This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Controlling the block sequence of multi-block oligomer ligands for neutralization of a target peptide

Hinata Takimoto\textsuperscript{a\textdh}, Sho Katakami\textsuperscript{a\textdh}, Yoshiko Miura\textsuperscript{a}, Yu Hoshino\textsuperscript{a\textast}

A series of block oligomers consisting of the same monomer composition but a different block sequence was prepared via reversible addition-fragmentation chain transfer (RAFT) polymerization to screen high affinity ligands for a toxic peptide. Activity and affinity screening of mono-, di-, and tri-block oligomers revealed that in addition to the localization and combination of functional groups, the sequence of the functional block and end groups are of significant importance to design the ligands that bind and neutralize the peptide.

Affinity ligands recognizing target biomolecules are drawing significant attention regarding applications in disease treatment, diagnosis, and protein purification. These ligands were developed by direct evolution of biomacromolecules such as polypeptides and oligonucleotides through cycles of library generation, screening, and amplification.\textsuperscript{1,2} However, the application of biomolecular ligands is impeded due to high production costs and low stabilities. Thus, synthetic polymer ligands consisting of versatile functional monomers are of significant interest as a stable and inexpensive substitute for biomolecular ligands.

Radical polymerization is a facile method to prepare stable synthetic polymers, that have a stable C-C backbone, from inexpensive raw materials such as acrylates and acrylamides.\textsuperscript{3} Schrader et al. reported that the free radical polymerization of optimized combinations of functional monomers leads to their transformation into strong polymeric protein hosts. The optimized functional polymers interact with the surface of target proteins by multi-mode interactions such as electrostatic, hydrophobic, aromatic, and hydrogen bonding.\textsuperscript{4,5} Shea et al. prepared polymeric nanoparticle ligands via radical and/or imprinting polymerization of combination of functional acrylamides, and employed the product for neutralizing,\textsuperscript{6,7,8} purifying,\textsuperscript{9} and refolding\textsuperscript{10} of target biomacromolecules.

Recent advances in controlled radical polymerization techniques enabled the synthesis of polymers of well-defined block sequence\textsuperscript{11-13}. Thus far, researchers have revealed that synthetic polymers produced by living radical polymerization of monomers with various functionalities function as polymer ligands for biomacromolecules.\textsuperscript{14-16} Haddleton et al. prepared multi-block glycopolymers containing defined block sequences via single electron transfer living radical polymerization and evaluated their binding properties to HIV gp120.\textsuperscript{14,15} Miura et al. reported that optimizing the size and arrangement of the sugar cluster in glycopolymers facilitates the control of its molecular lectin recognition.\textsuperscript{16} Effect of topology of glycopolymers on the affinity to target proteins\textsuperscript{17} and virus\textsuperscript{18} have also been reported. Perrier et al. reported that multi-block copolymer consisting of negatively charged monomers and nonionic monomers can stabilize fibroblast growth factors depending of molecular weight and charge dispersion.\textsuperscript{19} We have prepared a small library of di-block oligomer with a uniform number of functional groups and evaluated the interaction with their target peptide.\textsuperscript{20,21} It was revealed that the multi-modal interaction is important for strong affinity, and the affinity and sequence specificity significantly depends on the number of functionalities. However, the effect of the block sequence of the multiblock copolymers on the interaction with the target biomolecules has not been evaluated.

In this study, we prepared a series of block copolymers consisting of the same monomer composition but different block sequence via reversible addition-fragmentation chain transfer (RAFT) polymerization. The interaction between the polymers and a target peptide was evaluated for the first time. The toxic peptide melittin was selected as model peptide (Figure 1a). Melittin consists of 26 amino acids and contains consecutive positively charged and hydrophobic sequences. Since melittin shows strong hemolytic activity, it was employed as model target peptide to prepare synthetic polymer ligands working as antidotes.\textsuperscript{21} To synthesize multi-block polymer ligands binding to melittin for neutralizing its toxicity, we employed negatively charged acrylic acid (AAc) and hydrophobic N-tert butyl acrylamide (TBAm) as functional monomers (Figure 1b). N-isopropylacrylamide (NIPAm) was also

\textsuperscript{\ast} Both authors contributed equally to this work.
selected as the spacer monomer. It has been reported that random ter-oligomers consisting of 3 unit of AAc and 6 unit of TBAm recognize melittin via combination of electrostatic and hydrophobic interaction. Density of the functional units have to be diluted by 21 mer NIPAm unit in order to achieve higher binding specificity to melittin. Affinity purification experiments revealed that certain sequence of the randomly copolymerized ter-oligomers has stronger affinity to melittin than the as polymerized random oligomers.

Three homo oligomers were first polymerized by RAFT polymerization using AAc, TBAm and NIPAm as components (Figure 1b). Six di-block oligomers were then prepared by using the three homo oligomers as a macro chain transfer agent and one of the remaining two functional monomers as a second component. Six tri-block oligomers were finally prepared using the six di-block oligomers as a macro chain transfer agent and the remaining functional monomer as a third component. The average number of monomer units in the AAc and TBAm blocks were tuned to be 3 mer and 6 mer, respectively; this was because it has been reported that those were the minimum number of functional groups required to interact with the target peptide via combination of multipoint electrostatic and hydrophobic interaction.

The activity of those oligomers to neutralize melittin hemolysis was evaluated and compared with that of the randomly copolymerized polymers.

Six di-block oligomers were synthesized using oligo(tBA) (AAc-NIPAm-TBAm = 21/3/6). The conversion was 97.2% and 20.8 mer of NIPAm were introduced. The residual monomers were removed by dialysis against methanol. TheGPC curve shifted to higher molecular weight after polymerization (Figure 2a). The M<sub>n</sub> value was 3.80 × 10<sup>5</sup> and the PDI value 1.12. Homo-oligomers of NIPAm and TBAm were synthesized in the same manner using 21 and 6 equivalents of each monomer with PDOTT, respectively (SI, Table S1). Conversion, GPC, M<sub>n</sub>, degree of polymerization (DP) after purification and PDI of oligo(NIPAm) and oligo(TBAm) are shown in Figure 2 and listed in Table 1 and S2.

Six di-block oligomers were synthesized using oligo(tBA) (AAc-NIPAm-TBAm = 21/3/6). The conversion was 97.2% and 20.8 mer of NIPAm were introduced. The residual monomers were removed by dialysis against methanol. The GPC curve shifted to higher molecular weight after polymerization (Figure 2a). The M<sub>n</sub> value was 3.56 × 10<sup>5</sup> and 1.18, respectively. Conversion, GPC, M<sub>n</sub>, degree of polymerization (DP) after purification and PDI of six di-block oligomers are shown in Figure 2 and listed in Table 1 and S2.

The third blocks were prepared using di-block oligomer as macro chain transfer agent. For example, TBAm (191 mg, 1.5 M, 6 equivalent), the AN-Tb di-block oligomer (734 mg, 0.25 M, 1 equivalent) and AIBN (8 mg, 0.083 M) were dissolved in degassed methanol (1 mL) and heated at 70 °C for 6 h to prepare oligo(AAc-b-NIPAm-b-TBAm) (Ant-AN). The conversion was 99.2% and 7.2 mer of TBAm were introduced. The M<sub>n</sub>, and PDI values were 3.56 × 10<sup>5</sup> and 1.18, respectively. Conversion, M<sub>n</sub>, and PDI of the six tri-block oligomers are shown in Figure 2 and listed in Table 1 and S2.

For easy purification and analysis of AAc block oligomers, tert-butyl acrylate (tBA), which is AAc protected by a tert-butyl group, is employed for the polymerization instead of AAc. The 1-phenylethyl-2,3-propanediolyltrithiocarbonate (PDOTT), which showed a chain transfer efficiency high enough to control the polydispersity index (PDI) of oligomers, was designed and synthesized as chain transfer agent (SI). Tert-butyl acrylate (960 mg, 1.5 M, 3 equivalent of PDOTT) was polymerized in degassed methanol (5 mL) at 70 °C for 6 h in the presence of PDOTT (720 mg, 0.5 M, 1 equivalent) using 2,2′-azobis(isobutyronitrile) (AIBN, 82 mg, 0.1 M) as radical initiator to obtain oligo(tBA). The monomer conversion, analyzed by 1H NMR, was 85.2%, which indicates that 2.4 mer of tBA was introduced (Table 1). Residual monomers were removed by extraction (MeOH/heptane). The average molecular weight (M<sub>n</sub>, M<sub>w</sub> and the dispersity (PDI) were determined by gel permeation chromatography (GPC) (Figure 2a). The M<sub>n</sub> value was 3.80 × 10<sup>5</sup> and the PDI value 1.12. Homo-oligomers of NIPAm and TBAm were synthesized in the same manner using 21 and 6 equivalents of each monomer with PDOTT, respectively (SI, Table S1). Conversion, GPC, M<sub>n</sub>, degree of polymerization (DP) after purification and PDI of oligo(NIPAm) and oligo(TBAm) are shown in Figure 2 and listed in Table 1 and S2.

Other di- and tri-block polymers were prepared and purified at similar conditions, shown in SI and listed in Table S1. GPC analysis indicated that all polymerizations successfully proceeded as designed (Figure 2 and Table 1). A series of homo-, di-, and tri-block oligomer ligands with the same composition (A: 2.3 ± 0.3 mer, N: 21.3 ± 0.5 mer, and T: 6.3 ± 0.9 mer) but different block sequence was obtained. As control samples, random 9 mer oligomers (R<sub>9</sub>-OH) consist of 3 mer of AAc and 6 mer of TBAm. Random 30 mer oligomers (R<sub>30</sub>-OH) consisting of 3 mer of AAc, 6 mer of TBAm and 21
mer of NIPAm were also prepared and purified at similar conditions, as shown in SI and Table S1. The Mₙ and PDI values of \( nR9 \text{-ON} \) were \( 1.28 \times 10^{3} \) and 1.15, respectively (Table 1). This indicates that the random oligomers have a molecular weight and composition comparable to that of \( n \text{AT-OH} \) and \( n \text{TA-OH} \), but the functional groups are differently located. The Mₙ and PDI values of \( nR30 \text{-OH} \) were \( 4.47 \times 10^{3} \) and 1.20, respectively (Table 1), which indicates that random oligomers with molecular weight and composition comparable to that of tri-block oligomers but with differently localized functional groups were prepared.

The neutralization assay for the hemolytic activity of melittin was performed after the deprotection of the tert-butyl group (SI and Figure S2); the red blood cell lysis behavior of melittin (9 µM) was investigated in the presence of oligomer ligands (60 µM) under physiological conditions (37 °C, 35 mM phosphate buffered saline (150 mM NaCl, pH 7.4), SI). The quenching of the tryptophan (Trp-19) fluorescence of melittin, which has a consecutive sequence of positively charged and hydrophobic amino acids.

Neutralization assay for the hemolytic activity of melittin was performed after the deprotection of the tert-butyl group (SI and Figure S2); the red blood cell lysis behavior of melittin (9 µM) was investigated in the presence of oligomer ligands (60 µM) under physiological conditions (37 °C, 35 mM phosphate buffered saline (150 mM NaCl, pH 7.4), SI). The results for the neutralization activity of homolog oligomers are shown in Figure 3a and indicate little neutralization activity against melittin. The neutralization activity of the di-block oligomers is summarized in Figure 3b. The \( n \text{AT-OH} \) and \( n \text{TA-OH} \) di-block oligomers displayed a moderate neutralization of 39% and 53%, respectively. However, the other four di-block oligomers containing NIPAm-block did not neutralize the hemolytic activity of melittin, although, length of the NIPAm block (21 mer) is longer than the AAc-block (3 mer) and TBAm-block (6 mer). It is suggested that the combination of electrostatic and hydrophobic interaction made the oligomer interact with melittin and neutralize melittin. On the other hand, \( nR9 \text{-OH} \), the random oligomer with the same number of AAc and TBAm as those of \( n \text{AT-OH} \) and \( n \text{TA-OH} \) oligomers, showed only a 29% neutralization activity. The value is lower than that of the \( n \text{TA-OH} \) oligomers, suggesting that the carboxylic acid and tert-butyl groups have to be localized in an oligomer in such a way that they can effectively interact with melittin, which has a consecutive sequence of positively charged and hydrophobic amino acids.

The neutralization activities of tri-block oligomers were summarized in Figure 3c. The \( n \text{ANT-OH}, n \text{ATN-OH}, n \text{NAT-OH}, n \text{NTA-OH}, n \text{TNA-OH} \) tri-block oligomers neutralized the hemolytic activity of melittin (98%, 74%, 97%, 46% and 76%, respectively). However, \( n \text{TAN-OH} \) and \( nR30 \text{-OH} \) did not show neutralization activity. Based on these results, we concluded that the neutralization activity of tri-block oligomer ligands depends on the block sequence, even if the amount and density of functionalities were identical. The position of the long spacer monomer block (oligo(NIPAm)) in tri-block oligomer ligands affected its neutralization activity. Interestingly, although the order of monomer blocks is identical, \( n \text{NAT-OH} \) and \( n \text{TAN-OH} \) provided a different neutralization behavior. This result indicate that the location and properties of terminal group have to be optimized in order to maximize the neutralization ability: The higher hydrophobicity of the phenyl group end group as compared to that of the diol group was sufficient to preferably interact with the hydrophobic amino acids of melittin. The long pNIPAm block on the hydrophilic end of \( n \text{TAN-OH} \) might hindered AAc block to interact with positive charges on melittin.

To evaluate the interaction between tri-block oligomer ligands and melittin, the fluorescence emission (340 nm) of melittin (9 µM) was quantified in the presence of tri-block oligomer ligands (60 µM) under physiological conditions (37 °C, 35 mM phosphate buffered saline (150 mM NaCl, pH 7.4), SI). The quenching of the tryptophan (Trp-19) fluorescence of melittin, induced by the interaction with oligomer ligands, is summarized in Figure 3d. The tri-block oligomers \( n \text{ANT-OH}, n \text{ATN-OH}, n \text{NAT-OH}, n \text{NTA-OH}, n \text{TNA-OH} \) that have high neutralization activity, showed quenching adequately the tryptophan fluorescence of melittin. On the other hand, \( n \text{TAN-OH} \) and \( nR30 \text{-OH} \) exhibited little fluorescence quenching. These results indicate that hemolytic toxicity of melittin was neutralized by the oligomer ligands as a result of interaction between the
peptide and the ligands. Interestingly, the oligomers that showed strongest neutralization activity (such as m\textsuperscript{ANT-oh}) did not always show strongest quenching of tryptophan (Figure 3c and 3d). This results indicate that each oligomers neutralized melittin by binding to different sequence on melittin. Sequence specificity was observed in the case of homogeneous di-block oligomers of A and T.\textsuperscript{20} A di-block hexamer consisting of 4 units of A and 2 units of T recognize negatively charged KRKR sequence on melittin, though, the hexamer consisting of 2 units of A and 4 units of T recognized hydrophobic amino acids including tryptophan next to the KRKR sequence.\textsuperscript{20}

These results demonstrated that the synthetic oligomer ligands, which effectively interact with the target peptide via multi-modal interactions, can be prepared by controlling the block sequence of the multi-functional oligomers. Screening of mono-, di-, and tri-block oligomer ligands revealed that not only the localization and combination of functional groups but also the sequence of the functional block and end groups are of importance to design high affinity ligands that binds and neutralize activity of target biomacromolecules.

Figure 3. Neutralization of the hemolytic activity of melittin by (a) mono-, (b) di-, and (c) tri-block oligomers, screened by a hemolysis neutralization assay in PBS at 37 °C. (d) Fluorescence quenching by tri-block oligomers in PBS at 37 °C. The oligomer concentration was 60 μM in both experiments.
