The matter produced in the early stages of heavy ion collisions consists mostly of gluons, and is penetrated by the coherent magnetic field produced by spectator nucleons. The fluctuations of gluonic matter in an external magnetic field couple to real and virtual photons through virtual quark loops. We study the resulting contributions to photon and dilepton production that stem from the fluctuations of the stress tensor $T_{\mu\nu}$ in the background of a coherent magnetic field $B$. Our study extends significantly the earlier work [G. Basar, D. E. Kharzeev, and V. Skokov, Phys. Rev. Lett. 109, 202303 (2012)], in which only the fluctuations of the trace of the stress tensor $T_{\mu\mu}$ were considered (the coupling of $T_{\mu\nu}$ to electromagnetic fields is governed by the scale anomaly). In the present paper we derive more general relations using the operator product expansion (OPE). We also extend the previous study to the case of dileptons, which offers the possibility to discriminate between various production mechanisms. Among the phenomena that we study are magneto-sonoluminescence [MSL, the interaction of magnetic field $B(x,t)$ with the sound perturbations of the stress tensor $\delta T_{\mu\nu}(x,t)$] and magneto-thermoluminescence [MTL, the interaction of $\delta T_{\mu\nu}(x,t)$ with smooth average $\langle T_{\mu\nu}\rangle$]. We calculate the rates of these processes and find that they can dominate the photon and dilepton production at early stages of heavy ion collisions. We also point out the characteristic signatures of MSL and MTL that can be used to establish their presence and to diagnose the produced matter.

I. INTRODUCTION

A. Overview

Dileptons and photons are “penetrating probes” originally proposed as the signature of quark-gluon plasma (QGP) formation [1]. Unlike hadrons, they are not produced from the final freeze-out surface, but from the bulk of the matter, throughout the entire history of the collision. In QCD matter, only quarks possess electric charges and can produce dileptons and photons; however, these quarks may not only be real but also virtual, in the form of quantum loops in gluonic matter. In this paper we will focus on the latter, quantum contributions to the photon and dilepton production that originates from the presence of the magnetic field created by spectator nucleons.

Since the coherent magnetic field exists mostly at the early stage of the collision [2,3], we will not discuss the later hadronic stage of the collision and various hadronic mechanisms of photon and dilepton production. As explained in [1,4], the early stages contribute noticeably to dilepton production only in a certain window of invariant mass $M$:

$$m_\phi \approx 1 \text{ GeV} < M < m_\phi \approx 3 \text{ GeV};$$  (1)

these are the intermediate mass (IM) dileptons. This range of $M$ is limited from below by the region in which hadronic processes dominate, and from above by both the charmonium decay background and the Drell-Yan processes (prompt partonic production).

In the case of photons, the transverse momentum spectrum at $p_\perp \sim$ few GeV is affected by early thermal radiation with a high initial temperature, but is still “contaminated” by the late-stage emission. While the photon transverse momenta can be boosted (blueshifted) by collective flow of matter, the dilepton mass $M$ is a Lorentz invariant quantity and cannot be affected by the collective flow.

Experimentally, the detection of the IM dileptons suffers from a background arising from the leptonic charm decays. At the CERN Super Proton Synchrotron (SPS) this issue was finally resolved by the NA60 experiment few years ago, which has determined that most of the IM dileptons are in fact “prompt,” emitted from thermal medium and not from charm decays. At the Relativistic Heavy Ion Collder (RHIC) these issues still remain to be solved. PHENIX hopes to do so using new vertex detectors and STAR is expected to use its ability to detect events with $e-\mu$ charm decays. At the Large Hadron Collider (LHC) the charm background is perhaps overwhelming, and will have to be removed.

Theoretically, the production of photons and dileptons is tied to the presence of quarks, and is thus sensitive to the quark chemical equilibration. The initial stages of the high energy collisions are believed to be dominated by gluons. Perturbative arguments [5] show that chemical equilibration via quark-antiquark pair production is relatively slow and should be delayed relative to thermal equilibration of the glue. This idea led to a scenario in which the quark-antiquark sector in early stage matter (so-called “hot glue”) is suppressed by some fugacity $\xi < 1$. If so, the basic process of the dilepton production

$$q + \bar{q} \rightarrow \gamma^* \rightarrow l_+ + l_-.$$  (2)

is expected to be suppressed quadratically, $\sim \xi^2$. While the strongly coupled nature of QGP, which is related to early hydrodynamics, may invalidate the perturbative arguments, one is still motivated to search for processes that involve gluons and do not require the existence of quarks and antiquarks in the medium.
Lacking real quarks, one can think of higher order processes with virtual quark loops as an intermediary between the glue and the electromagnetic signals. In a recent paper [6] such processes have been considered, e.g., with three gluons converting into a dilepton:

\[ ggg \rightarrow (\text{quark loop}) \rightarrow \gamma^* \rightarrow l^+_l + l^-_. \]  

(3)

Furthermore, the processes with the number of gluons \( n > 3 \)—permitted by the global conservation laws such as \( P \) and \( C \) parity—are equally important, because in the “glasma” picture used by these authors the gauge field is \( O(1/\alpha_s) \), which compensates the powers of \( \alpha_s \) in the loop. A detailed quantitative assessment of the rates of such processes would be of great interest.

Another development is the Basar-Kharzeev-Skokov (BKS) approach [7], introducing a photon production mechanism due to the coupling to the trace of the stress tensor and the ambient QED magnetic field induced by the scale anomaly (also a virtual quark loop):

\[ T_{\mu\nu} + \bar{B} \rightarrow (\text{quark loop}) \rightarrow \gamma. \]  

(4)

Due to the scale anomaly, the trace of the stress tensor in the chiral limit is given by the scalar gluon operator. Therefore the initial state here can be considered as a scalar gluon pair \( \sigma \equiv gg \) and a virtual photon (from \( \bar{B} \)), so the vertex is of the \( \sigma \gamma \gamma \) type. Since the magnetic field in heavy ion collisions is on the average directed perpendicular to the reaction plane [2], the photons are produced mainly in-plane [7]. For discussions of the effects of axial anomaly in the magnetic field on photon and dilepton production, see [8–14] and a recent review [15]. Note also that the scale anomaly was argued to play an important role in the gluon distributions at small \( x \) [16], and in the presence of the magnetic field could lead to the photon production even before the hydrodynamical description becomes valid.

The PHENIX Collaboration at RHIC [17] and then the ALICE Collaboration at LHC [18] recently discovered an unexpectedly large second azimuthal coefficient \( \langle \cos(2\phi) \rangle \) of the produced photons. This feature is known as the “large photon elliptic flow puzzle,” because the conventional photon sources have a difficulty explaining these observations. Since the BKS process predicts [7] a photon production rate which depends on the direction of the magnetic field, it generates a strong angular anisotropy for the emitted photons, and provides a possible explanation for this puzzle.

In this paper we follow the BKS ideas and extend them in several directions as follows:

(i) We include the full stress tensor \( T_{\mu\nu} \) and not just its trace \( T_{\mu\nu} \) that is suppressed for the case of near-conformal strongly coupled quark gluon plasma (sQGP) and classical glue.

(ii) We implement the space-time dependence of the magnetic field into the kinematics of the process and show that its short lifetime is directly related to the characteristic invariant masses and energies of the produced photons.

(iii) Last but not least, we will not restrict ourselves to on-shell photons \( \gamma \). Virtual (positive-mass) photons \( \gamma^* \) are observable via the dilepton channel, and they add to the overall momentum \( \vec{q} \) extra observables: the dilepton mass and polarization. These observables are very valuable for the separation of various production mechanisms.

Since we discuss different processes and kinematic domains, we feel that it is useful to introduce some new terminology. While the calculations presented below are based on a single effective action, we will distinguish two types of processes by their kinematics. We will call the interaction of the ambient electromagnetic field and the “average” matter stress tensor \( (T_{\mu\nu}) \), producing photons (real or virtual), magneto-thermoluminescence, MTL for short. By “average” we mean that the value of the stress tensor is averaged over the fireball and is nearly constant, with negligible momentum harmonics \( p \sim 1/R \). Individual events, however, are known to also possess fluctuations of the matter stress tensor \( \delta T_{\mu\nu} \), with complicated spatial distribution and thus non-negligible momenta. Although these fluctuations include both longitudinal and transverse modes, in a somewhat a loose way we will refer to all of them as “sounds.” We will thus call the interaction of the ambient electromagnetic field and the fluctuations of the matter stress tensor that produces photons and dileptons magneto-sonoluminescence, MSL.

The theoretical task is divided into two steps. The first step is the derivation of a local effective action from a quark-loop-induced nonlocal action that couples two photons to two gluons, the \( gg\gamma\gamma \) vertex. We first combine the gluons into three colorless combinations and then describe the coupling to photons by a local effective action. This can be done in two ways: using “generalized vector dominance” in scalar and tensor hadronic channels, or using the operator product expansion (OPE). The latter is based on the approximation in which the photon momenta are considered to be large as compared to that of the gluons, so that the photon-gluon vertex is effectively local. Needless to say, all steps must be both QED and QCD gauge invariant. The second step is the derivation of the dilepton production rate using this effective Lagrangian.

From the point of view of phenomenology, the main proposal of this paper is development of new diagnostic tools. Neither the collective magnetic field in the collisions, nor perturbations of the stress tensor have been studied in a detailed quantitative manner so far. (We will briefly review what is known about those in the Secs. 1B and VI B, respectively.) The MTS and MSL phenomena may relate them to photons or dileptons which are directly observable.

The structure of the paper is as follows. In Sec. II, we explain the basic kinematics of the processes we consider and present the outline of the calculation. Sections III and IV are devoted to the derivations of two alternative effective Lagrangians that couple the gluonic stress tensor to two photons, the magnetic field, and the produced (virtual) photon. In Sec. III, we follow a hadronic approach and use the tensor meson dominance to evaluate the \( gg\gamma\gamma \) coupling. This section concludes with an order-of-magnitude comparison of the MTL rate to the conventional quark annihilation process. The core of the paper is Sec. IV, in which we use the operator product expansion (OPE) methods to derive the effective Lagrangian. In Sec. V, we use the OPE result to calculate the MTL rate and compare
the OPE prediction to the prediction of the hadronic approach. In Sec. VI we focus on the MSL process and discuss the stress tensor correlators. Our results are summarized in the concluding Sec. VII.

B. Coherent magnetic field in heavy ion collisions

Coherent fields of the heavy ions are proportional to their charge $Z$ and also to Lorentz factor of the beam $\gamma$. These large factors provide several orders of magnitude enhancement. Furthermore, in the middle point between two ions the electric fields are opposite and tend to cancel out, while magnetic fields are parallel and add up. Thus matter produced in the collision is subject to strong magnetic fields [2]. The field vanishes for central collisions $b=0$ and has well defined orientation: normal to the beam and impact parameter. Those features should help to identify the effects induced by it.

We further assume that the magnetic field is directed in the transverse direction $\mu = 3$ (normal to impact parameter, direction 2; and to the beam, direction 1). We use the gauge in which $A_1 = x_2 B_3 = -i \frac{\partial}{\partial x_1} B_3(k)$, so that

$$A_\nu^B = \delta_{\nu 1} B_3(q),$$

where for brevity we use notations in which the index after a comma denotes a partial derivative. We will parametrize $x$ dependence of the magnetic field by a Gaussian, and $t$ dependence by a function (6).

According to calculations [2,3,19–22], the magnetic field strength for RHIC energies reaches $eB \sim 0.2$ GeV$^2 = 10 m_\pi^2$ at $b = 10$ fm, where it has a maximum. This is only a few times less than that of the gluon fields in the “glasma” $gG \sim Q_s^2 \sim 1–2$ GeV$^2$. Due to the same Lorentz factor, it has a decay time $\tau_B \sim 1/\sqrt{\gamma}$; note, however, that the combination of Faraday [20,21,23] and Hall [22] effects significantly delays the decay of magnetic field in the (electrically conducting) quark-gluon plasma. In addition to the coherent field $B_3$ at the center of the collision, there are also fluctuations of $B_{2,3}$ due to the event-by-event fluctuations of the positions of the nucleons inside the source nuclei [19,24]. The sampling over events leads to the following time dependence of the magnetic field at the center of the collision:

$$B_3(t) = \frac{B_3^0}{1 + (t/\tau_B)^2}. \tag{6}$$

The duration parameter is fitted to be

$$\tau_B \approx 0.15 \text{ fm} \tag{7}$$

for RHIC full collision energy, which is roughly the Lorentz contracted nuclear diameter. The Fourier transform of this time dependence is exponential, $\sim \exp(-\omega t_B)$.

Due to the finite electric conductivity of the quark-gluon plasma, the magnetic field can be partially trapped by the QGP as a result of Faraday induction [20,21,23]. A recent analysis [22] including the collective expansion of the fluid and the resulting Hall effect confirms the existence of this phenomenon and points out its signatures in directed flow of charged hadrons. Nevertheless, the strongest magnetic field is achieved at early times as discussed above.

The energy scale conjugated to $\tau_B$ is about a GeV, so one can indeed produce dileptons with energies and masses in the IM dilepton window. The transverse momenta associated with the $B$ field are, however, quite small, of the order of the inverse nuclear size $1/R \sim 30$ MeV, as they are associated with the distance to the “spectator” nucleons creating this magnetic field. Therefore the transverse momenta of the produced dileptons in fact originate mainly not from magnetic field $B$ but from the phonons.

Let us discuss further the spatial and time dependencies of the magnetic field and the parametrizations that we use to describe them. We assume for simplicity (neglecting fluctuations) that $B$ is in the transverse plane and normal to the impact parameter, thus it has direction 3 in our notation. We further assume that it has a Gaussian profile in the transverse plane:

$$eB_3 = (eB) \exp\left(-\frac{x_2^2/R_3^2 - x_3^2/R_3^2}{(1 + x_2^2/R_3^2)(1 + x_3^2/R_3^2)}\right).$$

Following convention, we combine the electron charge with the field strength; this will allow us to compare the strength of electromagnetic and strong forces. $(eB)$ is the field magnitude, and 3 is an index indicating the direction of magnetic field. In principle there are two different radii in transverse directions 2 and 3, as we consider noncentral collisions.

We can now make a Fourier transform

$$e\tilde{B}_3 = \pi^3 (eB) R_3 R_3^2 \delta\left(\frac{R_1}{2R_3^2}\right) \times \exp\left(-\frac{p_2^2 R_3^2}{4} - \frac{p_3^2 R_3^2}{4}\right) \exp\left(-|p_0|\tau_B - |p_1|\tau_B\right) \tag{9}$$

for the gauge potential $A_1 = x_2 B_3$ using $x_2 = -i \partial/\partial p_2$ we get

$$\tilde{A}_1(p) = \frac{\pi^3}{2} (eB) p_2 R_3 R_3^2 \delta\left(\frac{R_1}{2R_3^2}\right) \times \exp\left(-\frac{p_2^2 R_3^2}{4} - \frac{p_3^2 R_3^2}{4}\right) \exp\left(-|p_0|\tau_B - |p_1|\tau_B\right).$$

In the propagator of two magnetic potentials, we prefer to read backwards and absorb the four-dimensional volume into the definition, so that it becomes a product of the Fourier transforms (dimension 6):

$$\langle A_\mu^B A_\nu^B \rangle d^4x \rightarrow \tilde{A}_\mu^B(q) \tilde{A}_\nu^B(q).$$

Let us now comment on the normalization of the yield. The Fourier transforms $\tilde{A}$ are space integrals and are thus proportional to the four-volume $V_4$ of the system. Since the rates include the square of $\tilde{A}$, the volume squared appears. After the integrals over momenta $q$ are performed, one gets another $V_4^{-1}$ factor, which restores the expected dependence of the total yield, $\sim V_4$.

II. KINEMATICS AND THE OUTLINE OF THE CALCULATION

A. Kinematics

Before we embark on the rather involved calculation of the photon and dilepton rates, let us define the kinematics of the processes we will consider, and discuss some qualitative
features of the problem. We define the four-momenta of leptons as \( l_+^\mu \) and \( l_-^\mu \); momentum conservation yields
\[
l_+^\mu + l_-^\mu = q^\mu = k^\mu + p^\mu, \tag{12}
\]
where momenta \( k \) and \( p \) correspond to Fourier harmonics of the stress tensor and the magnetic field, respectively. The stress tensor and the magnetic field are two components that carry out two different tasks in the kinematics of the production process. The magnetic field comes as a short burst in time, therefore its frequency \( p^0 \sim 1/t_B \) is large and thus it contributes most of the energy of the produced dileptons \( q^0 \sim p^0 \). However, the magnetic field is nearly homogeneous in space, and thus its three-momentum \( p \) is very small. Therefore the dilepton momentum comes mostly from those of the sound harmonics, \( q \approx p \).

This “separation of responsibilities” greatly simplifies the calculation. As we will see below, the dilepton yield is proportional to complicated kinematical expressions times the space-time integral of the product of magnetic field and the matter energy density correlators. We can approximate this integral by a factorized form,
\[
\int d^4x \langle BB \rangle_{(e\epsilon)} \approx \left( \int dt \langle BB \rangle \right) \left( \int d^3x \langle e\epsilon \rangle \right) = \left( \int \frac{dp^0}{2\pi} B^z(p^0) \right) \left( \int \frac{d^3k}{(2\pi)^3} \tilde{\varepsilon}^z(k) \right), \tag{13}
\]
where in the first set of parentheses we have (mostly) the time Fourier component of the magnetic field \( B \), and in the second mostly the Fourier space components of the stress tensor (energy density denoted by \( \epsilon \)). These are parts of the so called spectral densities; see Sec. VI C for details. The energy and momentum conservation then translates these components into dilepton observables.

To preview our subsequent discussion, let us indicate that the MSL dilepton yield appears proportional to the product of two factors:
\[
\frac{dN}{dq^2} \sim \exp \left(-2q^0 t_B - \frac{c_s|q|}{T_i} \right) \tag{14}
\]
The first factor describes the distribution over the dilepton energy \( q^0 \), controlled by the lifetime of the \( B \) field \( t_B \). Since the energy dependence happens to be exponential, one may call the inverse lifetime of the \( B \) field an “effective temperature.” Its value \( T_{\text{eff}} = (2t_B)^{-1} \approx 0.66 \text{ GeV} \) (at RHIC) is rather high, exceeding the actual initial QGP temperature \( T_i \approx 0.35 \text{ GeV} \) which governs the thermal lowest-order dilepton production \( \sim \exp(-q^0/T_i) \) due to the \( \bar{q}q \rightarrow l^+l^- \) process, the dominant source of the IM dileptons. The second factor defining the dilepton momentum distribution comes from the stress tensor perturbations. It contains the temperature and the speed of sound \( c_s \approx 1/\sqrt{3} \). On top of these exponential dependences, there are also important powers of \( q^0 \) and/or dilepton mass, as well as various numerical factors, which will be evaluated in what follows.

B. The outline of the calculation

For completeness, let us start with the (well known since [1]) perturbative thermal rate in the zeroth order in the strong interaction, due to the \( \bar{q}q \rightarrow l^+l^- \) process. In Fig. 1(a) this process is shown in the form of a “unitarity diagram.” It consists of the lepton loop \( L \) and the quark loop \( Q \), cut by the vertical line indicating the unitarity cut. All lines which are cut represent physical (on-shell) quarks and leptons, with momenta denoted by \( q_+, q_- \) and \( l_+, l_- \), respectively. Two dashed lines are the propagators of the virtual photons, with momentum \( q^\mu = q^z + q^0 l_+ + l_- \).

In the following two sections, we will introduce two separate effective Lagrangians that we will use to calculate the dilepton rates. In Sec. III, we will use a local effective Lagrangian that couples two photons to two gluons whose coupling is set by hadronic phenomenology.

In Sec. IV, we will use the operator product expansion (OPE) framework to derive an effective Lagrangian by integrating out the quark loop evaluated in background gluon fields which, in medium, show up as components of the gluonic stress-energy tensor (basically the energy density in the comoving frame of the medium). The MTL and MSL rates are schematically given by the diagram shown in Fig. 2.
Together with the lepton loop $L_{\mu\nu}$ unitarity cut, it has two (uncut) copies of the polarization operator $\Pi_{\mu\nu}$ (or vertex $\Gamma_{\mu\nu}$) connecting the virtual photon with momentum $q$ with the photon with momentum $p$ and representing the external magnetic field. The MTL process has no sound but just a near-homogeneous medium with the energy density directly appearing as a factor in the OPE-based polarization operator $\Pi_{\mu\nu}$. The corresponding effective Lagrangian has a form $A^\mu A^\nu \Pi_{\mu\nu}$. Note that gluon fields, which are presumed soft, appear as a stress tensor operator (inside the polarization tensor), but two electromagnetic fields appear as vector potentials. This happens because their momenta are not soft. In the case of MTL process the transverse momentum of the dilepton pair is determined by the inverse size of the fireball and is thus very small.

The MSL case additionally has a dotted line with momentum $k$ passing via the unitarity cut. This line corresponds to the imaginary part of the correlation functions $\rho_{\mu\nu\alpha\beta} \sim \text{Im}(T_{\mu\alpha}T_{\nu\beta})$ of two stress tensors in the medium instead of the squared matter energy density in MTL

$$\epsilon^2 \rightarrow \rho(k) d^4k; \quad (15)$$

this will be explained in detail in Sec. VI. In the MSL process, the dileptons get a substantial “kick” $q^\perp$ from the fluctuations of the stress-energy tensor, which transfer them into a more interesting kinematical region accessible to current experiments. Near equilibrium, the spectral density $\rho(k)$ has a “sound peak” with a width given by the viscosity but, in early time matter, is perhaps very far from equilibrium and includes large fluctuations one would like to study.

In Sect. V we will compare the results of the two different approaches (“hadronic” and OPE) and deduce that the OPE gives a more reliable answer.

III. THE HADRONIC APPROACH

A. The effective Lagrangian

We now move on to the calculation of the effective Lagrangian that couples two gluons to two photons via a quark loop. One phenomenological source of information about the virtual quark loop coupling to two photons comes from hadronic $\gamma\gamma$ decays; for the scalar meson channel it has been used, e.g., in [7]. Since in this paper we will deal with the stress tensor, we can use in a similar way the tensor meson decay to $\gamma\gamma$ to derive an effective coupling. This approach is similar to the well known vector meson dominance, and is thus known as the “tensor meson dominance” [25].

Before we do so, we would like to say a word of caution. The sigma meson, a chiral partner of the pion, represents the channel in which the strong attraction between quark and antiquark is known to exist. Originally invented by Nambu-Jona-Lasinio (NJI) to describe the chiral symmetry breaking, those forces act at a scale $\sim 1$ GeV. They were later attributed to the instanton-induced effects and explain the pattern of chiral symmetry breaking and the $U_A(1)$ anomaly by providing repulsion in the $\eta'$ channel; for a review see [26]. These effects make $\sigma$ lighter but also more compact. There is evidence that the lowest multiplet of the vector mesons are also, in a way, waves in the chiral condensate: in particular the “vector meson dominance” in hadronic physics and dilepton production is well established. There is no such evidence for the tensor $f_2$ channel. Thus the accuracy of the “tensor meson dominance” remains unknown, and the analogy on which this subsection is based may be misleading.

We define the effective Lagrangian for couplings between gluonic and photon stress tensors and their traces as

$$\mathcal{L} = gT_{\gamma\gamma}^{\mu\nu}\rho_{\mu\nu} + gS T^{\mu
u}_{glue}; \quad (16)$$

here $T_{\gamma\gamma}^{\mu\nu} = F^{\mu\alpha} F^{\nu}_{\alpha} - 1/4 g^{\mu\nu} F^2$ is the electromagnetic stress tensor and $T^{\mu\nu}_{glue}$ is the color traced gluonic stress tensor. We fix the coupling $g$ in two steps. First, we use the tensor meson dominance; namely in the matrix element between the vacuum and photons, we keep only the lightest tensor meson, $f_2(1270)$, term:

$$(0|\bar{\Psi}\gamma\gamma\Psi|f_2) = m_f^2 f_f (0|f^{\mu\nu}|f_2) = m_f^2 f_f \epsilon^{\mu\nu}. \quad (17)$$

Here $f^{\mu\nu}$ is the corresponding meson field and $\epsilon^{\mu\nu}$ is the polarization tensor that satisfies $\epsilon^{\mu\nu} = \epsilon^{\mu\nu}$, $\epsilon^{\mu\nu} = 0$, and $q_{\mu\nu} = 0$ for the $f_2$ momentum $q^\nu$. Notice that the polarization tensor has five degrees of freedom as expected for a spin-2 particle.

The decay constant $f_f$ can be deduced using the input from the dominant decay channel, $f_2 \rightarrow \pi\pi$. Indeed, the effective Lagrangian for $f_2\pi\pi$ is

$$\mathcal{L}_{f_2\pi\pi} = g_{f_2\pi\pi} \partial_\mu \pi \partial_\nu \pi \ f^{\mu\nu} \quad (18)$$

and the tensor meson dominance relates the decay constant to the effective coupling as $g_{f_2\pi\pi} f_f = 1$ in our normalization. The decay width is [25]

$$\Gamma(f_2 \rightarrow \pi\pi) = g^2_{f_2\pi\pi} \frac{m_f^3}{320\pi} \left(1 - \frac{4m_f^2}{m_f^2}ight)^{3/2}. \quad (19)$$

The most recent values for the decay width and the mass of $f_2$ are $\Gamma(f_2 \rightarrow \pi\pi) \approx 157$ MeV and $m_f \approx 1275$ MeV [27]. Therefore we obtain the value of the decay constant $f_f \approx 108$ MeV.

The next step is to fix the coupling of $f_2$ to electromagnetism. This can be achieved by analyzing the $f_2 \rightarrow \gamma\gamma$ decay. From the $f_2\gamma\gamma$ effective Lagrangian

$$\mathcal{L}_{f_2\gamma\gamma} = g_{f_2\gamma\gamma} f_f T_{\gamma\gamma}^{\mu\nu}, \quad (20)$$

we obtain the decay width as

$$\Gamma(f_2 \rightarrow \gamma\gamma) = g^2_{f_2\gamma\gamma} \frac{m_f^3}{80\pi}. \quad (21)$$

Using the most recent value $\Gamma(f_2 \rightarrow \gamma\gamma) \approx 3$ keV from [27], we fix $g_{f_2\gamma\gamma} = 0.014$ GeV$^{-1}$. By connecting the matrix elements of Lagrangians (16) and (20), we obtain the effective $gg\gamma\gamma$ coupling

$$g_T = \frac{g_{f_2\gamma\gamma}}{m_f^2 f_f} \approx (1.87 \text{ GeV})^{-1}. \quad (22)$$

In order to understand whether this coupling is large or small on the QCD scale, one can also redefine it by dividing by the
TABLE I. Comparison of the hadronic couplings to the $γγ$ in scalar and tensor channels

|       | $m_h$ (GeV) | $f_h$ (GeV) | $g_{hγγ}$ (GeV$^{-1}$) | $λ_{hγγ}$ | $g_l$ (GeV$^{-4}$) |
|-------|-------------|-------------|------------------------|-----------|-----------------|
| $σ$ 0++ | 0.55        | 0.10        | 0.02                   | 1.5       | 0.66            |
| $f$ 2++ | 1.27        | 0.108       | 0.014                  | 2.43      | 0.08            |

The electromagnetic coupling $α_{em}$ and the relevant scale, taken to be the resonance mass

$$λ_{hγγ} = g_{hγγ} m_h / α_{em}.$$  (23)

The results are collected in the Table I, in which we also included those for the scalar channel from \[7\]. Such dimensionless couplings are indeed numbers $O(1)$.

In what follows, we will however need an effective Lagrangian in the form of (16). The relation we need, in order to get the scalar coupling analogous to (17), is the matrix element of the divergence of the dilatational current:

$$λ_{hγγ} = g_{hγγ} m_h / α_{em}. $$ (23)

The results are collected in the Table I, in which we also included those for the scalar channel from \[7\]. Such dimensionless couplings are indeed numbers $O(1)$.

Let us now compare the MTL process to the standard $\bar{q}q$ annihilation in QGP. Since the dilepton production in QGP and the processes we consider in this paper take place at different times, instead of comparing the rates, one should compare the yields. The temperatures are also quite different, due to two reasons. The first is that the system is expanding and thus $T$ is time dependent. We take care of the time dependence by assuming a one-dimensional Bjorken expansion and entropy conservation. The other reason is the different number of degrees of freedom ($N_{DOF}$) in “hot glue” and QGP:

$$N_{DOF}_q = 16 + N_c N_f × 2 × (7/8) ≈ 47. $$(32)

The relation between the two temperatures is then

$$T_g = T_{qgp} ((N_{DOF}_q) × τ_g)/(N_{DOF}_{qgp} τ_{qgp})^{1/3};$$ (33)

the typical values we will use for comparison are

$$τ_g = τ_B = 0.15 \text{ fm}, \quad T_g = 1 \text{ GeV},$$ (34)

$$τ_{qgp} = 2 \text{ fm}, \quad T_{qgp} = 0.3 \text{ GeV}. $$ (35)

Note that the quark suppression fugacity in the comparison so far is put to $ξ = 1$. However, if the suppression is real and the “hot glue” scenario is correct, the ratio $T_{qgp}/T_g$ is to increase by a factor $1/ξ^2$ and may actually be around 1.

For particular kinematics, in which the dilepton transverse momentum is very small ($p_T = 1/R_2$) and for parameters listed above, we plot the ratio of the yields in Fig. 3.

IV. THE OPE APPROACH: DEEP-INELASTIC SCATTERING ON A GLUONIC MEDIUM

In this section, we calculate the effective $ggγγ$ Lagrangian using the tools of the operator product expansion (OPE), analogous to the study of deep-inelastic scattering (DIS). DIS is a traditional tool used since the early days of QCD to describe the interaction of virtual photons with quarks located inside the former is treated as the smooth mean describing the matter inside the fireball. At an early time and in the comoving frame, the stress tensor is dominated by gluons and has the form $T^{μν} = diag(e, p, p, p)$. We also assume that the (collective) magnetic field has only one component, $B_3$. This reduces the tensor part of the Lagrangian to

$$L_{eff} = \frac{g_T}{2} (ε + p) B_3^4 B_3^8.$$ (28)

Going to the Fourier transforms of the fields one gets the MTL yield

$$dN_{MTL} = \left( \frac{g_T}{2} \right)^2 (ε + p)^2 B_3^2(q) q_2^2 \frac{L_{11}}{M^4} PS(l^+, l^-),$$ (29)

where $q = l^+ + l^-$ and the lepton phase space

$$PS(l^+, l^-) = \frac{d^3 l_+}{(2π)^3} ε_+ \frac{d^3 l_-}{(2π)^3} ε_- $$ (30)
The distance to that of lowest order annihilation process as a function of the quark momentum $q_2$. In this case, the effective field $G_{\mu\nu}$ is approximately evaluated on a background with a “soft” colored field $G_{\mu\nu}$. The distance $x \sim 1/q$ is considered small, and therefore the calculation represents an example of the OPE, expressing a bilocal (nonlocal in general) expression as a series in powers of $x$ with coefficients representing local operators at point 0.

On general grounds (gauge invariance and current conservation), the polarization tensor is transverse to the vector $q_\mu$. This fact, as well as the fact that matter has a rest frame, defined by the unit four-vector $n_\mu$, allows for the traditional decomposition into two structure functions (analogous to DIS on a nucleon)

$$\Pi_{\mu\nu} = P_{\mu\nu}^1(q) W_1 \mp P_{\mu\nu}^2(q) W_2,$$

$$P_{\mu\nu}^1(q) = - (g_{\mu\nu} - q_\mu q_\nu/q^2),$$

$$P_{\mu\nu}^2(q) = \left( n_\mu - (n.q)/q^2 q_\mu \right) \left( n_\nu - (n.q)/q^2 q_\nu \right).$$

However unlike in DIS, the kinematics here correspond to a timelike $q^2$ with a positive dilepton mass. In general, there are two rest frames: that of the medium $n_\mu = (1,0,0,0)$ and that of the dilepton. In general they do not coincide and this fact produces the second structure function.

One similar example in QCD is the celebrated derivation of the scalar gluon operator $G^2$ (known as the gluon condensate) correction to the polarization tensor, by Shifman,Vainshtein, and Zakharov (SVZ) [32], which involved a rather complicated diagrammatic calculation. (Of course in vacuum there is no matter and no $n_\mu$ vector, so there is only one transverse structure made of the $q$ vector and only one structure function $W_1$.) We will, however, follow a different path, developed by Vainshtein and Shuryak [33], in connection to power corrections to DIS on the (polarized) nucleon. For a pedagogical introduction see, e.g., [34].

One element of this calculation is the use of the so called fixed-point gauge

$$x_\mu A_\mu(x) = 0,$$ \hspace{1cm} (38)

invented by Fock, Schwinger, and perhaps others. In this gauge $A_\mu(0) = 0$ and next order terms in $x$ expansion can be written as covariant derivatives of the field strength

$$A_\mu(x) = \sum_{k=0} A_\mu(x) = \sum_{k=0} x_\mu x_{\alpha_1} \cdots x_{\alpha_k} D_{\alpha_1} \cdots D_{\alpha_k} G_{\mu\nu}(0).$$ \hspace{1cm} (39)

In coordinate representation, the polarization operator is simply a fermionic loop

$$\Pi_{\mu\nu}(x) = \text{Tr}[\gamma_\mu S_G(0,x) \gamma_\nu S_G^+(x,0)],$$ \hspace{1cm} (40)

where the main ingredients—the quark propagators $S_G$—are to be calculated in a background field $G$, as indicated by the subscript. The OPE expansion proceeds in powers of distance $x$, that is assumed small compared to the typical variation scale of the field and its derivatives. In what follows, we will assume that the gauge field $G$ is approximately constant and therefore neglect its gradients.

Let us present the calculation for one flavor of massless quark with a unit charge. The propagator in the fixed-point gauge has been calculated in [33] in momentum space to the order that we need. We only include the terms that involve one and two field strengths, and ignore the covariant derivatives of the fields (because we assume it to be constant for now):

$$m_S G(q) = \frac{1}{q} - g_2 q_\alpha \tilde{G}_{\alpha\beta} \gamma_\beta \gamma_5,$$

$$- \frac{g_2^2}{2 q^6} q_\alpha G_{\alpha\beta} G_{\beta\gamma} q_\gamma + \frac{g_2^2}{4 q^6} q^2 q_\alpha [G_{\alpha\beta}, G_{\beta\gamma}] \gamma_\gamma + O \left( \frac{1}{q^6} \right).$$ \hspace{1cm} (41)
where $q = q_{\mu} \gamma_{\mu}$ and the gluon field strength is assumed to be a color matrix $G_{\mu\nu} = G^{a}_{\mu\nu} t^a$, where $t^a$ are the SU(3) Gell-Mann matrices.

The symmetric part of the term quadratic in the field strength can be expressed as $\frac{g^2}{4 \pi^2} T_{a\beta}(q^2 q^\beta - q^2 \gamma^\beta)$, where $T_{a\beta}$ is the traceless gluonic energy momentum tensor:

$$T_{a\beta} = \frac{1}{2} (G_{a\mu\nu} G^{\mu\nu}) - \frac{1}{4} g g_{\mu\nu} G^{\mu\nu} G^{\mu\nu}. \quad (42)$$

We remind the reader that this is still a matrix in the color space. The fermion loop leads to a color trace, and projects on the colorless part, which is denoted by a bar above the operator

$$\bar{T}_{a\beta} = \frac{1}{2} \text{Tr}_c T_{a\beta} \quad (43)$$

In momentum space, the loop is an integral over the convolution of the two propagators with different arguments, which is complicated. However, going to coordinate representation, one finds simpler Feynman rules, in which the loop is just a product of two propagators $S(x)$ without the integral. Following this idea, we rewrite the propagator in the coordinate space:

$$S_G(x) = \frac{i \gamma_{\mu} x^\mu}{2 \pi^2 x^4} - i \frac{g}{16 \pi^2 x^4} x^\mu \gamma^\nu \gamma^\sigma G_{\mu\nu} x^\sigma + i \frac{g^2}{96 \pi^2} x^\mu \gamma^\nu T_{\mu\nu} \ln(\mu x). \quad (44)$$

In the expression of the position space propagator above, we did not include the commutator term because being a traceless matrix, it will not contribute to the self energy up to second order in field strength. In position space, the self-energy $\Pi_{\mu\nu}$ is simply a product of two propagators:

$$\Pi_{\mu\nu}(x) = \text{Tr}[\gamma_{\mu} S(x) \gamma_{\nu} S^\dagger(-x)], \quad (45)$$

where the trace is both over color and Dirac structure. Using the result (44) for the position space propagator, we obtain

$$\Pi_{\mu\nu}(x) = -\frac{3}{\pi^2 x^8} (2 x_{\mu} x_{\nu} - g_{\mu\nu} x^2)$$

$$-\frac{g^2}{64 \pi^2} x^2 x^\beta \left[ \bar{G}_{\mu\alpha} G_{\nu\beta} + G_{\mu\alpha} \bar{G}_{\nu\beta} \right]$$

$$+ \frac{g^2}{64 \pi^2} x^2 x^\beta \left[ \bar{G}_{\nu\alpha} G_{\mu\beta} + G_{\nu\alpha} \bar{G}_{\mu\beta} \right]$$

$$+ \frac{\ln(\mu x)^2}{48 \pi^2} x^2 \text{Tr}_c \left[ x_{\mu} x_{\nu} T_{\alpha\nu} + x_{\nu} x_{\mu} T_{\alpha\mu} \right]$$

$$+ \frac{\ln(\mu x)^2}{48 \pi^2} x^2 \text{Tr}_c \left[ g_{\mu\nu} x^2 x^\beta T_{\alpha\beta} \right]$$

$$+ \frac{\ln(\mu x)^2}{96 \pi^2} x^2 \left[ 2 x_{\mu} x_{\nu} x^\alpha x^\beta - g_{\mu\nu} x^2 x^\alpha x^\beta \right] \text{Tr}_c [ T_{\alpha\beta} ] . \quad (46)$$

The color trace $\text{Tr}_c (t^m t^n) = 2 \delta^{mn}$ will lead to an extra factor of 2 in the quadratic terms. Evaluating the color trace and going back to momentum space, we get

$$\Pi_{\mu\nu}(q) = -\frac{1}{4 \pi^2} (q_{\mu} q_{\nu} - g_{\mu\nu} q^2) \ln(q^2/4 \mu^2)$$

$$+ \frac{g^2}{4 \pi^2} q^2 q^\beta \bar{G}_{\mu\alpha} G_{\nu\beta} \frac{\delta^{\alpha\beta}}{q^4} T_{\alpha\beta}$$

$$+ \frac{g^2}{36 \pi^2 q^4} (q^2 T_{\mu\nu} - (q_{\mu} T_{\nu\alpha} + q_{\nu} T_{\mu\alpha}) q^\alpha q^\beta)$$

$$+ \frac{g^2}{6 \pi^2} \ln(q^2/m^2) \left[ q^2 T_{\mu\nu} - (q_{\mu} T_{\nu\alpha} + q_{\nu} T_{\mu\alpha}) q^\alpha \right]$$

$$+ \frac{g^2}{6 \pi^2} \ln(q^2/m^2) \left[ g_{\mu\nu} q^2 q^\beta \bar{T}_{\alpha\beta} \right]. \quad (47)$$

Note that the $CP$-odd structure $\Lambda \sim \vec{E} \cdot \vec{B}$ does not appear in our effective interaction, to the order we consider. As for the scalar part, one can now recall the scale anomaly (25) to $g^2$ order and rewrite it in terms of trace $T^{\alpha\beta}$.

Using the direction averaged parametrization for the gluon field, we arrive at the desired form of the self-energy:

$$\langle \Pi_{\mu\nu} \rangle = -\left( q^2 \frac{\ln(q^2/m^2)}{4 \pi^2} + \frac{2}{3 b q^2} T^{\alpha\beta} \right) P^{1\alpha\beta}_{\mu\nu}$$

$$+ \frac{g^2 C}{9 \pi^2 q^2} \left[ 22 + 24 \ln\left( \frac{q^2}{\mu^2} \right) \right] P^{2\alpha\beta}_{\mu\nu}$$

$$- \frac{g^2 C}{9 \pi^2 q^2} \left[ 5 - 2 (n q^2/q^2) \right]$$

$$+ 12 \left[ 1 + 2 \left( \frac{n q^2}{q^2} \right) \right] \ln\left( \frac{q^2}{\mu^2} \right) P^{1\alpha\beta}_{\mu\nu}, \quad (48)$$

where the two projectors $P^{1\alpha\beta}_{\mu\nu}$ and $P^{2\alpha\beta}_{\mu\nu}$ are defined in (37). The first term is the usual QED beta function, the second is the famous SVZ result, used for evaluation of the effect of vacuum gluon condensate on the correlator. Of course, in our case the operator should be evaluated over the medium, not the vacuum.

Observation shows that, while the coefficients of the invariant $C$ (proportional to the stress tensor, see Appendix B for the definition) are proportional to $g^2/4 \pi^2 = \alpha_s/\pi = O(1/10)$ and are parametrically suppressed, the trace term is only numerically suppressed. However, the suppression of the trace term by the beta function parameter $1/b = 1/9$ is of similar smallness. Thus at the level of coefficients, the two channels seem comparable. Yet the near conformality of the sQGP suppresses the magnitude of the trace further, as indicated in (27) by an additional order of magnitude. We expect the scalar combination be in fact subleading, and thus will keep the stress tensor only in estimates to follow.

V. THE DILEPTON YIELDS FOR MTL PROCESSES

A. The dilepton rates

In this section, we gather all the ingredients of our effective Lagrangian to calculate the dilepton yield. In coordinate

014905-8
representation it is a nonlocal action

\[ S_{\text{eff}} = \int d^4x d^4y A_{\mu}^A(x) \Pi_{\mu\nu}(x - y) A_{\nu}^B(y) \]  

(49)

which is simplified in momentum representation.

We start with the MTL case, in which there are no phonons and the stress tensor of the medium is just a smooth collective energy density. The effective action for MTL is given by the convolutions of the polarization tensor, derived above, with two photon fields. Therefore, in the effective diagram shown in Fig. 1(b) there is no line marked by momentum \( k \). In this case there is only the one-loop four-momentum \( p^\mu = q^\mu \) on which the polarization tensors \( \Pi_{\mu\nu} \) depend, as already derived in (48).

The same momentum is the argument of two “propagators” of the photons, including dilepton bracket and magnetic source. The dilepton rate of the MTL process is

\[ dN_{\text{M}} = \frac{d^4q d^4x}{(2\pi)^4} \left[ \langle A_{\mu}^A A_{\nu}^B \rangle \Pi_{\mu\nu}(q) \langle A_{\mu}^A A_{\nu}^B \rangle \Pi_{\mu\nu}(q) \right] \]  

(50)

The labels \( A \) and \( B \) correspond to the virtual photon producing dileptons and to the magnetic field, respectively.

The angular brackets imply that these quantities are “propagators” of the gauge fields. In ordinary diagrams they are defined via Fourier transforms of the fields

\[ A(k) = \int d^4x e^{ikx} A(x) \]  

(51)

and their bilinears are replaced with propagators as follows:

\[ \langle \tilde{A}(k) \tilde{A}(k') \rangle \rightarrow \langle \tilde{A}_k \tilde{A}_{k'} \rangle (2\pi)^4 \delta^4(k - k') \]  

(52)

The mass dimensions of \( A \), \( \tilde{A} \), \( \langle \tilde{A}_k \tilde{A}_{k'} \rangle \) are 1, -3, -2, respectively. The dimension of \( \Pi \) is 2, and sequence of propagators and \( \Pi \)'s in equal number is dimensionless, and so is the phase space in (50).

However, the propagators with the unitarity cut are slightly different, and include certain spectral densities of on-shell objects. The one for the dilepton is

\[ \langle A_{\mu}^A A_{\mu}^B \rangle = \frac{4}{(2\pi)^6} \frac{L_{\mu\nu}}{M^4} \frac{d^4l_+}{2\epsilon^+} \frac{d^4l_-}{2\epsilon^-} (2\pi)^4 \delta^4(l_+ + l_- - q) \]  

(53)

in which the (polarization summed) lepton tensor corresponds to the usual fermion loop; the factor 4 in front is from spin summation. Since mass dimension of \( L_{\mu\nu} \) is 2, it has the same dimension as the propagator. Note that in the center-of-mass frame of the dilepton, the \( 6 - 4 = 2 \) remaining integrals, after the delta function is fully used, are dimensionless and taken over the solid angle of the lepton directions in this frame. One cannot, however, easily perform these integrations in general, since the indices of \( L_{\mu\nu} \) are coupled to others in the diagram.

The MTL dilepton yield is thus given by

\[ dN_{\text{M}} = |\tilde{A}^0(l_+ + l_-)|^2 \frac{(\Pi L \Pi)_{11}}{M^4} P S(l^+, l^-) \]  

(54)

The \( \Pi L \Pi \) is a shorthand notation, in which the convolution in the indices of the polarization and lepton tensors are assumed, and the subscript 11 indicates the values of the remaining outer indices; they are longitudinal due to our selection of the \( A^\mu \) field gauge. We have also obtained the general expression for the yield, but it is too lengthy to be given here.

\section{Dilepton kinematics}

Let us now define the kinematics of the dileptons and make some assumptions for simplicity, as the six-dimensional distribution is too complicated to study. We first assume that the dilepton pair has no longitudinal momentum in the medium, \( q_1 = 0 \), but may have a transverse one. The lepton momenta can then be defined in terms of two vectors, the sum (still called \( q \)) and a new vector \( m \):

\[ l_{\pm}[1] = \pm \frac{m}{2} \cos \theta \]  

\[ l_{\pm}[2] = \frac{q_t}{2} \cos \psi \pm \frac{m}{2} \cos \phi \sin \theta \]  

\[ l_{\pm}[3] = \frac{q_t}{2} \sin \psi \pm \frac{m}{2} \sin \phi \sin \theta \]  

(55)

Note that now we have three angles: \( \theta, \phi, \psi \). The angle \( \theta \) is associated with the polarization of the virtual photon, and \( \psi \) is associated with the total dilepton direction of motion in the transverse plane. The so-called elliptic flow is thus a moment associated with \( \cos(2\psi) \). \( \phi \) is the relative angle of the leptons in the transverse plane.

Since the mass of the leptons is negligible, one can consider the lepton energies to be simply the modulus of their momenta. The general expressions for these energies are somewhat complicated. However, if one assumes that the dilepton transverse momentum is small compared to its mass, i.e.,

\[ q_t \ll m \]  

(56)

many expressions are simplified greatly, in particular the invariant mass

\[ M = \sqrt{-q^2} = m + O(q_t^2/k) \approx m \]  

(57)

(thus the name of the vector). This kinematical window is where the main contribution to dilepton production in the IM range.

For \( q_t = 0 \) we are left only with the vector \( m \). In this case

\[ (\Pi L \Pi)_{11}^{q_t=0} = g^2 C^2 \frac{8 sin^2 \theta}{9\pi^4 M^2} \ln^2 \left( \frac{M^2}{\mu^2} \right) \]  

(58)

which depends only on one angle \( \theta \) in a simple way, namely \( sin^2 \theta \). This happens because in this case \( n_\perp = 0 \) and the second structure function in the DIS on matter disappears; it corresponds to a purely longitudinally polarized virtual photon. We also defined \( \mu \equiv e^{\pi \mu} \).

\section{Comparison of OPE estimates to the hadronic estimates for the MTL rates}

The resulting dilepton yield obtained from the (perturbative) OPE in the preceding section should be compared to the one obtained by tensor dominance in Sec. III. The matter density, leptonic phase space, and magnetic field strength
The conclusions of the comparison of OPE and hadronic approaches are as follows. (i) One should believe the explicit OPE calculation, rather than a presumed local effective Lagrangian. (ii) The OPE calculation should be reliable at $M > 1.5$ GeV or so, but can be modified at lower $M$.

D. MTL process in experiment?

Let us now discuss the MTL process in more detail. Theoretically, it is much simpler than MSL. For example, simpler kinematics transforms the polarization tensor $\Pi_{\mu\nu}$ into the forward-scattering amplitude. This makes, for example, checking the gauge invariance much simpler.

However, the price one has to pay for such simplicity is high: the MTL dileptons must have rather small transverse momenta $q_\perp \sim p_\perp \sim 1/R_{\text{fireball}}$, and this is the kinematical domain populated by numerous background sources of the dileptons. For example, a critical reader might have already wondered if the presence of hadronic matter is really necessary, since there exists a simpler process shown in Fig. 1(b) in which a (time-dependent) collective magnetic field of the two passing ions can create the dileptons directly. Since the magnetic field extends well beyond the ions themselves, these processes should happen as well at large distances from both ions, including collisions in which the two ions pass at large impact parameters without strong interactions. There exist also higher order processes (not shown), in which two Weizsacker-Williams photons collide and produce dileptons, or bremsstrahlung accompanying a Coulomb scattering, which have huge cross sections due to powers of the ion charge appearing due to coherence of the field; see [36] for review. On top of these textbook processes, there are also “semicoherent” processes identified in [37]. All of these processes can create dileptons which extend down to very small transverse momenta of the order of the lepton mass $q_\perp \sim m_l$. (Note that we do not discuss here the transverse momenta of the individual leptons, but of the pair.)

Experimental studies of the dilepton production in this kinematics have not been performed so far. For example, the standard setting of the PHENIX detector magnetic field at RHIC at present simply cuts off these dileptons, observing only dielectrons with $q^2 > 100$ MeV or so. At the boundary of this kinematical region, an enhancement of the rate has been observed, but its nature has not yet been clarified. (It can be done, e.g., by lowering the magnetic field.)

For these reasons, the evaluation of the MTL rate is at present of purely academic interest, and we will not go further into a detailed study of the diagram (b), or of the multiple background processes mentioned. Instead, we will concentrate on the MSL processes that, as we will soon see, do contribute substantially to the observable photon and dilepton production.
VI. THE SOUND-TO-LIGHT CONVERSION: MSL PROCESS

A. The kinematics of MSL

In the calculations of the MTL process above, we assumed that the smooth (gluonic) stress tensor is constant, and carries no momentum. Therefore the dilepton four-momentum that the smooth (gluonic) stress tensor is constant, and particular kinematics which we will use. Note first that, if the size) is ignored, the glue. At a given order

photons, tensor will be lifted to their correlation functions (see below).

QED gauge invariance requires transversality of both photons,

\[ q_\mu \Gamma_{\mu \nu}^{\delta}(p,q) = 0, \quad \Gamma_{\mu \nu}^{\delta}(p,q)p_\nu = 0. \]  

This can be enforced by a straightforward modification of two projectors defined in (37) into the following form:

\[ \tilde{P}_{\mu \nu}^{1} = P_{\mu \nu}^{1}(q)P_{\alpha \nu}^{1}(p), \]

\[ \tilde{P}_{\mu \nu}^{2} = \left( n_\mu - \frac{(n \cdot q)}{q^2} q_\mu \right) \left( n_\nu - \frac{(n \cdot p)}{p^2} p_\nu \right). \]  

Unfortunately, there exists one more structure which satisfies both transversality conditions, namely

\[ P_{\mu \nu}^{1} = \frac{P_{\mu \nu}^{1}(q) + P_{\mu \nu}^{1}(p)}{pq} + \frac{q_\mu q_\nu}{q^2} - \frac{q_\mu q_\nu}{p^2} \]  

which vanishes at \( p = q, k = 0 \). Thus the corresponding structure function cannot be recovered from the \( k = 0 \) calculation.

Although we will not need to do so, for reasons to be explained shortly, it is instructive to note how one should calculate such terms. In the selected gauge, the expression for \( A_{\mu} (39) \) contains the operators of the structure \( D_{\alpha \mu} \cdots D_{\alpha \mu} P_{\mu \nu} \). The derivative \( D \) appears if the gauge field is not constant, and can be identified with the momentum \( k \) of the glue. At a given order \( n \) of \( k \), one needs to keep the same number of derivatives. At the end, all structures proportional to the \( n \)th power of \( k \) can be recovered.

However, the calculation can be greatly simplified in the particular kinematics which we will use. Note first that, if the small three-momentum of the \( B \) field (related to the inverse ion size) is ignored, \( p_\mu \) has only one nonzero component \( p_0 \neq 0 \). Furthermore, for any rapidity of the produced dilepton, the largest contribution comes from the part of matter comoving with it with the same rapidity. Focusing on the midrapidity \( y = 0 \) and the matter at rest \( n_\mu = (1,0,0,0) \), we observe that the last bracket in \( \tilde{P}_{\mu \nu}^{2} \) vanishes.

Moreover, for the magnetic field, we use the gauge where the only nonvanishing component of the potential for magnetic field, \( A_\mu^B \), is along the longitudinal direction \( \mu = 1 \). If the dilepton and phonon have both zero longitudinal momenta \( q_1 = 0, \quad p_1 = 0 \), we find that the projector \( P_{\mu \nu} \) does not contribute to the rate. We thus find that the only contributing term is the projector \( \tilde{P}_{\mu \nu}^{1} \), since it contains \( \delta_{11} \). As a result, the longitudinal index is simply passed to the lepton tensor, and we only need \( L_{11} \). This makes the “parent” of the lepton—the virtual photon—longitudinally polarized, as we noticed before. The resulting expansion for the \( L_{11} \) up to \( O(q^2) \) is rather simple:

\[ L_{11} = \frac{\sin^2 \theta}{2} \left[ k_\perp^2 - q_\perp^2 \cos^2(\psi - \phi) + O(q^2/k^2) \right]. \]  

The MSL rate is proportional to the spectral density of the stress tensor, integrated over the phonon momentum. We will first discuss the properties of the spectral function, and eventually compare the MSL rate with the quark annihilation process.

B. Sounds

Matter produced in heavy ion collisions is not in global equilibrium; even if locally equilibrated, it expands hydrodynamically. In individual events, there are local density perturbations, due to quantum fluctuations in the locations of the individual nucleons. Propagation of small perturbations on top of the expanding fireball has been studied, e.g., on top of the so-called Gubser flow [38], the corresponding Green function has been evaluated in [39]. The correlator of the two stress tensors can be expressed, in the Langevin form of hydrodynamics [40], through the two Green functions connecting two observation points to the origin of the signal; i.e., as the Langevin noise term. Since lower harmonics of sounds (small \( k \)) have very small dissipation, given the time available \( \tau_{\text{lifetime}} \sim 10 \text{ fm}/c \), they can travel far across the fireball. Thus the correlator is very nonlocal, and quite complicated, compared to the correlator in matter at rest that we discussed in the preceding subsection. Fortunately, such complicated expressions for the sounds generated in flowing matter by thermal fluctuations are not really needed. Phenomenology of heavy ion collisions has yet to discover this phenomenon. What is actually observed, which is in agreement with theoretical expectations such as in [39], is a “boundary term”: the sounds induced by the fluctuating initial conditions at the initiation surface.

The schematic map of the sound perturbations is shown in Fig. 5. The horizontal axis is (the log of) the perturbation momentum: it ranges from the smallest momentum, the inverse of the fireball dimensions \( R_{\text{fireball}} \sim 30 \text{ MeV} \), to the highest one \( \sim 1 \text{ GeV} \). The vertical axis is (proper) time, starting from the collision moment and ranging up to the final freeze-out of secondaries at \( \tau_f \sim 10 \text{ fm}/c \). The most important element of this map is the solid line which shows how viscous damping (by a factor \( 1/e \)) depends upon the phonon momentum. It is based on acoustic damping in QGP (for the theory see, e.g., [37] and for phenomenology [41]),

\[ \left| \frac{\delta T_{\mu \nu}(k,t)}{\delta T_{\mu \nu}(k,0)} \right| = \exp \left( -\frac{2 \gamma k^2 t}{3 s T} \right), \]  

which can be rewritten as \( \exp(-t/t_{\text{damp}}) \), with the characteristic damping time

\[ t_{\text{damp}} \equiv \frac{3 s}{2 \gamma k^2 T}. \]  

This is the solid curve plotted in Fig. 5.
At small $k$ this time is large, and can be longer than the freeze-out time $\tau_f$. In general, in the region below this curve $t < t_{\text{damp}}$, such sound waves do survive viscous damping, from the beginning to the freeze-out time. Therefore, in this region the stress tensor fluctuations are dominated by the initial fluctuations, as we discuss below.

In the region well above this curve $t > t_{\text{damping}}$, the initial perturbations are already damped. The stress tensor perturbations in this region are described by equilibrium fluctuations with the stress tensor spectral densities; for a review, see, e.g., [42].

In Fig. 5 we indicate the kinematical regions in which we will discuss the dilepton and photon production. The relevance of the scale $k \sim 200$ MeV follows from the fact that it corresponds to the largest observed flow perturbations. Indeed, the angular harmonics with $n_{\text{max}} = 6$ have the smallest wavelength of those sounds, which is $2\pi R_{\text{fireball}}/n_{\text{max}} \sim 6$ fm, or equivalently $k \sim 200$ MeV. The studies of the fluctuations have been done in connection to higher harmonics of the flow [39,43], which are also well described hydrodynamically. Recent work [44] shows that model distribution over initial values of the angular moments $P(\epsilon_n)$, combined with hydrodynamics, also describe well the distributions of the observed flow components $P(\nu_n)$ for $n = 2,3,4$. The normalized distributions have nearly a universal form $P(\epsilon_n/\langle \epsilon_n \rangle)$, the same for all $n$, which is rather wide, with a non-Gaussian tail toward the larger values.

The sounds with higher momenta $k > 200$ MeV have not yet been observed. But of course they still can produce dileptons of interest. The proof of their existence may become an important discovery. But how large can the momentum of a phonon be? At what point does the notion of the sound modes lose its meaning?

One historically important observation comes from the theory of solids. As observed by Debye, the cutoff $k_{\text{max}}$ should be determined by the condition that the total number of degrees of freedom in phonons should not exceed the total number of phonon states:

$$V \int_{k_{\text{max}}}^{k_{\text{max}}} \frac{d^3 k}{(2\pi)^3} < \langle N_{\text{particles}} \rangle. \tag{66}$$

In other words, the sound wavelength cannot be shorter than the interparticle distance. Applying this idea to the “hot glue,” one would argue that $k_{\text{max}} < T N_c^{2/3}$, where $N_c$ is the number of colors. But perhaps it is incorrect to mix colorless and colored degrees of freedom. Indeed, the gauge theories in the limit of large number of colors, $N_c \to \infty$, such as the ones described by the Anti de Sitter/conformal field theory (AdS/CFT) correspondence, yield an expression for $k_{\text{max}}$ that does not involve $N_c$. While the interparticle distance goes to zero in this limit, the “end of the sound” is dictated by the imaginary part of the dispersion relation becoming comparable to the real part. The AdS/CFT correspondence tells us that this actually happens at $k_{\text{max}} \sim \pi T$.

Whether the phonon is or is not a well defined quasiparticle, its occupation numbers at high frequencies are in any case limited at least by the thermal weights

$$f(k^0) \approx \exp(-k^0/T) = \exp(-c_s k/T), \tag{67}$$

providing a standard thermal cutoff at high energies. So, the upper momentum of the phonons is given by $k < T/c_s$.

Since there are two pictures of the initial state, the “perturbative hot glue” and the “glasma,” let us discuss them step by step, starting with the former case. The frequency integral for the rate will get the dominant contribution from the sound peak in the spectral function (we ignore the divergence at large $\omega$ for now). The width of the peak is $\delta \omega \sim \Gamma, k^2$ and the height is $\sim 1/\delta \omega$, so it is clear that the integral is independent of the width. Indeed, by changing $\omega \to c_s k$ anywhere except the denominator, we get a Breit-Wigner shape which is easily integrated over, yielding a simple answer:

$$\int_{\omega_{\text{peak}}} d\omega \frac{\rho_L}{\omega} = \frac{\epsilon + p}{2}. \tag{68}$$

The remaining integral over $d^3 k$ leads us to the UV issues that are related to the “end of sound” which we discussed above. All the previous formulas in this section were derived within hydrodynamics, assuming small $\omega, k \ll T$. When this assumption is no longer true, not only is the sound modified to a highly dissipative and thus a rapidly equilibrating mode, but also its amplitude is relaxed to that of the thermal excitations. Therefore the correlator gets its Botzmann factor $\exp(-\omega/T)$ which provides a standard thermal cutoff. Noting that the remaining integral is nothing but Debye’s phonon thermal energy,

$$\int \frac{d^3 k}{(2\pi)^3} k e^{-c_s k/T} = \frac{3T^4}{c_s^4 \pi^2}, \tag{69}$$

we get the following expression for the integrated sound correlator:

$$\int \frac{d^4 k}{(2\pi)^4} \langle \epsilon_k \epsilon_k \rangle_{\text{corr}} = (\epsilon + p) \frac{3T^4}{c_s^4 16 \pi^3} \approx \frac{3T^8 N_c^2}{5\pi}, \tag{70}$$

where in the last expression we used the equation of state of an ideal gluon gas and ignored the $1/N_c^2$ correction.
C. Stress tensor correlators in equilibrium

The fluctuation-dissipation theorem, which originates from Einstein’s famous Brownian motion paper, states that, in equilibrium, the dissipation rate of fluctuations should be balanced by the production rate of new ones. And it is the latter, the source of fluctuations, that we need, as it enters in any production process, including absorption of the “phonons” in the media, and their conversion to light in an external magnetic field.

Hydrodynamics governs the low-energy excitations. Two spectral densities, the longitudinal (or the sound one), and the transverse (the diffusive one) are usually defined as the basic ones. For a general discussion and definitions of all stress tensor correlators see, e.g., [45] and, from a lattice perspective, [42]. The imaginary part of the retarded correlator divided by $\pi$ is known as the spectral density. The equilibrium values for its longitudinal and transverse parts are

$$\rho_{L,eq}(\omega, k) = \frac{(\epsilon + p)}{\pi} \frac{\omega^3 \Gamma_{\epsilon \epsilon}}{(\omega^2 - c_s^2 k^2)^2 + (\omega \Gamma_{\epsilon \epsilon} k^2)^2}$$  \hspace{1cm} (71)

and

$$\rho_{T,eq}(\omega, k) = \frac{1}{\pi} \frac{\eta \omega k^2}{(\epsilon + p)^2}$$  \hspace{1cm} (72)

where

$$\Gamma_{\epsilon \epsilon} = \frac{4\eta/3 + \zeta}{\epsilon + p}$$  \hspace{1cm} (73)

is the sound attenuation length. The correlator of the energy densities $\epsilon = T^{00}$ is related to the spectral density via

$$\chi_{\epsilon \epsilon} = \frac{\omega^2}{k^2} \rho_{L,eq}(\omega, k).$$  \hspace{1cm} (74)

Note that $k^2$ in the numerator then cancels, which allows us to get the $k \to 0$ limit first, and $\omega \to 0$ second, as required for the Kubo formula.

The trace of the stress tensor $\theta = T^\mu_\mu$ is a special combination, related to trace anomaly and discussed in [7]; its spectral density is

$$\rho_0 = \frac{9\omega}{\pi} \left( \frac{\Gamma_{\epsilon \epsilon}}{\omega^2 - c_s^2 k^2} \right)^2 \frac{(\epsilon + p) \Gamma_{\epsilon \epsilon} k^4}{(\omega^2 - c_s^2 k^2)^2 + (\omega \Gamma_{\epsilon \epsilon} k^2)^2}.$$  \hspace{1cm} (75)

At $T \gg T_c$, the sQGP is approximately conformal, and thus this combination is strongly suppressed. The small factor $(1/3 - c_s^2)^2 \sim 10^{-2}$ is the consequence of this fact. The same small factor is actually present in the first term; the bulk viscosity $\zeta$ as well. Therefore, this contribution is in fact small compared to that of the $L$ and $T$ spectral densities, except for the region $T \sim T_c$, where the bulk viscosity is expected to be relatively large [46–49].

D. Stress tensor out of equilibrium

We need the momenta of stress tensor perturbations to be as large as possible, limited only by our assumption $q_t \ll M$. Such “ultrasounds” have a short damping time by viscosity which prevents them from being observed at freeze-out, in correlations of the secondary hadrons. Nevertheless, there is no doubt that the quantum fluctuations inside the colliding nuclei/nucleons do produce these sounds at the collision time, and for the early time dilepton production processes, especially for the MSL process driven by the short-lived magnetic field, they are important.

In general, one may argue that at the momentum scale of interest $k \sim 1$ GeV, the early time stress tensor perturbations can be of order 1,

$$\frac{\delta T^{\mu\nu}}{\langle T^{\mu\nu} \rangle} \sim \frac{1}{\sqrt{N}}.$$  \hspace{1cm} (76)

Indeed, at such momentum scale the structure of the colliding protons gets resolved to partonic substructure: but the number of resolved patrons, $N$, is not actually large. In the “glasma” model the scale 1 GeV is comparable to saturation momentum $Q_s$, and so we here speak about individual “color field” cells. According to McLerran-Venugopalan model, these cells are uncorrelated and fluctuate of the order $O(1)$. This means that the total yield of the dileptons due to the MSL and MTL processes may even become comparable.

Parametrically, the ratio is further suppressed by the ratio of the number of colorless “hydrodynamical modes” in the correlation function to the total number of all colored gluonic modes (in the energy density),

$$\frac{\text{MSL}}{\text{MTL}} \sim \frac{3}{8}.$$  \hspace{1cm} (77)

VII. SUMMARY AND DISCUSSION

The stress tensor and its perturbations—Lorentz spin-2 tensors—can be connected (via the quark virtual loop) to two photons, one of which can be a coherent magnetic field present at noncentral heavy ion collisions. Such processes, if identified and studied, can be used as valuable diagnostic tools of produced matter.

The terminology proposed in this paper identifies two distinct processes: magneto-thermoluminescence [an interaction of $B(x,t)$ with near-constant average stress tensor $\langle T_{\mu\nu} \rangle$], and magneto-sonoluminescence [an interaction of $\tilde{B}$ with perturbations of the stress tensor $\delta T_{\mu\nu}(k)$ possessing a certain four-momentum $k$].

We argued that the most promising application of these phenomena is the contribution to the “intermediate mass dileptons” (IMD) [defined in (1)]. We calculated the rates of these processes, in some simplified kinematics, and indicated their qualitative features which can be used to separate them from other production mechanisms. The magnitude of the process calculated by the hadronic approach—as shown in Fig. 3—is below the magnitude of the lowest-order process roughly by an order of magnitude. The OPE approach, on the other hand, leads to a rate which is comparable to the lowest-order quark annihilation. However these estimates depend on many factors, including, e.g., the unknown quark fugacity, and provide qualitative guidance only.

How can the contribution of the MSL process be experimentally separated from others? The first distinctive feature of MSL is a very specific centrality dependence. While most other
processes are maximal at central collisions, the MSL is zero at \( b = 0 \) and peaks at the impact parameter value \( b \sim 10 \) fm. Of course, this is because the yield of MSL is proportional to the coherent magnetic field (one should of course keep in mind also the role of fluctuations).

Another rather unusual property of these processes is that they produce virtual photons which are longitudinally polarized, since the dilepton angular distributions are proportional to \( \sin^2 \theta \). In terms of the polarization parameter \( a \) defined via \( (1 + a \cos^2 \theta) \), the produced dileptons are characterized by \( a = -1 \). For comparison, let us remind the reader what the angular dependence is for other dilepton production processes. The classic partonic Drell-Yan process at leading order yields \( a = 1 \), corresponding to a transverse photon. A thermally equilibrated medium would produce unpolarized photons and thus no theta dependence, \( a = 0 \). It has been recently argued by one of us [50], that the lowest-order \( \bar{q}q \) processes in a nonequilibrium plasma can also lead to a (smaller in magnitude) negative \( a \) in some interval of invariant mass, albeit with no anisotropy with respect to the heavy ion reaction plane.

We urge further experimental studies of the angular dependence of photon and dilepton production at RHIC and LHC, and hope that they would allow us to establish the existence of magneto-sonoluminescence in quark-gluon plasma.

APPENDIX A: NOTATIONS

In this paper we use the same normalizations for both QED and QCD couplings and fields, so that \( e^2/4\pi = \alpha \approx 1/137, \ g^2/4\pi = \alpha_s \), and, e.g., the energy density of both gluonic and electromagnetic fields is given by \( T^{00} = (1/2)(\vec{E}^2 + \vec{B}^2) \).

APPENDIX B: RANDOM GAUSSIAN GLUE

One may assume a Gaussian ensemble of the gluonic fields, in which only colorless quadratic combinations of the fields are nonzero. We will also take the average over orientations of the fields in the amplitude, denoted by angular brackets. In three-dimensional notations, in the rest frame of matter one can think of three scalars: \( \vec{E}^2, \vec{B}^2, \vec{E} \cdot \vec{B} \). In four-dimensional notations, the corresponding three structures can define the following decomposition of the field strength:

\[
\langle G_{\mu_1\mu_2}^m G_{\mu_3\mu_4}^n \rangle = \delta^{mn} \left[ A P_{\mu_1\mu_2\mu_3\mu_4}^a + B P_{\mu_1\mu_2\mu_3\mu_4}^b + C P_{\mu_1\mu_2\mu_3\mu_4}^c \right],
\]

These three tensors are orthogonal to each other. The meaning of the three structures follows from convolutions of these expressions with \( P^a, P^b, P^c \), respectively:

\[
\langle G_{\mu_1\mu_2}^m G_{\mu_3\mu_4}^n \rangle P_{\mu_1\mu_2\mu_3\mu_4}^a = -24 A \delta^{mn},
\]

\[
\langle G_{\mu_1\mu_2}^m G_{\mu_3\mu_4}^n \rangle P_{\mu_1\mu_2\mu_3\mu_4}^b = 24 B \delta^{mn},
\]

\[
\langle G_{\mu_1\mu_2}^m G_{\mu_3\mu_4}^n \rangle P_{\mu_1\mu_2\mu_3\mu_4}^c = 6 C \delta^{mn},
\]

which defines three parameters \( A, B, C \) that, in Gaussian approximation, contain all the information about the local properties of the “glasma.”

The dual field strength is defined as

\[
\tilde{G}_{\mu\nu} = (1/2)\epsilon_{\mu\nu\alpha\beta} G_{\alpha\beta}.
\]

The action of the electric-magnetic duality transformation is more clear in the usual three-dimensional notations, in which it is simply an interchange of electric and magnetic fields. Under it, the combinations

\[
A \sim \tilde{E} \cdot \tilde{B},
\]

\[
B = G_{\mu\nu}^a G_{\mu\nu}^{a,\mu\nu} \frac{1}{12(N_c^2 - 1)},
\]

\[
C = \frac{2}{3(N_c^2 - 1)} T^{00} = \frac{1}{3(N_c^2 - 1)} (\vec{E}^2 + \vec{B}^2)
\]

remain unchanged, while the second one \( B \sim (\vec{E}^2 - \vec{B}^2) \) obviously changes sign. (In this expressions we have taken matter at rest.) Therefore one finds

\[
\langle G_{\mu_1\mu_2}^m G_{\mu_3\mu_4}^n \rangle = \delta^{mn} \left[ A P_{\mu_1\mu_2\mu_3\mu_4}^a - B P_{\mu_1\mu_2\mu_3\mu_4}^b + C P_{\mu_1\mu_2\mu_3\mu_4}^c \right].
\]

APPENDIX C: CALCULATING COMPONENTS OF THE SELF-ENERGY

Applying, as usual, the tensor structures \( P_1, P_2 \) to the polarization tensor, one finds (since \( P_1 \) and \( P_2 \) are not mutually orthogonal) a system of two linear equations,

\[
\Pi_1 = \Pi_{\mu\nu} P_{\mu\nu}^{11} W_1 + P_{\mu\nu}^{12} W_2,
\]

\[
\Pi_2 = \Pi_{\mu\nu} P_{\mu\nu}^{22} W_1 + P_{\mu\nu}^{22} W_2,
\]

where (for simplicity) we give the coefficients in the rest frame of the matter, \( n_0 = 1, n_1 = n_2 = n_3 = 0 : \)

\[
P_{\mu\nu}^{11} = P_{\mu\nu}^{11} P_{\mu\nu}^{11} = 3,
\]

\[
P_{\mu\nu}^{22} = P_{\mu\nu}^{11} P_{\mu\nu}^{12} = \frac{q^4}{(q_0^2 - q^2)^2},
\]

\[
P_{\mu\nu}^{12} = P_{\mu\nu}^{11} P_{\mu\nu}^{12} = -\frac{q^2}{q_0^2 - q^2}.
\]
The solution is obvious; we only note that in order for it to exist the determinant of the system
\[ p^{11} p^{22} - p^{12} p^{12} = 2 \frac{q^4}{(q_0^2 - q^2)^2} \neq 0 \] (C3)
should be nonzero, thus the spatial part of the vector \( q \) cannot vanish.

For the color-averaged gauge fields, the result is
\[ \delta \Pi_1 = c_1 B + c_1 c C, \]
\[ \delta \Pi_2 = c_2 B + c_2 c C, \]
\[ c_1 B = -3(q_0^2 - q^2), \]
\[ c_1 c = 1/2(3q_0^2 + q^2), \]
\[ c_2 B = q^2, \]
\[ c_2 c = -(1/2)q^2(q_0^2 + 3q^2) \frac{q_0^2}{q_0^2 - q^2}. \] (C4)

Solving this \( 2 \times 2 \) system, we get our effective action
\[ L_{\text{eff}} = \Pi_{\mu \nu} A_\mu A_\nu. \] (C5)

**APPENDIX D: FOURIER TRANSFORMS**

In order to evaluate the Fourier transforms we use the standard dimensional regularization scheme where \( d = 4 + 2\epsilon \). Another useful tool is the proper time representation:
\[ \frac{1}{(q^2)^{d+1}} \frac{1}{\Gamma(1 + n)} \int_0^\infty ds s^n e^{-q^2 s}. \] (D1)

By standard integrations we obtain
\[ \frac{q_\mu q_\nu q_\lambda}{q^8} \rightarrow \frac{i x_\mu}{192 \pi^2} \left[ x_\lambda x_\nu x_\lambda + 12 x_\nu g_{\lambda \mu} \left( \ln x^2 - \frac{1}{\epsilon} \right) \right]. \] (D2)

The relevant transforms to convert the self-energy (46) from position to momentum space are
\[ \frac{x_{\mu} x_{\nu}}{x^4} \rightarrow \frac{2 \pi^2}{q^4}(g_{\mu \nu} - 2 q_\mu q_\nu), \]
\[ \frac{x_{\mu} x_{\nu} x_{\alpha} x_{\beta}}{x^6} \rightarrow \frac{\pi^2}{2 \rho^6} \left[ 8 q_\mu q_\nu q_\alpha q_\beta - 2q^2(g_{\mu \nu} q_\alpha q_\beta + g_{\mu \alpha} q_\nu q_\beta)ight. \]
\[ + q_\beta q_\mu q_\nu + q_\nu q_\alpha q_\beta + q_\alpha q_\mu q_\nu + g_{\mu \nu} q_\alpha q_\beta \]
\[ + q^4(q_{\mu \nu} g_{\alpha \beta} + g_{\mu \alpha} g_{\nu \beta} + g_{\mu \beta} g_{\nu \alpha})]. \]

**APPENDIX E: THE LOWEST-ORDER RATE**

Even though the total and differential rates in the lowest (zeroth) order in strong interactions coupling, \( \alpha_s \), have been known for a long time [1], it is useful to put them in a form similar to the expressions in this paper, so that the common factors cancel in the ratio. Diagrammatically the calculation consists of a convolution of quark and lepton “cut loops” shown in Fig. 1(a) which corresponds to the following expression:
\[ \frac{dN}{d^4 x} = e^4 \sum_f Q_f^2 N_c \frac{Q_{\mu \nu} L_{\mu \nu}}{M^4} f_F \left( \frac{q_{+0}}{T} \right) f_F \left( \frac{q_{-0}}{T} \right) \]
\[ \times P S(l^+ l^-) P S(q^+, q^-) \]
\[ \times (2\pi)^4 \delta^4(q_+ + q_- - l_+ - l_-), \] (E1)

where
\[ P S(q^+, q^-) = \frac{d^3 q_+}{(2\pi)^3 q_{+0}} \frac{d^3 q_-}{(2\pi)^3 q_{-0}}, \] (E2)

and the same for leptons. The fermion loop summed over polarizations for massless leptons is
\[ L_{\mu \nu} = (1/4) \text{Tr}(g_\mu g_\nu g_\lambda g_\beta) l_\mu^l l_\nu^l \]
\[ = l_\mu^l l_\nu^l + 4l_\mu^l l_\nu^l - g_{\mu \nu} (l_+^l l_-^l). \] (E3)

\( Q_{\mu \nu} \) is the same tensor for quarks, with appropriate change of momenta. The covariant convolution \( Q_{\rho \sigma} L^{\rho \sigma} \) expressed in the center-of-mass frame of the dilepton is \( M^4(1 + \cos^2 \theta) \), where \( \theta \) is the angle between the quark and lepton directions in this frame. For isotropic quark distribution the latter factor averages to \( 4/3 \).

The Fermi distribution functions \( f \) stand for distributions of the original quark and antiquark. For arbitrary kinematics of the dileptons the integral over quark phase space is complicated. However, in the dominant kinematics we use for comparison—the dilepton as a whole is at rest in matter rest frame—this integration becomes trivial. In the Boltzmann approximation the thermal distribution reduces to
\[ f_F(\epsilon^+ / T) f_F(\epsilon^- / T) \approx \exp \left( -\frac{M}{T} \right). \] (E4)
