Takotsubo cardiomyopathy (TTC) is defined as a reversible, acute ventricular dysfunction without any evidence of coronary artery obstruction. There have been reports of TTC caused by emotional or physical stress, drug use, hormone imbalance, or medical conditions such as pulmonary disease, sepsis, and trauma, but a relationship between TTC and pulmonary tuberculosis has not previously been reported. From our knowledge, this is the first report of TTC caused by pulmonary tuberculosis.

Keywords: Takotsubo Cardiomyopathy; Tuberculosis, Pulmonary; Catecholamines

Introduction

Takotsubo cardiomyopathy (TTC) is an acute syndrome characterized by reversible ventricular dysfunction in the absence of significant coronary artery disease. Several inconsistent hypotheses have been proposed regarding the pathophysiology of TTC. Currently, catecholaminergic overstimulation caused by mental and/or physical stress is accepted as a reasonable pathophysiology of TTC. However, the etiology and intensity of how stress causes TTC are still unclear. In this case, we suggest that pulmonary tuberculosis may be a precipitant.

Case Report

A 54-year-old Korean man presented with a month-long history of cough and yellowish sputum, an 8-kg weight loss over the course of three months and Modified Medical Research Council Dyspnea Scale grade 1 dyspnea. He had no history of surgery or other medical illness and he was a current smoker (30 pack-years). On examination, his blood pressure was 100/80 mm Hg, pulse rate was 76 beats/min, respiratory rate was 24 breaths/min, and body temperature was 36.5°C. On chest auscultation, breathing sounds were abnormal with coarse rales in both upper lung fields. Initial arterial blood gas results were pH 7.428, pCO₂ 32.8 mm Hg, pO₂ 85.1 mm Hg, HCO₃⁻ 21.2 mmol/L, and SaO₂ 97.8% in ambient air. Blood tests showed a white blood cell count of 6,700/mm³ (normal, 4000−10000/mm³), hemoglobin of 12.8 g/dL (normal, 12.5−15 g/dL), and a platelet count of 178/mm³ (normal, 150−450/mm³). The C-reactive protein level was found to be 5.23 mg/L (normal, 0−0.75 mg/L). A blood chemistry panel revealed a blood urea nitrogen level of 45.3 mg/dL (normal, 7−20 mg/dL), creatinine of 1.0 mg/dL (normal, 0.5−1.5 mg/dL), total protein of 8.3 g/dL (normal, 6.0−8.3 g/dL), albumin of 3.2 g/dL (normal, 3.5−4.5 mg/dL), and aspartate aminotransferase/alanine aminotransferase of 78/54 IU/L (normal, 8−40/5−35, respectively). Cardiac enzyme labs were found to be elevated.
Figure 1. (A) Initial chest radiograph shows numerous nodules in both apices suggesting active pulmonary tuberculosis. (B) Chest computed tomography (CT) shows cavitary lesions in the right upper lobe and multiple small nodules and patchy consolidation in both upper lobes. (C) Chest CT shows an approximately 1.9-cm ovoid filling defect (arrow) in the apex of the left ventricle.

Figure 2. Transthoracic echocardiography. (A) The typical apical ballooning of Takotsubo cardiomyopathy in the initial apical four-chamber view. (B) The 1.6×1.2-cm thrombus in the apex of the left ventricle is noted in the initial apical two-chamber view. (C) In a follow-up of echocardiography, apical ballooning is completely normalized. (D) On follow-up echocardiography, the thrombus was still noted, but decreased in size. Arrows indicate the apical thrombus.
The apex wall; 2) absence of coronary lesion in coronary CT; criteria for TTC diagnosis: 1) typical balloon-like akinesia of cytoma or myocarditis in serum cardiac enzymes; and 4) absence of pheochromo beyond a single epicardial vascular distribution; 2) absence involvement and regional wall motion abnormality extending or dyskinesis in the L V mid segments with or without apical TTC include the following: 1) transient hypokinesis, akinesis, teria for TTC diagnosis. The proposed diagnostic criteria for period, there was no physical evidence of recurrence in TTC. Rifampin and isoniazid for four months. During the follow-up ethambutol and pyrazinamide for two months, followed by completed a six months of treatment with rifampin, isoniazid, tuition test revealed all sensitive results. He of pulmonary tuberculosis through positive tuberculosis cul (Figure 2D). Seventeen days later, we confirmed a diagnosis L V thrombus was still noted on imaging, but decreased in size (Figure 2C). The left ventricular ejection fraction was 58%. The cal wall motion and no evidence of akinesia of the apex wall later, follow-up echocardiography showed normalized L V apical wall motion and no evidence of akinesia of the apex wall (Figure 2C). The left ventricular ejection fraction was 38%. The LV thrombus was still noted on imaging, but decreased in size (Figure 2D). Seventeen days later, we confirmed a diagnosis of pulmonary tuberculosis through positive tuberculosis cul. Drug susceptibility test revealed all sensitive results. He a six months of treatment with rifampin, isoniazid, ethambutol and pyrazinamide for two months, followed by rifampin and isoniazid for four months. During the follow-up period, there was no physical evidence of recurrence in TTC.

Discussion

The Mayo Clinic Criteria are the most widely applied criteria for TTC diagnosis. The proposed diagnostic criteria for TTC include the following: 1) transient hypokinesia, akinesis, or dyskinesis in the LV mid segments with or without apical involvement and regional wall motion abnormality extending beyond a single epicardial vascular distribution; 2) absence of an obstructive coronary lesion or evidence of acute plaque rupture; 3) new electrophoretic abnormalities and/or elevation in serum cardiac enzymes; and 4) absence of pheochromocytoma or myocarditis. In our case, the patient met all four criteria for TTC diagnosis: 1) typical balloon-like akinesia of the apex wall; 2) absence of coronary lesion in coronary CT; 3) elevated cardiac enzymes and inverted T-wave in ECG; 4) absence of pheochromocytoma on CT and no evidence of myocarditis.

A common theme among TTC patients is a precipitating stressful event. This event may be either an emotional or a physical stressor; a serious medical or surgical issue, or iatrogenic drug administration. As a cause of TTC, we could not identify any specific stressful events aside from pulmonary tuberculosis in this patient. Chronic infection such as pulmonary tuberculosis is not generally considered to be a common cause of TTC. However, a few reports suggest that there is a higher plasma norepinephrine concentration in pulmonary tuberculosis patients compared to normal people, which is a typical accepted pathophysiological mechanism of TTC.

Thus, we postulate that pulmonary tuberculosis may be a possible precipitant of TTC.

In this patient, cardiac biomarkers were rapidly normalized. In general, the significance of cardiac enzyme elevation is less than in myocardial infarction. The elevation of CK-MB and troponin I are reported around in 53% and 85% of TTC patients. These findings may suggest that TTC is associated with less myonecrosis and transient elevation of cardiac biomarkers, consequently. Also, supportive care such as oxygen therapy could improve myocardial ischemia after admission.

Another interesting finding was the development of LV thrombus. There have been some reports of TTC complicated with thrombus. The clinical importance of this thrombus is that it may be a potential source of embolic events. In one study, thromboembolism was found to be the second most frequent cardiovascular complication following TTC. Despite the fact that left ventricular dysfunction in TTC is a transient phenomenon, it favors the formation of intracardiac mural thrombus through catecholamine-induced platelet activation and low blood flow from wall motion abnormalities in the apical region. When LV thrombus or significant apical akinesia is present, intravenous heparin followed by oral anticoagulation is recommended until the thrombus and ventricular dysfunction have resolved.

In conclusion, we report the first case of TTC accompanied by pulmonary tuberculosis, suggesting that pulmonary tuberculosis may be a cause of TTC.
