The brain serotonergic system has an essential role in the physiological functions of the central nervous system and dysregulation of serotonin (5-HT) homeostasis has been implicated in many neuropsychiatric disorders. The tryptophan hydroxylase-2 (TPH2) gene is the rate-limiting enzyme in brain 5-HT synthesis, and thus is an ideal candidate gene for understanding the role of dysregulation of brain serotonergic homeostasis. Here, we characterized a common, but functional single-nucleotide polymorphism (SNP rs1386493) in the TPH2 gene, which decreases efficiency of normal RNA splicing, resulting in a truncated TPH2 protein (TPH2-TR) by alternative splicing. TPH2-TR, which lacks TPH2 enzyme activity, dominant-negatively affects full-length TPH2 function, causing reduced 5-HT production. The predicted mRNA for TPH2-TR is present in postmortem brain of rs1386493 carriers. The rs13864923 variant does not appear to be overrepresented in either global or multiplex depression cohorts. However, in combination with other gene variants linked to 5-HT homeostasis, this variant may exhibit important epistatic influences. Keywords: TPH2; serotonin (5-HT); SNP; alternative splicing

Introduction

Dysregulation of the brain serotonergic (5-HT) system has been implicated in disorders such as major depression,1 attention-deficit/hyperactivity disorder,2 schizophrenia,3 aggression and suicidal behavior.4 Among the genes involved in the brain 5-HT system, the 5-HT transporter, especially its functional polymorphism in the promoter region, has been well characterized for its association with anxiety and depression.5,6 Tryptophan hydroxylase-1 (TPH1) gene was long considered the only rate-limiting enzyme in 5-HT synthesis, and its potential association with various neuropsychiatric disorders has been widely explored, but not without controversies.4 However, a second gene (TPH2) has been recently discovered as a neuronal-specific gene7 that controls brain 5-HT synthesis,8 whereas the previously known TPH1 gene is essential for peripheral 5-HT synthesis.7 Since its discovery in 2003,7 the TPH2 gene has been extensively studied for its association with various neuropsychiatric disorders, yielding over 500 genetic variants in human. Except for a few examples of functional characterization,6,9–12 the majority of human TPH2 genetic variants that have been found in the introns, untranslated regions and promoter regions, remain to be physiologically characterized.10

In this study, we developed a functional approach to characterize an intronic single-nucleotide polymorphism (SNP rs1386493) that was previously identified in cohorts of neuropsychiatric disorders and controls.13,14 We used a minigene construct carrying a partial TPH2 genomic DNA sequence to address the physiological consequence of this SNP. Our data indicate that SNP (rs1386493) reduces normal splicing of intron 5 by generating an alternatively spliced transcript Q8N1X9 that can be detected in postmortem brainstem tissues. The truncated protein of Q8N1X9 is devoid of TPH2 enzyme activity, and exerts a dominant-negative effect in vitro
on the ability of the normal Tph2 enzyme to support 5-HT synthesis. Although the allele frequency of this SNP is not significantly different in cohorts we have analyzed so far, our data provide a novel mechanism that could regulate brain 5-HT synthesis and suggest that genetic variations in the TPH2 gene could contribute to the etiology of conditions associated with dysfunction of the 5-HT system. Moreover, homozygous carriers of this SNP were identified in a subset of multiplex Caucasian families from the NIMH Depression Pedigree. Therefore, our data suggest that mutations in the TPH2 gene could be one of the many contributing risk factors for major depression.

**Materials and methods**

**IRB approval**

The use of human genomic DNA samples and human brainstem tissues was approved by Duke University Medical Center Institutional Review Board. Brain samples from human dorsal raphe were obtained at autopsy at the Coroner's Office of Cuyahoga County, Cleveland, OH, USA. The study was performed using a protocol approved by the Institutional Review Boards of University Hospitals of Cleveland and the University and the Mississippi Medical Center. Informed consent was obtained from the legally determined next-of-kin for all subjects.

**Genotyping for SNP (rs1386493) by restriction fragment length polymorphism**

Genomic DNA (10 ng) was amplified by PCR using forward primer (5’-TAGCGTTGAAATTTCTGACACCTCTCTCTTCTCAAGAGG-3’) and a diluted PCR solution from the first PCR as template. 40 cycles of amplification using the second set of primers for genotyping and PCR amplification following RT–PCR. The nested PCR was conducted by 20 cycles of amplification using the first set of primers, followed by denatured at 95 °C for 3 min followed by 40 cycles of amplification at 95 °C for 2 s, 60 °C for 20 s and 72 °C for 30 s. Gene expression was normalized to neomycin-resistance gene (NeoR).

**PC12 cell lines and 5-HT detection**

PC12 cell lines were maintained in DMEM media with 5% iron-supplemented bovine calf serum (HyClone, Logan, UT, USA) and 5% equine serum (HyClone), and 10% CO2. PC12 cells were transfected by electroporation (Bio-Rad, Hercules, CA, USA) as previously described. The production of 5-HT was analyzed by HPLC using an electrochemical detector as described previously for the characterization of loss-of-function TPH2 mutants in mice and human. Western blotting was performed using anti-hemagglutinin (Covance, Princeton, NJ, USA) and anti-actin (Millipore, Billerica, MA, USA) monoclonal antibodies and goat anti-mouse secondary antibody conjugated with horseradish peroxidase (Pierce, Rockford, IL, USA).

**PCR amplification**

Human TPH2 genomic DNA from bacterial artificial chromosome clone RP11-89M22 (BACPAC Resource Center, Oakland, CA, USA) was amplified using EXL DNA polymerase (Stratagene, La Jolla, CA, USA). Taq DNA polymerase (Fisher, Pittsburgh, PA, USA) was used for genotyping and PCR amplification following RT–PCR. The nested PCR was conducted by 20 cycles of amplification using the first set of primers, followed by 40 cycles of amplification using the second set of primers and a diluted PCR solution from the first PCR as template.

**RT–PCR and real-time RT–PCR analyses**

Total RNA from PC12 cells stably transfected with minigene constructs and human brainstem tissues was prepared using TRI Reagent RNA Isolation Reagent (Sigma, St Louis, MO, USA). Total RNA was then treated with DNase I (Sigma). ProtoScript First Strand cDNA Synthesis Kit (NEB) was then used to obtain cDNA from total RNA or an Intron 5 specific sequence (5’-TTTTTTCTCAATTTTTCTCAATTCAGGT) was used for detecting alternative splicing transcript in PC12 cells (Figures 2c and e). Real-time RT–PCR was performed using Platinum® SYBR® Green qPCR SuperMix-UDG (Invitrogen, Carlsbad, CA, USA) with the following conditions: denatured at 95 °C for 3 min followed by 40 cycles of amplification at 95 °C for 2 s, 60 °C for 20 s and 72 °C for 30 s. Gene expression was normalized to neomycin-resistance gene (NeoR).

**Truncated TPH2 gene**

The full-length human TPH2 gene (Ensembl: ENST00000333850) possesses 11 exons and spans
A functional alternative splicing mutation in human TPH2
X Zhang et al

Minigene constructs using partial TPH2 genomic DNA

As constitutive splicing of primary transcript RNA requires both cis- and trans-acting factors, the existence of Q8N1X9 suggested that mutation(s) in intron 5 and surrounding exon a6A junction might give rise to conditions that compromised the normal splicing of intron 5 leading to abnormal exon 5 and exon a6A recognition. We searched known SNPs in the NCBI database and located two candidate SNPs: rs1386493 (G/A SNP) that was 154 bp upstream of exon a6A and rs10506644 (A/G SNP) that was within exon a6A. To determine whether these two candidate SNPs were functional by causing alternative splicing, we used a previously established minigene construct strategy consisting of constitutively active adenovirus exons and introns for splicing and neomycin-resistance gene (NeoR) for antibiotic selection. As the TPH2 gene possesses a 22863 bp-long intron 5, and most of the cis-acting elements for splicing are usually in proximity of exons, we chose to use partial genomic DNA with 1000 bp each upstream and downstream of the exons of interest. We thus amplified 2000 bp of TPH2 genomic DNA sequences flanking exon 5 and exon 6, respectively, and then cloned these DNA sequences into the minigene construct to generate a vector construct (WT construct). We subsequently generated mutant constructs at these two particular positions: 6493A construct (G-to-A substitution corresponding to rs1386493) and 6644G (SNP rs10506644) substitutions were introduced (Figure 1b).
SNP (rs1386493), but not (rs10506644) reduced normal splicing efficiency through alternative splicing

We transfected plasmids encoding vector alone, WT, 6493A, 6644G constructs into PC12 cells and generated stable cell lines expressing TPH2 minigene constructs. RT–PCR was then performed using a 622-bp fragment of NeoR as internal control (Figure 2a). The normal splicing was detected by PCR using primer set (P1–P2) specific for the adenovirus exonic sequences (Figure 2b). The vector construct produced a single, 397 bp PCR product (Figure 2b), which was confirmed by sequence analysis as the normal splicing product (Figure 2d, data not shown). When PC12 cells expressing the minigene constructs encoding WT and mutants (6493A and 6644G) were analyzed, the same single PCR product was shown. However, the normal transcript of 397bp was reduced when 6493A construct was present (Figure 2d). To determine whether this decrease of normal exon 5–exon 6 transcripts in PC12 cells expressing 6493A was significant, we performed real-time RT–PCR using primer set (P3–P4) and NeoR as an internal control indicated a significant decrease in the efficiency of normal splicing only when SNP (rs1386493) was expressed. (All data are presented as means ± s.d. Statistical significance of all data presented was analyzed by Student’s t-test; N = 10.)

**Figure 2** Assessment of the influence of intronic single-nucleotide polymorphisms (SNPs) on TPH2 splicing. (a–c) RT–PCR detected a 397-bp normal spliced transcript (b, d) and a 622-bp NeoR transcript (a) as an internal control. Nested PCR using primer set (P1–P2) followed by (P6–P7) revealed a 222-bp transcript (c) as predicted by alternative splicing of exon a6A (e). All PCR products were confirmed by sequence analysis (data not shown). (f) Real-time RT–PCR to measure normal splicing of intron 6 using primer set (P3–P4) and NeoR as an internal control indicated a significant decrease in the efficiency of normal splicing only when SNP (rs1386493) was expressed. (All data are presented as means ± s.d. Statistical significance of all data presented was analyzed by Student’s t-test; N = 10.)

TPH2-TR is a dominant-negative mutant

As Q8N1X9 was isolated from a cDNA library,16 a 3’-untranslated region sequence should be present downstream of exon a6A, which is required for mRNA stability.19 To test this, we designed a green fluorescent protein (GFP) construct under the CMV promoter in the backbone of a pBluescript vector (pBS-GFP; Figure 3a). In the absence of a downstream 3’-untranslated region, pBS-GFP was unable to express GFP protein (Figure 3b). In contrast, when the 1500-bp downstream sequence of exon a6A (a6A/U) was cloned to generate pBS-GFP-a6A/U, GFP expression was abundantly detected by western blotting (Figure 3b), indicating a6A/U was sufficient to stabilize Q8N1X9 mRNA. We next amplified exon a6A and generated full-length cDNA of Q8N1X9 (TPH2-TR; Figure 4b), with an N-terminal hemagglutinin epitope tag, and co-transfected it alone or along with hemagglutinin-tagged full-length TPH2 into PC12 cells and determined TPH2 activity by measuring 5-HT production.8,9 Western blotting indicated that TPH2-TR was co-expressed with TPH2 (Figure 3c). Whereas TPH2-TR alone in PC12 cells was devoid of enzyme activity, co-expressing full-length TPH2 and increasing amounts of TPH2-TR, indicated that despite being expressed at lower levels, TPH2-TR exerted a dominant-negative effect on TPH2 for 5-HT production (Figure 3d).
Q8N1X9 in human brainstem tissues

In order to confirm Q8N1X9 mRNA in human, postmortem brainstem tissues were obtained from the brain collection at the University of Mississippi Medical Center. We first developed a restriction fragment length polymorphism analysis for SNP (rs1386493), and genotyped 143 genomic DNA samples (A-allele frequency 0.19) from the brain collection and obtained available brainstem tissue (pons/medulla) of one wild-type (6493GG), one heterozygous (6493GA) and two homozygous samples (6493AA). We performed RT–PCR using nested PCR amplification with primer set (P8–P5) followed by primer set (P9–P10) to obtain the full-length Q8N1X9 transcript (Figure 1a). The 995-bp fragment was detected in the two homozygous 6493AA and the one heterozygous 6493GA samples (Figure 4) and confirmed by sequence analysis (data not shown), whereas Q8N1X9 transcript was absent in wild-type 6493GG sample. Therefore, Q8N1X9 transcript is expressed in human brainstem tissues carrying the SNP (rs1386493).

SNP (rs1386493) in depression cohorts

Given the functional significance associated with the A allele of SNP (rs1386493), we hypothesized that it could be associated with the clinical diagnosis of depression. We genotyped the A-allele frequency in Caucasian subjects of the STAR*D (N = 1084)20,21 and control (N = 1200) cohorts, but found no significant differences (0.17 vs 0.18). In addition, a similar distribution of the A-allele frequency (0.21) was found in a set of 99 Caucasian probands derived from multiplex families of the NIMH Center for Genetic Studies Depression Pedigree.22 However, further analysis of four families whose probands were homozygous for the A allele revealed 11 of 16 individuals were homozygous for the A allele (Figure 5).

Discussion

The average vertebrate gene is ~27 000 bp long separated by multiple small exons each of 150–300 bp.23 It has been estimated that at least 74% of human genes are alternatively spliced,24 and ~15% of all point mutations causing human genetic disease result from mRNA splicing defects.25 This suggests that diverse effects on development, physiology, as
A functional alternative splicing mutation in human TPH2
A. Zhang et al

Figure 5 Genotyping of samples from four pedigrees whose probands were homozygous AA in the NIMH Center for Genetic Studies Depression Pedigree. ‘AA,’ ‘GA,’ ‘GG’ indicate homozygous AA, heterozygous GA and wild-type GG for single-nucleotide polymorphism (SNP) (rs1386493), respectively. Arrows show probands where homozygous SNP (rs1386493) was identified. '?' indicates unknown genotypes (missing DNA samples).

well as disease-causing events might be due to aberrant splicing and abnormal protein function.26,27 In fact, emerging evidence indicates that splicing defects have an important role in many neurologic diseases.28–30 Here, we identify a functional intronic mutation in the human TPH2 gene that generates an alternatively spliced form Q8N1X9, consisting of the first 5 exons of TPH2 gene plus an additional 145 bp of exon a6A (Figures 1a, 2 and 4).

Our identification of a functional role for the SNP (rs13286493) in alternative splicing is also corroborated by bioinformatic examination of TPH2 intronic sequences. Exon recognition requires not only the traditional 5′-, 3′-splice sites and branch sites, but also both exonic and intronic splicing enhancers and silencers.28 A growing family of serine/arginine-rich proteins31 have been well characterized for their role as splicing factors through binding to exonic splicing enhancers. Upstream sequences of exon a6A conform to a ‘canonical’ intron–exon junction, and the ESEfinder tool32 predicts that sequences surrounding SNP (rs1386493) can serve as recognition sites for two splicing factors (SF2/ASF and SC35), whereas the A allele would cause reduced binding of these putative splicing factors. Interestingly, SF2/ASF has been previously shown to function as a repressor of downstream exon recognition when its binding site is located in an intron.33 Therefore, the accuracy of normal intron 5 splicing could, at least in part, be due to the binding of SF2/ASF, and the A allele could partially remove the inhibitory element thereby causing recognition of exon a6A.

TPH2 consists of an N-terminal regulatory domain, a catalytic domain and a C-terminal tetramerization domain, and belongs to the superfamily of aromatic amino-acid hydroxylases including tyrosine hydroxylase, phenylalanine hydroxylase and TPH1.34 As the truncated TPH2-TR retains the entire regulatory domain and a small portion of catalytic domain (Figure 1a), its dominant-negative activity may lie in its interference with the normal function of the regulatory domain in the full-length protein.35,36

A number of genetic analyses have indicated association between the TPH2 gene and central nervous system disorders like depression,14 bipolar disorder,37,38 and attention-deficit/hyperactivity disorder.39 A functional characterization was carried out for a rare loss-of-function R441H mutation in an elderly depression cohort whose patients experienced life-long depression, and were resistant to treatment.9 Recently, transgenic knock-in mice carrying the equivalent human R441H mutation were shown to recapitulate the predicted >80% decrease in brain 5-HT synthesis and to exhibit behavioral abnormalities similar to certain endophenotypes of depression and anxiety.40 Similarly, the SNP rs1386493 has been previously studied as a common genetic variant. Zill et al.14 identified an A-allele frequency of 19% in control subjects (N = 265), which was similar to that in a depression cohort (N = 300). In another study, Haghighi et al.15 showed an A-allele frequency of 7.2 and 21.3% in depression (N = 82) and control (N = 80), respectively (P = 0.001), but the authors concluded that ‘the association with SNP (rs1386493) might be spuriously’ due to a relatively small cohort in the study and somewhat unexpected finding that the mutated allele was more frequent in the control cohort. Haghighi et al.15 speculated that variants within this region of the gene might contribute to the generation of the shorter transcript from the TPH2 gene. Our functional characterization, however, reveals a potential mechanism for the pathological function of this common SNP. It will be of great interest for further investigation to ascertain the potential epistatic interaction between this common SNP and genetic variants in genes related to brain 5-HT homeostasis including the 5-HT transporter, the vesicular monoamine transporter 2 (VMAT2), 5-HT receptors as well as other TPH2 variants.

The identification of another functional SNP (rs1386493) in this study in addition to several other functional variants reported in the TPH2 gene10–12 are reminiscent of the characterization of over 400 functional mutations in phenylalanine hydroxylase (PAH) gene, which cause various degrees of hyperphenylalaninemia and its severe symptom, phenylketonuria.41 Moreover, a recent study of the TPH2 gene in postmortem brain tissues has identified a number of rare mutations that affect splicing or arise from RNA editing.42 Therefore, these data strongly suggest that multiple common or rare functional genetic variants in a single or multiple susceptibility genes could contribute to 5-HT-related psychiatric conditions.13,43–45

Major depression is a complex heterogeneous disorder with markedly different clinical profiles.
and responses to drug treatment,\textsuperscript{1,46–48} and may also represent a disorder with different endophenotypes\textsuperscript{49} or with other comorbid psychiatric conditions.\textsuperscript{50–53} Genetic susceptibility, in addition to environmental and biochemical influences, have been extensively studied for the etiology of depression.\textsuperscript{1} However, the existence of both genetic and non-genetic risk factors, as well as limitations in diagnostic criteria,\textsuperscript{7,44} are major challenges in understanding the molecular mechanisms underlying the symptoms of depression. This SNP (rs1386493) is a relatively common variant (18–20\% prevalence) of the \textit{THP2} gene that has been reported in previous studies.\textsuperscript{14,15} However, its relation to depression has been difficult to ascertain. Although the STAR*D cohort represents unrelated individuals diagnosed with depression, the 99 probands genotyped in this study were selected from multiplex families in the NIMH Depression Pedigree, which presumably harbors stronger genetic influences. In fact, in an examination of four families in which the probands were homozygous, 11 of 16 individuals were AA allele carriers (Figure 5). The identification of the homozygous mutant allele in these families raises the possibility that this mutation may contribute to familial forms of depression. As the number of probands from the multiplex families in NIMH Depression Pedigree is too small to achieve significance, further studies with larger cohorts of multiplex families will be needed to determine the relevance of this dominant-negative mutant allele to depression or other psychiatric disorders.

Functional genetic variants are important for our understanding of the pathophysiology of human disease. Although coding non-synonymous mutations are rare, but relatively easy to characterize, coding synonymous, intronic, as well as promoter and untranslated region variants are more common, but difficult to study. Minigene constructs using partial genomic DNA are useful tools to address the functionalities of these variants by comparing normal gene patterns with those carrying either one or more genetic variants. This is especially helpful for studying psychiatric disorders in which the availability of tissues is limited to postmortem brains. Functional characterization of SNP (rs1386493) and its pathological consequences suggest that the \textit{THP2} gene deserves further attention as a potential risk factor for depression.

Conflict of interest
The authors declare no conflict of interest.

Acknowledgments
The authors would like to dedicate this paper to the memory of our esteemed colleague Dr Marcy C. Speer who passed away in 2008.
