of Theorem 3.2 holds for any $D = o(n/\log n)$, much larger than the $D = \log^{1+\Omega(1)}(n)$ required by Conjecture 3.1. Since degree-$D$ polynomials should correspond to $n^{O(D)}$-time algorithms [Hop18], this suggests that the conclusion of Corollary 3.3 also holds for $2^{n^{1-\delta}}$-time algorithms, for any $\delta > 0$. In other words, strong detection requires nearly-exponential time.

### 3.2 Constrained PCA

We now give a reduction from strong detection in the spiked Wishart model to certification in the constrained PCA problem.

**Theorem 3.8.** Let $S$ be a constraint set and let $X$ be a normalized spike prior such that if $x \sim X_n$ then $x \in S_n$ with high probability. Suppose there exists $\varepsilon > 0$ and a randomized polynomial-time algorithm that certifies the value $2 - \varepsilon$ on PCA$(S)$. Then there exist $\gamma > 1$ and $\beta \in (0, 1)$ such that there is a randomized polynomial-time algorithm for strong detection in Wishart$(\gamma, \beta, X)$. 

We give the proof in Section 4. Note for the parameters $\gamma, \beta$ above, $\beta^2 < \gamma$ (the “hard regime”).

**Corollary 3.9.** Suppose Conjecture 3.1 holds. Let $\pi$ be subgaussian with $\mathbb{E}[\pi] = 0$ and $\mathbb{E}[\pi^2] = 1$. Let $S$ be a constraint set such that, if $x \sim \text{id}(\pi/\sqrt{n})$, then $x \in S_n$ with high probability. Then, for any $\varepsilon > 0$, there is no randomized polynomial-time algorithm to certify the value $2 - \varepsilon$ on PCA$(S)$.

**Proof.** The result is immediate from Theorem 3.2 and Theorem 3.8 $\square$

In particular, we obtain the hardness of improving on the spectral certificate in the SK model.

**Corollary 3.10.** If Conjecture 3.1 holds, then, for any $\varepsilon > 0$, there is no randomized polynomial-time algorithm to certify the value $2 - \varepsilon$ on the SK problem PCA$(\{\pm 1/\sqrt{n}\}^n)$.

**Proof.** Apply Corollary 3.9 with $\pi$ having the Rademacher distribution and $S_n = \{\pm 1/\sqrt{n}\}^n$. $\square$
4 Proof of Reduction from Spiked Wishart to Constrained PCA

Proof of Theorem 3.8. Let \( S \) be a constraint set and let \( X \) be a normalized spike prior such that, if \( x \sim X_n \), then \( x \in S_n \) with high probability. Suppose that for some \( \varepsilon > 0 \) there is a randomized polynomial-time algorithm \( f \) that certifies the value \( 2 - \varepsilon \) on \( \text{PCA}(S) \). We will show that this implies that there is a polynomial-time algorithm for strong detection in \( \text{Wishart}(\gamma, \beta, X) \) with certain parameters \( \gamma > 1 \) and \( \beta \in (-1, 0) \) (depending on \( \varepsilon \)). Note that these parameters lie in the “hard” regime \( \beta^2 < \gamma \).

Our algorithm for detection in the Wishart model is as follows. Fix \( \gamma > 1 \), to be chosen later. Since \( n/N \to \gamma \) we have \( n > N \) (for sufficiently large \( n \)). Given samples \( y_1, \ldots, y_N \sim \mathcal{N}(0, I_n + \beta xx^\top) \), let \( V = \text{span}\{y_1, \ldots, y_N\} \subseteq \mathbb{R}^n \) and let \( V^\perp \) be its orthogonal complement. We sample \( W \in \mathbb{R}^{n \times n} \) having the distribution \( \text{GOE}(n) \) conditioned on the event that the span of the top \( n - N \) eigenvectors of \( W \) is \( V^\perp \). Concretely, we can obtain a sample in the following way. Let \( v_1, \ldots, v_n \) be a uniformly random orthonormal basis for \( V \) and let \( v_{N+1}, \ldots, v_n \) be a uniformly random orthonormal basis for \( V^\perp \). Sample \( W' \sim \text{GOE}(n) \) and let \( \lambda_1 < \cdots < \lambda_n \) be the eigenvalues of \( W' \). Then, let \( W := \sum_{i=1}^n \lambda_i v_i v_i^\top \). Finally, run the certification algorithm \( f \) for \( \text{PCA}(S) \) on \( W \).

The detection algorithm \( \tilde{f} : (\mathbb{R}^n)^N \to \{0, 1\} \) can be defined as follows:

\[
\tilde{f}(y_1, \ldots, y_N) = \begin{cases} 
0 & \text{(report samples came from null distribution \( Q_n \)) if } f(W) \leq 2 - \varepsilon/2, \\
1 & \text{(report samples came from planted distribution \( P_n \)) if } f(W) > 2 - \varepsilon/2.
\end{cases}
\]

We now prove that \( \tilde{f} \) indeed achieves strong detection in \( \text{Wishart}(\gamma, \beta, X) \). First, if the samples \( y_i \) are drawn from the null model \( Q_n \), then \( V \) is a uniformly random \( N \)-dimensional subspace of \( \mathbb{R}^n \), so by Proposition 2.4 the distribution \( W \) constructed above is \( \text{GOE}(n) \). Thus \( f(W) \leq 2 - \varepsilon/2 \) with high probability by assumption, and therefore \( \tilde{f}(y_1, \ldots, y_N) = 0 \) with high probability, i.e., our algorithm correctly reports that the samples were drawn from the null model.

Next, suppose the samples \( y_i \) are drawn from the planted model \( P_n \) with planted spike \( x \sim X_n \). We will choose \( \gamma > 1 \) and \( \beta \in (-1, 0) \) so that \( x^\top W x \geq 2 - \varepsilon/3 \) with high probability. Since \( x \in S_n \) with high probability, this would imply \( f(W) \geq 2 - \varepsilon/3 \), so we will have \( \tilde{f}(y_1, \ldots, y_N) = 1 \) with high probability, i.e., our algorithm will correctly report that the samples were drawn from the planted model.

It remains to show that \( x^\top W x \geq 2 - \varepsilon/3 \). Let \( \lambda_1 < \cdots < \lambda_n \) be the eigenvalues of \( W \) and let \( v_1, \ldots, v_n \) be the corresponding (unit-norm) eigenvectors. By Proposition 2.5, with high probability, for all \( i \in [n] \), \( \lambda_i \in [-2 - o(1), 2 + o(1)] \). Furthermore, by the semicircle law [Wig93], with high probability, \( \lambda_{N+1} \geq 2 - g(\gamma) \) where \( g(\gamma) > 0 \) is a function satisfying \( g(\gamma) \to 0 \) as \( \gamma \to 1^+ \) (recalling that \( n/N \to \gamma \)). Letting \( \|x\|_V \) denote the norm of the orthogonal projection of \( x \) onto \( V \), we have, with high probability,

\[
x^\top W x = x^\top \left( \sum_{i=1}^n \lambda_i v_i v_i^\top \right) x \\
= \sum_{i=1}^n \lambda_i \langle x, v_i \rangle^2 \\
\geq \lambda_1 \|x\|_V^2 + \lambda_{N+1} \|x\|_V^2 \\
\geq (-2 - o(1)) \|x\|_V^2 + (2 - g(\gamma))(\|x\|^2 - \|x\|_V^2) \\
= (2 - g(\gamma)) \|x\|^2 + (-4 + g(\gamma) - o(1)) \|x\|_V^2 \\
\geq 2 - g(\gamma) - 4 \|x\|_V^2 - o(1).
\]
Thus we need to upper bound $\|x\|_V^2$. Let $P_V$ denote the orthogonal projection matrix onto $V$. Since $V$ is the span of $\{y_1, \ldots, y_N\}$, we have $P_V \preceq \frac{1}{\mu} Y$ where

$$Y = \frac{1}{N} \sum_{i=1}^N y_i y_i^\top$$

and $\mu$ is the smallest nonzero eigenvalue of $Y$. (Here $\preceq$ denotes Loewner order.) Since $Y$ is a spiked Wishart matrix, it follows from Theorem 1.2 of [DS06] that its smallest nonzero eigenvalue converges almost surely to $(1 - \sqrt{\gamma})^2$ as $n \to \infty$. Thus we have $\mu = (1 - \sqrt{\gamma})^2 + o(1)$. Therefore,

$$\|x\|_V^2 = \|P_V x\|^2 = x^\top P_V x \leq \frac{1}{\mu} x^\top Y x = \frac{1}{\mu N} \sum_{i=1}^N \langle x, y_i \rangle^2.$$

We have $y_i \sim \mathcal{N}(0, I_n + \beta xx^\top)$ and so $\langle x, y_i \rangle \sim \mathcal{N}(0, x^\top (I_n + \beta xx^\top) x) = \mathcal{N}(0, \|x\|^2 + \beta \|x\|^4)$. Therefore, letting $a_N^2 = \sum_{i=1}^N g_i^2$ for $g_i$ i.i.d. standard gaussian random variables, so that $a_N^2$ has the $\chi^2$ distribution with $N$ degrees of freedom, we have conditional on $x$ the distributional equality

$$x^\top Y x \overset{(d)}{=} (\|x\|^2 + \beta \|x\|^4) \frac{a_N^2}{N}.$$

Standard concentration inequalities imply $a_N^2/N \in [1 - o(1), 1 + o(1)]$ with high probability, and therefore $x^\top Y x = 1 + \beta + o(1)$ with high probability. Thus, with high probability, we find

$$\|x\|_V^2 = \frac{1 + \beta}{(1 - \sqrt{\gamma})^2} + o(1). \quad (11)$$

Finally, we choose $\gamma > 1$ close enough to 1 so that $g(\gamma) \leq \epsilon/8$. By (11), we can also choose $\beta \in (-1, 0)$ close enough to $-1$ so that $\|x\|_V^2 \leq \epsilon/32$ with high probability. Combining these, from (11) it follows that $x^\top W x \geq 2 - \epsilon/4 - o(1) \geq 2 - \epsilon/3$ with high probability, completing the proof. \hfill $\square$

**Remark 4.1.** We remark that we have ignored issues of numerical precision by assuming a model of computation where eigendecomposition computations can be done exactly in polynomial time. However, we believe all the operations we have used are stable, so that our reduction should also hold for weaker models of computation. (In particular, if we want to compute polynomially-many bits of precision of the $\text{PCA}(S)$ instance, this should require only polynomially-many bits of precision in the eigendecomposition computation.)

## 5 Proofs for Spiked Wishart Models

### 5.1 Preliminaries

**Spiked Wishart model statistics.** The following formulae pertaining to the spiked Wishart model are derived in [PWB18]. (Recall that in the spiked Wishart model, the parameter $N$ is determined by $n$ and $\gamma$ as $N = \lceil n/\gamma \rceil$.)

**Proposition 5.1.** Suppose $\gamma > 0$, $\beta \in [-1, \infty)$, and $\mathcal{X}$ is a $\beta$-good normalized spike prior. Then, the likelihood ratio of the null and planted probability distributions of Definition 2.10 is

$$L_{n, \gamma, \beta, \mathcal{X}}(y_1, \ldots, y_N) := \frac{dP_n}{dQ_n}(y_1, \ldots, y_N) = \mathbb{E}_{x \sim \mathcal{X}_n} \left[ (1 + \beta \|x\|^2)^{-N/2} \prod_{i=1}^N \exp \left( \frac{\beta}{2(1 + \beta \|x\|^2)} \langle x, y_i \rangle^2 \right) \right]. \quad (12)$$
If furthermore $\|x\|^2 < 1/|\beta|$ almost surely when $x \sim X_n$, then the second moment of the likelihood ratio is given by

$$\mathbb{E}_{y \sim Q_n} \left( L_{n, \gamma, \beta, X}(y_1, \ldots, y_N) \right)^2 = \mathbb{E}_{x^1, x^2 \sim X_n} \left[ (1 - \beta^2 \langle x^1, x^2 \rangle)^{-N/2} \right]$$

(13)

where $x^1, x^2$ are drawn independently from $X_n$.

**Hermite polynomials.** We recall the classical one-dimensional Hermite polynomials.

**Definition 5.2.** The polynomials $h_k \in \mathbb{R}[x]$ for $k \geq 0$ are defined by the recursion

$$h_0(x) = 1,$$

$$h_{k+1}(x) = xh_k(x) - h'_k(x),$$

and we define normalized versions

$$\hat{h}_k(x) = \frac{1}{\sqrt{k!}} h_k(x).$$

**Proposition 5.3.** The $\hat{h}_k$ are an orthonormal polynomial system for the standard Gaussian measure:

$$\mathbb{E}_{g \sim \mathcal{N}(0,1)} \left[ \hat{h}_k(g) \hat{h}_\ell(g) \right] = \delta_{k\ell}.$$

Similarly, we define the product Hermite polynomials. It is helpful to first define some notations for vectors of indices, which will also be used in the later derivations.

**Definition 5.4.** Let $\mathbb{N} = \{n \in \mathbb{Z} : n \geq 0\}$. For $\alpha \in \mathbb{N}^n$ and $x \in \mathbb{R}^n$, let

$$|\alpha| := \sum_{i=1}^n \alpha_i,$$

$$\alpha! := \prod_{i=1}^n \alpha_i!,$$

$$x^\alpha := \prod_{i=1}^n x_i^{\alpha_i}.$$

**Definition 5.5.** For $\alpha \in \mathbb{N}^n$ and $x \in \mathbb{R}^n$,

$$H_\alpha(x) := \prod_{i=1}^n h_{\alpha_i}(x_i),$$

$$\hat{H}_\alpha(x) := \prod_{i=1}^n \hat{h}_{\alpha_i}(x_i) = \frac{1}{\sqrt{\alpha!}} H_\alpha(x).$$

**Proposition 5.6.** The $\hat{H}_\alpha$ are an orthonormal polynomial system for the product measure of $n$ standard Gaussian measures:

$$\mathbb{E}_{g \sim \mathcal{N}(0,I_n)} \left[ \hat{H}_\alpha(g) \hat{H}_\beta(g) \right] = \delta_{\alpha\beta}.$$
Combinatorics. We will also need the (ordinary) generating function of the central binomial coefficients.

**Proposition 5.7.** For any $x \in \mathbb{R}$ with $|x| < \frac{1}{4}$,

$$(1 - 4x)^{-1/2} = \sum_{k \geq 0} \binom{2k}{k} x^k.$$

5.2 Norm of the Low-Degree Projection

In this section, we describe the formulas for the norm of the low-degree likelihood ratio in the spiked Wishart model, $\|L_{n,\gamma,\beta,X}^{\leq D}\|_{L^2(Q_n)}$. The full calculations are given in Appendix A.

The following result, the main technical one of this portion of the argument, computes the norm of the projection of the likelihood ratio onto a single Hermite polynomial.

**Lemma 5.8.** Let $\alpha \in (\mathbb{N}^n)^N$, and let $\alpha_i \in \mathbb{N}^n$ denote the $i$th component. Let $|\alpha| = \sum_{i=1}^N |\alpha_i|$. Suppose $\gamma > 0$, $\beta \in [-1, \infty)$, and $X$ is a $\beta$-good normalized spike prior. Then,

$$\langle L_{n,\gamma,\beta,X}, \overline{H}_\alpha \rangle_{L^2(Q_n)}^2 = \prod_{i=1}^N \beta |\alpha_i| \cdot \left( \frac{|\alpha_i| - 1}{\alpha_i!} \right)^2 \left( \mathbb{E}_{x \sim X_n} x^{\sum_{i=1}^N \alpha_i} \right)^2 \text{ if } |\alpha_i| \text{ even for all } i \in [N],$$

$$0 \text{ otherwise},$$

(14)

where when $\beta = 0$ and $\alpha = 0$ we interpret $0^0 = 1$.

Note in particular that the quantity in question does not depend on the sign of $\beta$; thus the calculation of the norm of the low-degree projection of the likelihood ratio will not distinguish between the positively and negatively spiked Wishart models. Interestingly, in our proof, which involves generalized Hermite polynomials that form families of orthogonal polynomials with respect to Gaussian measures of different variances, this corresponds to the fact that an “umbral” analogue of the Hermite polynomials corresponding to a fictitious Gaussian measure with negative variance satisfies many of the same identities as the ordinary Hermite polynomials.

Combining these quantities, we may give a simple description of the norm of the low-degree projection of the likelihood ratio.

**Lemma 5.9.** Suppose $\gamma > 0$, $\beta \in [-1, \infty)$, and $X$ is a $\beta$-good normalized spike prior. Define

$$\varphi_N(x) := (1 - 4x)^{-N/2},$$

$$\varphi_{N,k}(x) := \sum_{d=0}^k x^d \sum_{d_1, \ldots, d_N} \prod_{i=1}^N \left( \frac{2d_i}{d_i} \right),$$

(15) (16)

so that $\varphi_{N,k}(x)$ is the Taylor series of $\varphi_N$ around $x = 0$ truncated to degree $k$ (as may be justified by Proposition 5.7). Then,

$$\|L_{n,\gamma,\beta,X}^{\leq D}\|_{L^2(Q_n)}^2 = \mathbb{E}_{x^1, x^2 \sim X_n} \left[ \varphi_N[D/2] \left( \frac{\beta^2 (x_1, x_2)^2}{4} \right) \right]$$

(17)

where $x^1, x^2$ are drawn independently from $X$.

**Remark 5.10.** The squared norm of the low-degree likelihood ratio (17) is closely related via Taylor expansion to the squared norm (or second moment) of the full likelihood ratio (13), which is recovered by taking $D \to \infty$ while $n$ and $N$ remain fixed.
5.3 Asymptotics as \(n \to \infty\)

In this section, we use the formula from Lemma 5.9 to prove Part 1 of Theorem 3.2 (the case \(\beta^2 < \gamma\)). The proof of Part 2 (\(\beta^2 > \gamma\)) is deferred to Appendix B.2.

The following concentration result is the key property that we require from the spike prior \(\mathcal{X}\).

**Definition 5.11.** A normalized spike prior \(\mathcal{X}\) admits a local Chernoff bound if for every \(\eta > 0\) there exist \(\delta > 0\) and \(C > 0\) such that, for all \(n\),

\[
\Pr \left\{ \|x^1, x^2\| \geq t \right\} \leq C \exp \left(-\frac{1}{2}(1 - \eta)nt^2\right) \quad \text{for all } t \in [0, \delta] \tag{18}\]

where \(x^1, x^2\) are drawn independently from \(\mathcal{X}_n\).

**Proposition 5.12.** If \(\pi\) is subgaussian with \(\mathbb{E}[\pi] = 0\) and \(\mathbb{E}[\pi^2] = 1\) then \(\text{id}(\pi/\sqrt{n})\) and \(\text{trunc}_\beta(\text{id}(\pi/\sqrt{n}))\) (for any \(\beta > -1\)) each admit a local Chernoff bound.

We defer the proof to Appendix B.1.

**Proof of Theorem 3.2 (Part 1).** Let \(\beta^2 < \gamma\). We decompose the norm of the low-degree likelihood ratio into two parts, which we will bound separately:

\[
\|L^{\leq D}_{n, \gamma, \beta, \mathcal{X}}\|_{L^2(\mathbb{Q}_n)}^2 = \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \left[ \varphi_{N, \lfloor D/2 \rfloor} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right] = R_1 + R_2
\]

where

\[
R_1 := \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \left[ \mathbf{1}_{\|x^1, x^2\| \leq \varepsilon \varphi_{N, \lfloor D/2 \rfloor}} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right],
\]

\[
R_2 := \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \left[ \mathbf{1}_{\|x^1, x^2\| > \varepsilon \varphi_{N, \lfloor D/2 \rfloor}} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right].
\]

Here \(\varepsilon > 0\) is a small constant to be chosen later. We call \(R_1\) the small deviations and call \(R_2\) the large deviations.

The following two lemmas bound these two terms, respectively. First, we bound the large deviations.

**Lemma 5.13** (Large Deviations). Let \(\beta^2 < \gamma\). Suppose \(\mathcal{X}\) is a \(\beta\)-good normalized spike prior that admits a local Chernoff bound. Suppose that for any \(n\), \(x \sim \mathcal{X}_n\) satisfies \(\|x\|^2 \leq 2\) almost surely. If \(D = o(n/\log n)\) and \(\varepsilon > 0\) is any constant, then \(R_2 = o(1)\).

We give a proof summary, with the full proof deferred to Appendix B.2. Since \(\|x^1\|^2 \leq 2\) and \(\|x^2\|^2 \leq 2\),

\[
R_2 \leq \Pr \left\{ \|x^1, x^2\| > \varepsilon \right\} \varphi_{N, \lfloor D/2 \rfloor}(\beta^2).
\]

By the local Chernoff bound, \(\Pr \left\{ \|x^1, x^2\| > \varepsilon \right\}\) decays exponentially in \(n\). To complete the proof, we use elementary combinatorial bounds to control the polynomial expression (10) for \(\varphi_{N, \lfloor D/2 \rfloor}(\beta^2)\). Its growth is roughly of order \(O(n^D)\), which is counteracted by the exponential decay of \(\Pr \left\{ \|x^1, x^2\| > \varepsilon \right\}\) so long as \(D = o(n/\log n)\).

Next, we bound the small deviations. For this part of the argument, it is irrelevant that the likelihood ratio is truncated to its low-degree component, and we essentially reuse an existing argument for the full likelihood ratio from [PWBM18b].
Lemma 5.14 (Small Deviations). Let $\beta^2 < \gamma$. Suppose $\mathcal{X}$ is a $\beta$-good normalized spike prior that admits a local Chernoff bound. Let $D = D(n)$ be any function of $n$. If $\varepsilon > 0$ is a sufficiently small constant then $R_1 = O(1)$.

We again give a proof summary, with the full proof deferred to Appendix B.3. As mentioned above, unlike in the proof of Lemma 5.13 here we simply bound $\varphi_N \left\lfloor D/2 \right\rfloor \leq \varphi_N$ in the expression for $R_1$. To bound the resulting expression, we borrow an argument from [PWBM18]. This step crucially uses the local Chernoff bound, and amounts to showing that the exponential decay from the Chernoff bound sufficiently counteracts the exponential growth of the likelihood ratio term $\varphi_N (\frac{\beta^2}{4} (x^1, x^2)^2)$ when $\langle x^1, x^2 \rangle$ is small.

Combining Proposition 5.12 with Lemmas 5.13 and 5.14 completes the proof of Part 1 of Theorem 3.2. (The proof of Part 2 is deferred to Appendix B.4.)

Proofs for Computing the Low-Degree Likelihood Ratio

A.1 Generalized and Umbral Hermite Polynomials

We introduce some calculations with a useful generalization of the Hermite polynomials. While the usual Hermite polynomials are a family of orthogonal polynomials for the Gaussian measure with variance 1, and a straightforward generalization yields orthogonal polynomials for the Gaussian measure with any positive variance, we will use the surprising further generalization to fictitious Gaussian measures with negative variance, as described by the so-called umbral calculus. We follow the presentation of [Rom05] (specifically, Section 2.1 of Chapter 4).

Definition A.1. For any $v \in \mathbb{R}$, the Hermite polynomials with variance $v$ are defined by the recursion

$$h_0(x; v) = 1,$$

$$h_{k+1}(x; v) = xh_k(x; v) - v \partial_x[h_k](x; v). \tag{20}$$

The next facts are useful for translating between different versions of the basic recursion and other properties of the Hermite polynomials.

Proposition A.2 (Differentiation Identity). For any $v, x \in \mathbb{R}$,

$$\partial_x[h_k](x; v) = kh_k(x; v). \tag{21}$$

Proposition A.3 (Alternate Recursion). For any $v \in \mathbb{R}$, the Hermite polynomials are equivalently defined by the recursion

$$h_0(x; v) = 1,$$

$$h_{k+1}(x; v) = xh_k(x; v) - vh_k(x; v). \tag{23}$$

The following is yet another common way of defining the Hermite polynomials, in terms of the derivatives of the corresponding Gaussian density (or, in the negative variance case, a suitable generalization thereof).

Proposition A.4 (Rodrigues Formula). Let $v \in \mathbb{R}$ with $v \neq 0$. Then,

$$\frac{d^k}{dx^k} \left[ \exp \left( -\frac{1}{2v}x^2 \right) \right] = (-v)^{-k} h_k(x; v) \exp \left( -\frac{1}{2v}x^2 \right). \tag{24}$$

The next fact shows how the generalized Hermite polynomials transform under scaling.

Proposition A.5 (Scaling Identity). Let $v, w, x \in \mathbb{R}$, then

$$h_k(wx; v) = w^k h_k \left( x; \frac{v}{w^2} \right). \tag{25}$$

Finally, the following is a generalized version of Gaussian integration by parts. We only provide the version of this identity for the standard Hermite polynomials, which is the only one we will use, but analogous statements hold for the generalized and umbral Hermite polynomials.

Proposition A.6 (Integration by Parts). Let $f \in C^k(\mathbb{R})$ have $|f^{(i)}(x)| \leq Ce^{Cx}$ for all $i \in \{0, 1, \ldots, k\}$ and some $C > 0$. Then,

$$\mathbb{E}_{g \sim \mathcal{N}(0, 1)} [h_k(g; 1)f(g)] = \mathbb{E}_{g \sim \mathcal{N}(0, 1)} [f^{(k)}(g)]. \tag{26}$$
While the above results are standard, we now give two results we will use in our calculation that do not seem to appear explicitly in the previous literature, although they are straightforward to obtain from the preceding facts. First, we will use the following slightly more general version of the Rodrigues formula (Proposition 4.3) in our calculations.

**Proposition A.7** (Multidimensional Rodrigues Formula). Let \( x \in \mathbb{R}^n \), \( \alpha \in \mathbb{N}^n \), and \( v \in \mathbb{R} \) with \( v \neq 0 \). Then,

\[
\partial_y^\alpha \left[ \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) \right] = (-v)^{-|\alpha|} x^\alpha h_{|\alpha|}(\langle x, y \rangle; v) \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) . \tag{27}
\]

**Proof.** We proceed by induction on \(|\alpha|\). Clearly the result holds for \( \alpha = 0 \). Suppose the result holds for all \(|\alpha'| \leq k\), and \(|\alpha| = k + 1 > 0\). Let \( \alpha' \) having \(|\alpha'| = k\) differ from \( \alpha \) only in coordinate \( i \), so that \( \alpha'_i = \alpha_i - 1 \) and \( \alpha'_j = \alpha_j \) for all \( j \neq i \). Then,

\[
\partial_y^\alpha \left[ \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) \right] = \partial_{y_i} \left[ \partial_y^{\alpha'} \left[ \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) \right] \right] = (-v)^{-k} x^{\alpha'} \partial_{y_i} \left[ h_k(\langle x, y \rangle; v) \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) \right] = (-v)^{-k} x^{\alpha'} \left( x_i \partial_x[h_k](\langle x, y \rangle; v) - v^{-1} \langle x, y \rangle x_i h_k(\langle x, y \rangle; v) \right) \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) = (-v)^{-(k+1)} x^{\alpha} \left( \langle x, y \rangle h_k(\langle x, y \rangle; v) - v \partial_x[h_k](\langle x, y \rangle; v) \right) \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right) = (-v)^{-(k+1)} x^{\alpha} h_{k+1}(\langle x, y \rangle; v) \exp \left( -\frac{1}{2v} \langle x, y \rangle^2 \right),
\]

completing the proof. \( \Box \)

Second, we will need the following calculation evaluating the expectation of any Hermite polynomial under any centered Gaussian measure.

**Proposition A.8** (Expectation Under Mismatched Variance). Let \( v \in \mathbb{R} \) and \( k \geq 0 \). Then,

\[
\mathbb{E}_{g \sim \mathcal{N}(0, \sigma^2)}[h_k(\cdot; v)] = \begin{cases} 0 & \text{if } k \text{ odd,} \\ (k-1)!!(\sigma^2 - v)^{k/2} & \text{if } k \text{ even.} \end{cases}
\]

**Proof.** The result for odd \( k \) holds since \( h_k(\cdot; v) \) is an odd function for any \( v \in \mathbb{R} \) in this case. For even \( k \), we argue by induction on \( k \). The result clearly holds for \( k = 0 \). If the result holds for a given \( k \), then we may compute

\[
\mathbb{E}_{g \sim \mathcal{N}(0, \sigma^2)}[h_{k+2}(g; v)] = \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[h_{k+2}(\sigma g)] = \sigma \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[\sigma h_{k+2}(g; v)] - v(k+1) \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[h_k(\sigma g)] = \sigma^2 \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[\sigma \partial_x[h_{k+1}](\sigma g; v)] - v(k+1) \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[h_k(\sigma g)] = (k+1) \sigma^2 \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[h_k(\sigma g)] - v(k+1) \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[h_{k+2}(g; v)] = (k+1)(\sigma^2 - v) \mathbb{E}_{g \sim \mathcal{N}(0, 1)}[h_k(\sigma g)] = (k+1)(\sigma^2 - v) \mathbb{E}_{g \sim \mathcal{N}(0, \sigma^2)}[h_k(g)]
\]

completing the proof. \( \Box \)

22
We note two interesting features of this result. First, it generalizes two simple cases, on the one hand \(v = \sigma^2\) where the expectation is zero unless \(k = 0\), as may be seen from the orthogonality relations, and on the other \(v = 0\) where it recovers the moments of a Gaussian measure. Second, the quantities appearing on the right-hand side formally resemble the moments of a Gaussian measure of suitable variance, but the formula in fact still holds for \(\sigma^2 < v\), in which case these quantities may be viewed as the moments of a fictitious Gaussian measure of negative variance (the same as inspired the umbral Hermite polynomials).

### A.2 Individual Hermite Components of the Likelihood Ratio

**Proof of Lemma [5.9]** By Proposition [A.6] we find

\[
\langle L_{n,\gamma,\beta,\alpha}, \hat{H}_\alpha \rangle^2 \\
= \frac{1}{\alpha!} \left( \mathbb{E}_{y \sim \mathcal{Q}_n} \partial_y^\alpha L_{n,\gamma,\beta,\alpha}(y_1, \ldots, y_N) \right)^2 \\
= \frac{1}{\alpha!} \left( \mathbb{E}_{x \sim \mathcal{X}_n, y \sim \mathcal{Q}_n} (1 + \beta \|x\|^2)^{-N/2} \partial_y^\alpha \prod_{i=1}^N \exp \left( \frac{\beta}{2} \frac{1}{1 + \beta \|x\|^2} \langle x, y_i \rangle^2 \right) \right)^2 \\
= \frac{1}{\prod_{i=1}^N \alpha_i!} \left( \mathbb{E}_{x \sim \mathcal{X}_n} (1 + \beta \|x\|^2)^{-N/2} \prod_{i=1}^N \mathbb{E}_{y \sim \mathcal{N}(0, I_n)} \left[ \partial_y^{\alpha_i} \exp \left( \frac{\beta}{2} \frac{1}{1 + \beta \|x\|^2} \langle x, y \rangle^2 \right) \right] \right)^2, \tag{28}
\]

where the \(\alpha_i \in \mathbb{N}^n\) are the components of \(\alpha\) corresponding to \(y_i\), for each \(i \in [N]\). When \(\beta = 0\), our result follows from the above, giving \(\langle L_{n,\gamma,\beta,\alpha}, \hat{H}_\alpha \rangle^2 = \delta_{0,|\alpha|}\). (Indeed, in this case the null and planted models are identical, so \(L_{n,\gamma,\beta,\alpha} = 1\) is a constant, which is compatible with the above.) Let us suppose \(\beta \neq 0\) below.

In this case, using Proposition [A.7] we have

\[
\partial_y^{\alpha_i} \exp \left( \frac{\beta}{2} \frac{1}{1 + \beta \|x\|^2} \langle x, y \rangle^2 \right) \\
= \left( \frac{1 + \beta \|x\|^2}{\beta} \right)^{-|\alpha_i|} x^{\alpha_i} h_{|\alpha_i|} \left( \langle x, y \rangle; -\frac{1 + \beta \|x\|^2}{\beta} \right) \exp \left( \frac{1}{2} \frac{\beta}{1 + \beta \|x\|^2} \langle x, y \rangle^2 \right). \tag{29}
\]

(Note that the sign of the spike, or equivalently the sign of \(\beta\), is the opposite of the sign of the variance of the Hermite polynomials that appear; thus, it is the negatively spiked case that corresponds to the more natural positive variance Hermite polynomials.) Since when \(y \sim \mathcal{N}(0, I_n)\) then \(\langle x, y \rangle \sim \mathcal{N}(0, \|x\|^2)\), we find

\[
\langle L_{n,\gamma,\beta,\alpha}, \hat{H}_\alpha \rangle^2 = \frac{\beta^{2|\alpha|}}{\prod_{i=1}^N \alpha_i!} \left( \mathbb{E}_{x \sim \mathcal{X}_n} \frac{x^{\sum_{i=1}^N \alpha_i}}{(1 + \beta \|x\|^2)^{|\alpha| + N/2}} \right) \\
\times \prod_{i=1}^N \mathbb{E}_{y \sim \mathcal{N}(0, \|x\|^2)} h_{|\alpha_i|} \left( g; -\frac{1 + \beta \|x\|^2}{\beta} \right) \exp \left( \frac{1}{2} \frac{\beta}{1 + \beta \|x\|^2} g^2 \right)^2. \tag{30}
\]
We next focus on the innermost expectation. We may rewrite:

\[
\begin{aligned}
\mathbb{E}_{g \sim \mathcal{N}(0, \|x\|^2)} h_{|\alpha|} \left( g; - \frac{1 + \beta \|x\|^2}{\beta} \right) 
&= \frac{1}{\sqrt{2\pi \|x\|^2}} \int_{-\infty}^{\infty} h_{|\alpha|} \left( g; - \frac{1 + \beta \|x\|^2}{\beta} \right) \exp \left( \frac{1}{2} \frac{\beta}{1 + \beta \|x\|^2} \left( \|x\|^2 - \frac{\beta}{1 + \beta \|x\|^2} \right) g^2 \right) dg \\
&= \frac{(1 + \beta \|x\|^2)^{1/2}}{\sqrt{2\pi \|x\|^2(1 + \beta \|x\|^2)}} \int_{-\infty}^{\infty} h_{|\alpha|} \left( g; - \frac{1 + \beta \|x\|^2}{\beta} \right) \exp \left( - \frac{1}{2} \|x\|^2 \left( 1 + \beta \|x\|^2 \right) \right) dg \\
&= (1 + \beta \|x\|^2)^{1/2} \sum_{|\alpha| \in \mathbb{N}^n, i \in [N]} \mathbb{E}\left[ D_{g}^{2} \left| \sum_{i=1}^{N} \alpha_{i} \right| \right] h_{|\alpha|} \left( g; - \frac{1 + \beta \|x\|^2}{\beta} \right).
\end{aligned}
\]  

(31)

By Proposition A.8, this quantity will be zero unless $|\alpha_i|$ is even, and thus $\langle L_{n,\gamma,\beta,\chi, \hat{H}_{\alpha}} \rangle^2$ will be zero unless $|\alpha_i|$ is even for all $i$. In this case, by Proposition A.8,

\[
\begin{aligned}
\mathbb{E}_{g \sim \mathcal{N}(0, \|x\|^2)} h_{|\alpha|} \left( g; - \frac{1 + \beta \|x\|^2}{\beta} \right) \exp \left( \frac{1}{2} \frac{\beta}{1 + \beta \|x\|^2} \left( \|x\|^2 - \frac{\beta}{1 + \beta \|x\|^2} \right) g^2 \right) &= (|\alpha_i| - 1)! \left( 1 + \beta \|x\|^2 \right)^{\alpha_i + 1/2} \beta^{\alpha_i/2}. 
\end{aligned}
\]  

(32)

Substituting into (30), we find many cancellations after which we are left with

\[
\langle L_{n,\gamma,\beta,\chi, \hat{H}_{\alpha}} \rangle^2 = \prod_{i=1}^{N} (|\alpha_i| - 1)!^2 \beta^{\alpha_i} \left( \mathbb{E}_{x \sim X_{n}} \sum_{i=1}^{N} \alpha_{i} \right)^2,
\]

(33)

the final result.

\section{A.3 Norm of the Low-Degree Likelihood Ratio}

\textbf{Proof of Lemma 5.7} Recall that

\[
\| L_{n,\gamma,\beta,\chi}^{\leq D} \|_{L^2(Q_{n})}^2 = \sum_{\alpha \in (\mathbb{N}^n)^N, |\alpha| \leq D} \langle L_{n,\gamma,\beta,\chi, \hat{H}_{\alpha}} \rangle^2.
\]

(34)

We substitute in the result of Lemma 5.8 which, after introducing independent replicas $x^1, x^2 \sim X_{n}$, may be rewritten as

\[
\| L_{n,\gamma,\beta,\chi}^{\leq D} \|_{L^2(Q_{n})}^2 = \mathbb{E}_{x^1, x^2 \sim X_{n}} \sum_{\sum_{i=1}^{N} \alpha_{i} \in \mathbb{N}^n, |\alpha| \leq D} \prod_{i=1}^{N} \frac{(|\alpha_i| - 1)!^2 \beta^{\alpha_i} (x^1)_{\alpha_i} (x^2)_{\alpha_i}}{\alpha_i}.
\]

By the multinomial theorem,

\[
\langle x^1, x^2 \rangle_{\alpha} = \sum_{\alpha \in \mathbb{N}^n, |\alpha| = d} \left( \prod_{j=1}^{n} (x^1_j x^2_j)^{\alpha(j)} \right),
\]

(35)
and therefore
\[
\langle x^1, x^2 \rangle \sum_{i=1}^N d_i = \prod_{i=1}^N \langle x^1, x^2 \rangle_{d_i}
\]
\[
= \prod_{i=1}^N \sum_{\alpha \in \mathbb{N}^n, |\alpha| = d_i} \binom{d_i}{\alpha} \prod_{j=1}^n (x_j^1 x_j^2)^{\alpha(j)}
\]
\[
= \sum_{\alpha_i \in \mathbb{N}^n, i \in [N]} \prod_{i=1}^N \binom{d_i}{\alpha_i} \prod_{j=1}^n (x_j^1 x_j^2)^{\alpha_i(j)}.
\]
In our case, this shows
\[
\|L_{n, n/2, X, |D|/2}^{\leq D} \|^2_{L^2(Q_n)} = \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \sum_{0 \leq d \leq D} \beta^d \sum_{d_1, \ldots, d_N \text{ even}} \left( \prod_{i=1}^N \frac{(d_i - 1)!^2}{d_i!} \right) \left( \prod_{i=1}^N \langle x^1, x^2 \rangle_{d_i} \right)
\]
\[
= \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \sum_{0 \leq d \leq D} \beta^d \langle x^1, x^2 \rangle^d \sum_{d_1, \ldots, d_N \text{ even}} \prod_{i=1}^N \frac{d_i!}{d_i!^{1/2}}
\]
\[
= \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \sum_{0 \leq d \leq D} 2^{-d} \beta^d \langle x^1, x^2 \rangle^d \sum_{d_1, \ldots, d_N \text{ even}} \prod_{i=1}^N \frac{d_i}{d_i/2}
\]
where we have used the identities \(n! = n!! \cdot (n - 1)!!\) and \((2n)!! = 2^n \cdot n!\). We now pass to a notation making the restriction to even degrees clearer:
\[
\|L_{n, n/2, X, |D|/2}^{\leq D} \|^2_{L^2(Q_n)} = \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \sum_{0 \leq d \leq \lfloor |D|/2 \rfloor} \left( \frac{\beta^2 \langle x^1, x^2 \rangle^2}{4} \right)^d \sum_{d_1, \ldots, d_N \text{ even}} \prod_{i=1}^N \left( \frac{2d_i}{d_i} \right).
\]
The remaining function may be understood in terms of the generating function of the central binomial coefficients: using Proposition 5.7, we have that for any \(x \in (-\frac{1}{4}, \frac{1}{4})\),
\[
\varphi_N(x) := (1 - 4x)^{-N/2} = \left( \sum_{d \geq 0} \binom{2d}{d} \frac{x^d}{d^d} \right)^N = \sum_{d \geq 0} x^d \sum_{d_1, \ldots, d_N \text{ even}} \prod_{i=1}^N \left( \frac{2d_i}{d_i} \right).
\]
Writing \(\varphi_{N,k}(x)\) for the truncation of this Taylor series to degree \(k\), we see that
\[
\|L_{n, n/2, X, |D|/2}^{\leq D} \|^2_{L^2(Q_n)} = \mathbb{E}_{x^1, x^2 \sim \mathcal{X}_n} \left[ \varphi_{N, |D|/2}(\frac{\beta^2 \langle x^1, x^2 \rangle^2}{4}) \right],
\]
the final result. \(\square\)
B Proofs for Bounding the Low-Degree Likelihood Ratio

B.1 Local Chernoff Bound

Proof of Proposition 5.12. It is sufficient to show that $i.i.d. \frac{\pi}{\sqrt{n}}$ admits a local Chernoff bound. Since $\pi$ is subgaussian, $\pi^2 - E[\pi^2]$ is subexponential (see, e.g., [RH18]), i.e., the moment-generating function $M(t) = E[\exp(t(\pi^2 - E[\pi^2]))]$ satisfies $M(t) \leq \exp(t^2)$ for all $|t| \leq s$ for a suitable choice of a constant $s > 0$. In particular, $E[\exp(t\pi^2)] < \infty$ for all $|t| \leq s$ for this choice of $s > 0$.

Let $\Pi = \pi\pi'$, the product of two independent copies of $\pi$. Let $\sigma^2$ be the variance proxy of $\pi$ (see Definition 2.2). The moment-generating function of $\Pi$ is

$$M(t) = E[\exp(t\Pi)] = E[\exp(t\pi\pi')] = E[\exp(\sigma^2 t^2 \pi^2/2)] < \infty$$

provided $\frac{1}{2} \sigma^2 t^2 < s$, i.e., $|t| < \sqrt{2s/\sigma^2}$. Thus $M(t)$ exists in an open interval containing $t = 0$, which implies $M'(0) = E[\Pi] = 0$ and $M''(0) = E[\Pi^2] = 1$ (this is the defining property of the moment-generating function: its derivatives at $t = 0$ are the moments of $\Pi$).

Let $\eta > 0$ and $f(t) = \exp\left(\frac{t^2}{2(1-\eta)}\right)$. Since $M(0) = 1, M'(0) = 0, M''(0) = 1$ and $f(0) = 1, f'(0) = 0, f''(0) = \frac{1}{1-\eta} > 1$, there exists $\delta > 0$ such that for all $t \in [-\delta, \delta]$ $M(t)$ exists and $M(t) \leq f(t)$.

We now apply the standard Chernoff bound argument to $\langle x^1, x^2 \rangle = \frac{1}{n} \sum_{i=1}^{n} \Pi_i$, where $\Pi_1, \ldots, \Pi_n$ are i.i.d. copies of $\Pi$. For any $\lambda > 0$,

$$\Pr \{ \langle x^1, x^2 \rangle \geq t \} = \Pr \{ \exp(\lambda \langle x^1, x^2 \rangle) \geq \exp(\lambda t) \} \leq \exp(-\lambda t) E[\exp(\lambda \langle x^1, x^2 \rangle)]$$

(by Markov’s inequality)

$$= \exp(-\lambda t) E[\exp(\lambda n^{-1} \sum_{i=1}^{n} \Pi_i)]$$

$$= \exp(-\lambda t) E[\exp(\lambda/n)]^{n-1}$$

(provided $\lambda/n \leq \delta$)

$$\leq \exp(-\lambda t) \exp\left(\frac{\lambda^2}{2(1-\eta)n}\right).$$

Taking $\lambda = (1-\eta)nt$,

$$\Pr \{ \langle x^1, x^2 \rangle \geq t \} \leq \exp\left(-(1-\eta)nt^2 + \frac{1}{2}(1-\eta)nt^2\right) = \exp\left(-\frac{1}{2}(1-\eta)nt^2\right)$$

as desired. This holds provided $\lambda/n \leq \delta$, i.e., $t \leq \delta/(1-\eta)$. The same argument (with $-\Pi$ instead of $\Pi$) holds for the other tail bound $\Pr \{ \langle x^1, x^2 \rangle \leq -t \}$.  

B.2 Bounding the Large Deviations

Proof of Lemma 5.13. Recall that

$$\varphi_{N,D/2}(x) = \sum_{d=0}^{[D/2]} x^d \sum_{d_1, \ldots, d_N} \prod_{i=1}^{N} \binom{2d_i}{d_i}.$$
Note that the first sum above has \(|D/2| + 1\) terms and the second sum has at most \(N^d \leq N^{D/2}\) terms. It is combinatorially clear that \((2d_i \choose d_i)/(2d_i \choose d_i) \leq \left( \frac{2(d_i + d_j)}{d_i}ight)\), and therefore

\[
\prod_{i=1}^{N} \left( \frac{2d_i}{d_i} \right) \leq \left( \frac{2}{d} \sum_{i=1}^{N} d_i \right) = \left( \frac{2d}{d} \right) \leq (2d)^d \leq D^{D/2}.
\]

Since \(||x^1||^2 \leq 2\) and \(||x^2||^2 \leq 2\) we have \(\frac{1}{4} \beta^2 \langle x^1, x^2 \rangle^2 \leq \beta^2\). Since \(d \leq D/2\) we have \((\beta^2)^d \leq (1 + \beta^2)^{D/2}\), and therefore

\[
\varphi_{N, |D/2|} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \leq (D/2 + 1)(1 + \beta^2)^{D/2}N^{D/2}D^{D/2} \leq (1 + \beta^2)^{D/2}DN^{D/2}D^{D/2}.
\]

Combining these bounds,

\[
R_2 = \mathbb{E}_{x^1, x^2 \sim X_n} \left[ 1_{\langle x^1, x^2 \rangle > \varepsilon} \varphi_{N, |D/2|} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right]
\leq \Pr \{ \langle x^1, x^2 \rangle > \varepsilon \} (1 + \beta^2)^{D/2}DN^{D/2}D^{D/2}.
\]

Since \(R_2\) increases as \(\varepsilon\) decreases, we can assume without loss of generality that \(\varepsilon\) is small enough that we may apply the local Chernoff bound: \([18]\\]

\[
\leq \exp \left( -\frac{1}{3} n \varepsilon^2 \right) (1 + \beta^2)^{D/2}DN^{D/2}D^{D/2}
= \exp \left( -\frac{1}{3} n \varepsilon^2 + \frac{D}{2} \log(1 + \beta^2) + \log D + \frac{D}{2} \log N + \frac{D}{2} \log D \right)
= o(1)
\]

provided \(D = o(n/\log n)\), completing the proof.

\[\square\]

**B.3 Bounding the Small Deviations**

*Proof of Lemma 5.14.* We use the argument from Appendix K of [PWBM18b]. Since the Taylor series for \(\varphi_N(x)\) has nonnegative coefficients, we have \(\varphi_{N, |D/2|}(x) \leq \varphi_N(x)\) for all \(x \in [0, 1/4]\). Taking \(\varepsilon < 1/|\beta|\), we have

\[
R_1 = \mathbb{E}_{x^1, x^2 \sim X_n} \left[ 1_{\langle x^1, x^2 \rangle \leq \varepsilon \varphi_{N, |D/2|}} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right]
\leq \mathbb{E}_{x^1, x^2 \sim X_n} \left[ 1_{\langle x^1, x^2 \rangle \leq \varepsilon \varphi_N} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right]
= \mathbb{E}_{x^1, x^2 \sim X_n} \left[ 1_{\langle x^1, x^2 \rangle \leq \varepsilon} \left( 1 - \beta^2 \langle x^1, x^2 \rangle^2 \right)^{-N/2} \right]
= \mathbb{E}_{x^1, x^2 \sim X_n} \left[ 1_{\langle x^1, x^2 \rangle \leq \varepsilon} \exp \left( -\frac{N}{2} \log \left( 1 - \beta^2 \langle x^1, x^2 \rangle^2 \right) \right) \right].
\]
By the convexity of $t \mapsto -\log(1 - \beta^2 t)$, we have
\[-\log(1 - \beta^2 t) \leq -\frac{t}{\epsilon^2}(1 - \beta^2 \epsilon^2)\] for all $t \in [0, \epsilon^2]$. Letting $c := -\frac{N}{2\epsilon^2} \log(1 - \beta^2 \epsilon^2) > 0$, we proceed bounding
\[
\leq \mathbb{E}_{x^1, x^2 \sim X_n} \left[ 1_{|\langle x^1, x^2 \rangle| \leq \epsilon} \exp \left( c \langle x^1, x^2 \rangle^2 \right) \right] = \int_0^\infty \Pr \left\{ 1_{|\langle x^1, x^2 \rangle| \leq \epsilon} \exp \left( c \langle x^1, x^2 \rangle^2 \right) > u \right\} du
\]
\[
= \int_0^\infty \Pr \left\{ |\langle x^1, x^2 \rangle| \leq \epsilon \quad \text{and} \quad \exp \left( c \langle x^1, x^2 \rangle^2 \right) > u \right\} du
\]
\[
\leq 1 + \int_1^\infty \Pr \left\{ |\langle x^1, x^2 \rangle| \leq \epsilon \quad \text{and} \quad \exp \left( c \langle x^1, x^2 \rangle^2 \right) > u \right\} du.
\]
Applying the change of variables $u = \exp(\epsilon t)$,
\[
= 1 + \int_0^\infty \Pr \left\{ |\langle x^1, x^2 \rangle| \leq \epsilon \quad \text{and} \quad \langle x^1, x^2 \rangle^2 > t \right\} c \exp(\epsilon t) dt \leq 1 + \int_0^{\epsilon^2} \Pr \left\{ \langle x^1, x^2 \rangle^2 > t \right\} c \exp(\epsilon t) dt.
\]
Provided $\epsilon$ is sufficiently small, we can apply the local Chernoff bound
\[
\leq 1 + Cc \int_0^{\epsilon^2} \exp \left( -\frac{1}{2}(1 - \eta) + c \right) dt.
\]
Let $\hat{\gamma} := n/N$, so that $\hat{\gamma} \to \gamma$ as $n \to \infty$. Letting $c := \hat{c}n$ where $\hat{c} = -\log(1 - \beta^2 \epsilon^2)/(2\epsilon^2 \hat{\gamma})$,
\[
\leq 1 + C \cdot \hat{c}n \int_0^{\epsilon^2} \exp \left( \left( -\frac{1}{2}(1 - \eta) + c \right) nt \right) dt.
\]
We have $\lim_{\epsilon \to 0^+} \hat{c} = \frac{\beta^2}{2\hat{\gamma}}$. Since $\beta^2 < \gamma$, we have that for sufficiently large $n$, $\frac{\beta^2}{2\hat{\gamma}} < \frac{1}{2}$. Thus we can choose $\epsilon$ and $\eta$ small enough so that for sufficiently large $n$, $-\frac{1}{2}(1 - \eta) + \hat{c} \leq -\alpha$ for some $\alpha > 0$. Now
\[
\leq 1 + C \cdot \hat{c}n \int_0^{\infty} \exp(-\alpha nt) dt = 1 + \frac{C \cdot \hat{c}}{\alpha} = O(1),
\]
completing the proof.

\[\square\]

B.4 Above the BBP Threshold

Proof of Theorem 3.2 (Part 2). Let $\beta^2 > \gamma$. Recall
\[
\|L_{n, \gamma, \beta, x}^D\|_{L^2(Q_n)}^2 = \mathbb{E}_{x^1, x^2 \sim X_n} \left[ \varphi_{N, [D/2]} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right) \right] = \sum_{d=0}^{[D/2]} \mathbb{E}_{x^1, x^2 \sim X_n} \left( \frac{\beta^2}{4} \langle x^1, x^2 \rangle^2 \right)^d \sum_{d_1, \ldots, d_N} \prod_{i=1}^N \left( 2d_i \right).
\] (35)
Since each term in the outer summation of (35) is nonnegative, it suffices to fix a single $d \leq D/2$ and show that the corresponding term is $\omega(1)$. We can write $\langle x^1, x^2 \rangle = \frac{1}{n} \sum_{i=1}^{n} \Pi_i$ where $\Pi_1, \ldots, \Pi_n$ are i.i.d. with distribution of the product $\Pi = \pi \pi'$ of two independent copies of $\pi$. This means

$$
\mathbb{E}_{x^1, x^2 \sim X_n} \langle x^1, x^2 \rangle^{2d} = \mathbb{E} \left( \frac{1}{n} \sum_{i=1}^{n} \Pi_i \right)^{2d} = n^{-2d} \sum_{i_1, \ldots, i_{2d} \in [n]} \mathbb{E}[\Pi_{i_1} \Pi_{i_2} \cdots \Pi_{i_{2d}}].
$$

Since $\pi$ is symmetric about zero, $\Pi$ is also symmetric about zero, so all moments $\mathbb{E}[\Pi^k]$ are nonnegative. This means each term in the remaining sum is nonnegative, so we can obtain a lower bound by only considering terms where each index occurring among $i_1, \ldots, i_{2d}$ occurs exactly twice:

$$
\mathbb{E}_{x^1, x^2 \sim X_n} \langle x^1, x^2 \rangle^{2d} \geq n^{-2d} \binom{n}{d} \frac{(2d)!}{2^d} (\mathbb{E}[\Pi^2])^{d} = n^{-2d} \binom{n}{d} \left( \frac{(2d)!}{2^d} \right)^{d}.
$$

Next, we bound the inner summation of (35) below by taking only the terms with $d_i \in \{0, 1\}$ for all $i \in [N]$:

$$
\sum_{d_1, \ldots, d_N} \prod_{i=1}^{N} \binom{2d_i}{d_i} \geq \binom{N}{d}^{2d}.
$$

Combining these bounds, we find that for any fixed $0 \leq d \leq \lfloor D/2 \rfloor$, 

$$
\|L_{n, \gamma, \beta, X}^{D(\mathcal{Q})}\|_{L^2(\mathcal{Q}_n)}^2 \geq \frac{\beta^{2d}}{4^d n^{-2d}} \binom{n}{d} \left( \frac{(2d)!}{2^d} \right) \binom{N}{d}^{2d} = \left( \frac{\beta^2}{4n^2} \right)^d \frac{(2d)! n! N!}{(d!)^2 (n-d)! (N-d)!} \geq \left( \frac{\beta^2(n-d)(N-d)}{4n^2} \right)^d \binom{2d}{d}.
$$

Using the standard bound $\binom{2d}{d} \geq 4^d/(2\sqrt{d})$,

$$
\|L_{n, \gamma, \beta, X}^{D(\mathcal{Q})}\|_{L^2(\mathcal{Q}_n)}^2 \geq \frac{1}{2\sqrt{d}} \left( \frac{\beta^2(n-d)(N-d)}{n^2} \right)^d.
$$

This final expression will be $\omega(1)$ provided that $1 \ll d \ll n$, since $n/N \to \gamma$ and $\beta^2 > \gamma$. 

\[Q.E.D.\]
