We study a class of graph Hamiltonians given by a type of quiver representation to which we can associate (non)–commutative geometries. By selecting gauging data these geometries are realized by matrices through an explicit construction or a Kan-extension. We describe the changes in gauge via the action of a regauging groupoid. It acts via matrices that give rise to a noncommutative 2–cocycle and hence to a groupoid extension (gerbe).

We furthermore show that automorphisms of the underlying graph of the quiver can be lifted to extended symmetry groups of regaugings. In the commutative case, we deduce that the extended symmetries act via a projective representation. This yields isotypical decompositions and super–selection rules.

We apply these results to the PDG and honeycomb wire–networks using representation theory for projective groups and show that all the degeneracies in the spectra are consequences of these enhanced symmetries. This includes the Dirac points of the G(yroid) and the honeycomb systems.

1. Introduction

We study a class of graph Hamiltonians given by a type of quiver representation to which we can associate (non)–commutative geometries. Our particular focus are symmetries in these geometric realizations especially those coming from the symmetries of the graph. Via considering a re–gauge group(oid) action we can show that the classical graph symmetries lead to enhanced (centrally extended) symmetries which are realized as projective representations in the commutative case.

The physical motivation for considering such systems stems from considering wire–systems on the nano–scale where the presence of higher dimensional irreps in the decomposition of the above symmetries leads to degeneracies in the spectrum. After giving the general arguments we apply them to the PDG and the honeycomb wire systems. Here we are especially motivated by understanding the electronic properties...
of a novel material [1] based on the G(yroid) geometry [2]. We expect that our considerations can also be applied to other graph based setups, such as those coming from quiver representations, e.g. in field theory, or the coordinate changes in cluster algebras and varieties.

Mathematically, the initial data we start from is a finite graph $\bar{\Gamma}$ together with a separable Hilbert space $\mathcal{H}_v$ for each vertex $v$ of the graph and a unitary morphism for each oriented edge, such that the inverse oriented edge corresponds to the inverse morphism. Algebraically this data corresponds to a groupoid representation in separable Hilbert spaces, as we explain in §2.1. In this situation, as we derive, there is an associated Hamiltonian acting on the direct sum of all the Hilbert spaces $\mathcal{H}_v$.

In order to obtain a matrix representation of the Hamiltonian one has to fix some additional gauge data. The gauge data consists of a rooted spanning tree and an order on the vertices. With this choice in place, each edge corresponds to a loop and we can represent an isometry associated to an edge by an element of the $C^*$–algebra $\mathcal{A}$ generated by the morphisms corresponding to the loops of $\bar{\Gamma}$ at a fixed base point, cf. §2.1.4. Via pull–back this also yields a matrix representation of the Hamiltonian in $M_k(\mathcal{A})$ where $k$ is the number of vertices of $\bar{\Gamma}$.

From the noncommutative geometry point of view the $C^*$–algebra $\mathcal{A}$ represents a space. If $\mathcal{A}$ is commutative (since $\mathcal{A}$ is unital) this space can be identified as a compact Hausdorff space $X$ such that the $C^*$–algebra of complex valued continuous functions $C^*(X)$ is isomorphic to $\mathcal{A}$. In the applications we consider $X$ is the momentum space, which in the commutative case is the $n$–dimensional torus $X = T^n = (S^1)^n$ and in the noncommutative case $\mathcal{A}$ is the noncommutative $n$–torus $\mathbb{T}_\Theta^n$ for a fixed value of $\Theta$, that in physical situations is given by a background B–field. See below §2.2.

Concrete extended symmetry groups are constructed via a lift of the action of the underlying graph symmetries $\text{Sym}(\bar{\Gamma})$ on this data as re–gaugings. The lift of the classical symmetries is rather complicated and proceeds in several steps:

1. We first establish that the different matrix realizations of the Hamiltonian given by choosing different rooted spanning trees and orders are all linked by gauge–transformations—see Theorem 3.3. The specific gauge transformations that arise form the re–gauging groupoid $G$. It acts transitively on the set of all the matrix Hamiltonians that can be obtained from the decorated graph by all different choices of data. Using category theory these realizations are just Kan–extensions given by pushing forward to the graph obtained by contracting the spanning tree.
(2) We then show that the gauge transformations can be represented as conjugation with matrices with coefficients in \( \mathcal{A} \). We prove that these matrices lead to a noncommutative 2–cocycle. This in turn gives rise to a groupoid extension of \( \mathcal{G} \). Geometrically this corresponds to a gerbe.

(3) In the commutative case (§3.5), we furthermore show that these matrices give a projective representation of the re–gauging groupoid. Just like in ordinary theory of projective representations this means that there is a bona fide representation of a central extension of this groupoid.

(4) In the commutative setup, if we fix a point \( p \in X \) and evaluate the matrix Hamiltonian with coefficients in \( \mathcal{A} \) at \( p \) we obtain a matrix Hamiltonian with coefficients in \( \mathbb{C} \) that we denote by \( H(p) \in M_k(\mathbb{C}) \). In this way we can think of \( X \) as the base of a family of finite dimensional Hamiltonians. Likewise, the re–gauging actions give a groupoid representation in matrices \( M_k(\mathbb{C}) \) which commute with \( H(p) \). The stabilizer groups of a particular fixed Hamiltonian are the sought after enhanced symmetry groups.

(5) For applications this leaves the problem of identifying the points \( p \) and the stabilizer groups or at least subgroups. To address the latter question, we establish that the automorphism group \( Sym(\bar{\Gamma}) \) of the graph induces re–gaugings, by pushing forward the spanning tree and the order of the vertices. In this way, the symmetries of the graph give rise to a sub–groupoid of \( \mathcal{G} \). Going through the construction outlined above, we can restrict to this sub–groupoid and see that at a fixed point of the re–gauging action we get a projective representation of the stabilizer subgroup which leads to possible higher dimensional irreps and thus band sticking.

(6) In order to identify points of \( X \) —which we take to be \( T^n \) for concreteness— where such enhanced symmetry groups can occur, we show that under certain assumptions, that hold in all cases of our initial physical interest, the operations of the symmetry group of the graph \( Sym(\bar{\Gamma}) \) via re–gaugings lift to an action on the base torus \( T^n \) (Theorems 3.10 and 3.15)\(^1\). At points \( t \in T^n \) with non–trivial stabilizer groups, we automatically get a projective representation of these stabilizer subgroups of the automorphism groups of the underlying graph, 

---

\(^1\)We say lift to the base here, since any action on the base gives rise to an action on the parameterized family of Hamiltonians, but it is not clear that any such action comes from one on the base.
which commutes with the Hamiltonian. Hence we get isotypical decom-
positions, which can give us non–trivial information about the spec-
trum using the arguments above.

We wish to point out that this approach is broader than that of con-
sidering classical symmetries of decorated graphs and in the commuta-
tive case generalizes the extensive analysis of [3], see §3.1 for details.

We apply all these considerations to the cases of the PDG wire net-
works and the honeycomb lattice; see §4. Here the graph Γ arises
physically as the quotient graph of a given (skeletal) graph Γ ⊂ ℝn
by a maximal translation group L ≃ ℤn. Each edge of the quotient
graph is decorated with a partial isometry operator of translation in
the direction of any lift of that edge to the graph Γ. The Harper
Hamiltonian is constructed from these isometries; in the simplest ver-
sion (tight-binding approximation), it is simply the summation over
them. This Hamiltonian along with the symmetries of the given ma-
terial are the main input into the noncommutative geometry machine,
which constructs a C∗–algebra that encodes relevant information about
the system out of this data.

One main objective is to analyze and understand the branching be-
havior or stated otherwise the locus of degenerate Eigenvalues. The
motivation is that in solid-state physics such degenerate Eigenvalues
may lead to novel electronic properties, as is the case, for instance,
with the Dirac points in graphene [4]. The key observations are that
(a) non–Abelian extended symmetry groups by themselves can force
degeneracies via higher dimensional –i.e. > 1– irreducible representa-
tions and (b) any enhanced symmetries, also Abelian ones, give rise to
super–selection rules. The latter ones can facilitate finding the spec-
trum considerably, since the Hamiltonian Eigenspace decomposition
has to be compatible with the isotypical decomposition of the repre-
sentation.

Complementary to this group theoretic approach there is another one
via singularity theory, which is contained in [5]. Our main result for
the PDG and honeycomb networks is that both approaches yield the
same classification of degeneracies in the commutative case. Namely,
at all degenerate points, which were analytically classified in [5], there
is an enhanced symmetry group arising from graph automorphisms
in the above way which forces the degeneracy. Here the surprising
fact is that we find all the degeneracies and degenerate points through
the projective representations of (subgroups of) Sym(Γ) given by re-
gaugings.

Here the G–wire network corresponding to the double Gyroid which
was our original motivator is the most interesting case. As shown in [5]
there are exactly two points with triple degeneracies and two points with degeneracy (2, 2), that is two doubly degenerate Eigenvalues. The automorphism group of the graph is $S_4$. The representation theory becomes very pretty in this case. There are two fixed points $(0, 0, 0)$ and $(\pi, \pi, \pi)$ on $T^3$ under the whole $S_4$ action. The projective representation is just the ordinary representation of $S_4$ by $4 \times 4$ permutation matrices at the point $(0, 0, 0)$ which is known to decompose into the trivial and a 3–dimension irreducible representation which forces the triple degeneracy. This result was also found by [3], where an initially different system was considered that results in the same spectrum.

At the point $(\pi, \pi, \pi)$ things become slightly more interesting. There is a projective representation of $S_4$, but we can show that this projective representation corresponds to an extension which is isomorphic to the trivial extension. Hence after applying the isomorphisms we have a representation of $S_4$ and there is a trivial and a 3-dim irrep, giving the second triple degeneracy. The elucidates the origin of the symmetry stated in [3]. Notice that the classical symmetries of decorated graphs would only yield an $S_3$ symmetry at this point, which cannot explain a triple degeneracy as there are no 3-dim irreps for this group.

Things really get interesting at the two points $(\pm \pi/2, \pm \pi/2, \pm \pi/2)$. Here the stabilizer group is $A_4$. The projective representation gives rise to an extension which we show to be isomorphic to the non–trivial double cover $2A_4$ of $A_4$ aka. $2T$, the binary tetrahedral group or $SL(2, 3)$. Using the character table we deduce that the representation decomposes into two 2–dim irreps forcing the two double degeneracies.

These are completely novel results. We wish to point out that one absolutely needs the double cover as $A_4$ itself has no 2-dim irreps and hence the projective extension is essential.

We also use the fact that the diagonal of $T^3$ is fixed by a cyclic subgroup $C_3$ of $A_4$ in order to determine the spectrum analytically. Here we use the super–selection rules.

For the D and honeycomb case, we show that the degenerate points which are well known in the honeycomb case and were computed for D in [6] are all detected by enhanced symmetries. These however yield Abelian representations and hence we have to use the arguments of the type (b), that is super–selection rules, to show that the Eigenvalues are degenerate over these points. Similar results to ours have now also been independently found for the D case in [7] using different methods.
2. General setup

In this section, we show how to construct the $C^*$-algebra $\mathcal{A}$ and the Hamiltonian $H \in M_k(\mathcal{A})$ mentioned in the introduction from a graph representation of a finite graph $\Gamma$ with $k$ vertices. Furthermore we embed a copy $\mathcal{A}$ into $M_k(\mathcal{A})$ and define $\mathcal{B}$ to be the subalgebra generated by $H$ and $\mathcal{A}$ under this embedding. The pair $\mathcal{A} \hookrightarrow \mathcal{B}$ is the basic datum for our noncommutative geometry.

2.1. Groupoid graph representations in separable Hilbert spaces.

Given a finite graph $\Gamma$ we define a groupoid representation of $\Gamma$, an association of a separable Hilbert space $\mathcal{H}_v$ for each $v \in V(\Gamma)$ and an isometry $U_{\vec{e}} : \mathcal{H}_v \to \mathcal{H}_w$ for each directed edge $\vec{e}$ from $v$ to $w$.

This data indeed determines a unique functor $(\mathcal{H}, U)$ from the path groupoid of $\Gamma$ to the category of separable Hilbert spaces. The path groupoid $\mathcal{P}_\Gamma$ (or $\mathcal{P}$ for short) of $\Gamma$ is category whose objects are the vertices of $\Gamma$ and whose morphisms are generated by the oriented edges, where the inverse of a morphism given by $\vec{e}$ is the one given by $\vec{e}$. Notice, that we are looking at the morphisms generated by the oriented edges, this means that $\text{Hom}_\mathcal{P}(v, w)$ is the set of paths along oriented edges from $v$ to $w$ modulo the relation that going back and forth along an edge is the identity. Composition is only allowed if the first oriented edge terminates at the beginning of the second oriented edge. This is why we only obtain a groupoid and not a group.

In particular, this lets one view the fundamental group $\pi_1(\Gamma, v_0)$ in two equivalent fashions. First as the topological $\pi_1$ of the realization of a graph, and secondly as the group $\text{Hom}_\mathcal{P}(v_0, v_0) = \text{Aut}(v_0)$ where $\text{Hom}_\mathcal{P}$ are the morphisms in the path groupoid $\mathcal{P}$.

The collection of automorphisms in $\mathcal{P}$ forms a subgroupoid $\mathcal{L}$. It is the disjoint union $\mathcal{L} = \coprod_{v \in V(\Gamma)} \pi_1(\Gamma, v)$. These are the classes of free loops on $\Gamma$.

2.1.1. Hamiltonian, symmetries and the $C^*$-geometries. Given a groupoid representation as above, set $\mathcal{H} = \bigoplus_{v \in V(\Gamma)} \mathcal{H}_v$ and define $H$ by

\begin{equation}
H = \sum_{\vec{e} \in E(\Gamma)} (U_{\vec{e}} + U_{\bar{e}}) \in B(\mathcal{H})
\end{equation}

where $B(\mathcal{H})$ is the $C^*$ algebra of bounded operators on $\mathcal{H}$.

We let $\mathcal{A}$ be the abstract $C^*$-algebra $\pi_1(\Gamma, v_0)$ generates in $B(\mathcal{H})$ via the representation. This is a bit subtle, as the concrete algebra
depends on the choice of base point $v_0$. We will use the notation $\mathcal{A}_{v_0} := U(\pi_1(\Gamma, v_0))$ to emphasize this.\footnote{Here and below for any subgroupoid $\mathcal{P}'$ of $\mathcal{P}$ we denote the $C^*$-subalgebra of $B(\mathcal{H})$ generated by the morphisms of $\mathcal{P}'$ via $U$ by $U(\mathcal{P}')$.}

Of course any two choices of a base vertex give isomorphic algebras but there is no preferred isomorphism between them. In the physical situation of wire networks, we are interested in §2.2, there is however a global identification of these algebras which comes from the embedding of the system into Euclidean space. Algebraically we realize this as extra coherence isomorphisms $\alpha_{v*} : \mathcal{A} \sim \rightarrow \mathcal{A}$ with inverse $\alpha_{v*}^{-1}$. The direct sum of the $\alpha_{v*}$ gives a representation $\alpha$ of $\mathcal{A}$ into $\tilde{\mathcal{A}} := \bigoplus_{v \in V(\bar{\Gamma})} \mathcal{A}_v \subset B(\mathcal{H})$. The algebra $\mathcal{B}$ is now the sub $C^*$-algebra generated by $H$ and $\alpha(\mathcal{A})$. We also set $\tilde{\mathcal{B}} = U(\mathcal{P}_{\Gamma 1}) \subset B(\mathcal{H})$.

The $C^*$-geometry we are interested in is the inclusion $\mathcal{A} \rightarrow \mathcal{B}$. We call the system commutative, if $\mathcal{B}$ (and hence $\mathcal{A}$) is commutative. We call the situation fully commutative if in addition for any all $v$ and $w$ and any contractible edges path $\gamma$ from $v$ to $w$ $\alpha_{v*}U_{\gamma}\alpha_{w*} = id$.

In the wire–network case, the condition to be fully commutative corresponds to the case of zero magnetic field.

**NOTATION:** If we choose a fixed base point $v_0$ we will tacitly use the isomorphism $\alpha_{v_0*}$ to identify $\mathcal{A}$ and $\mathcal{A}_{v_0}$.

### 2.1.2. Matrix Hamiltonian.

If we fix a rooted spanning tree and an order on the vertices, we can identify $\mathcal{H} \simeq \mathcal{H}^k_{v_0}$ via a unitary $U$ as follows and $H$ becomes equivalent to a matrix in $M_k(\mathcal{A})$.

A spanning tree $\tau$ is by definition a contractible subgraph of $\bar{\Gamma}$ which contains all the vertices of $\bar{\Gamma}$. It is rooted if one of the vertices is declared the root; denote it by $v_0$. In order to obtain a honest $k \times k$ matrix, we also have fix an order $<$ on all the vertices, where we insist that the root is the first vertex in this order. That is we fix a rooted ordered spanning tree $\tau := (\tau, v_0, <)$.

For each vertex $v$ of $\bar{\Gamma}$ there is a unique shortest path in $\tau$ to $v_0$. This defines a choice of fixed isomorphism $U_{v \tau v_0}^\tau : \mathcal{H}_{v_0} \rightarrow \mathcal{H}_v$ by translations along the edge path, see §3.2 for details. Assembling these maps gives the desired isomorphism $\mathcal{H} \simeq \mathcal{H}^k_{v_0}$. Pulling back $H$ to $\mathcal{H}_{v_0}^k$ using this isomorphism, we obtain a matrix version $H_\tau$ where we include the subscript to stress that this matrix depends on the choice of rooted ordered spanning tree $\tau$.

To fix the notation, which we will need later, we give the full details: let $v_i$ be the $i$–the vertex in the enumeration $<$. Then we obtain a
8 RALPH M. KAUFMANN, SERGEI KHLEBNIKOV, AND BIRGIT KAUFMANN

matrix $H_\tau$ by using the isomorphisms $U_{v_iv_0}^\tau$, which are defined as follows. Let $v_0, w_1, \ldots, w_k, v_i$ be the sequence of vertices along the unique shortest path $\gamma_{v_iv_0}^\tau$ from $v_0$ to $v_i$ in $\tau$, then

$$(2) \quad U_{v_iv_0}^\tau = U_{v_1w_1}U_{w_kw_{k-1}} \cdots U_{w_2w_1}U_{w_1v_0} = U(\gamma_{v_iv_0}^\tau)$$

and $U_{v_0v_i}^\tau = (U_{v_1v_0}^\tau)^*$. Given the choice of $\tau$, we get the corresponding matrix Hamiltonian as

$$(3) \quad H_\tau : \bigoplus_{i=1}^k \mathcal{H}_{v_0} \Theta_i U_{v_iv_0}^\tau \bigoplus_{i} \mathcal{H}_{v_i} \xrightarrow{H} \mathcal{H} = \bigoplus_{i} \mathcal{H}_{v_i} \Theta_i U_{v_0v_i}^\tau \bigoplus \mathcal{H}_{v_0}$$

Of course, all the $\mathcal{H}_\tau$ are equivalent, although not canonically. For the equivalence one has to choose a path from one root to the other. We will exploit this fact extensively below.

2.1.3. A weighted graph. After having fixed an initial spanning tree the matrix Hamiltonian has a different description. To each edge $e$ from $v$ to $w$, we can associate $wt(e) := U_{v0} U_e U_{v0} \in U(A)$. That is, we can regard $\Gamma$ as having a weight function on ordered edges with weights in $U(A)$. If $e$ is an edge of $\tau$ then with this definition $wt(e) = wt(e) = 1$.

An alternative way of viewing this data is as a certain type of quiver representation, we will comment on this more below.

2.1.4. Weights as a representation of the fundamental group. For any finite graph $\Gamma$ the Euler Characteristic is $\chi(\Gamma) = |V(\Gamma)| - |E(\Gamma)| = 1 - b_1$ where $b_1$ is the rank of $H_1(\Gamma)$ which is the same as the “number of loops”. More precisely, if $\Gamma$ is connected, $\pi_1(\Gamma) = \mathbb{F}_{b_1}$ that is the free group in $b_1$ generators. In the applications $b_1$ is the rank of the lattice of translational symmetries.

One way to view a rooted spanning tree $(\tau, v_0)$ is to think of it as fixing a base point $v_0$ and a set of symmetric generators/basis for $\pi_1(\Gamma, v_0) = Hom_\mathcal{F}(v_0, v_0)$. Topologically after contracting the spanning tree one is left with a wedge of $S^1$'s. There are $b_1$ of these, one for each non–contracted edge. Each simple loop around one of the $S^1$'s gives a generator. Picking one generator per loop gives a basis.

Without doing the contraction the correspondence on $\Gamma$ itself is given by all the (ordered) edges not contained in $\tau$. To each such ordered edge $e$ from $v$ to $w$, we associate the loop starting at $v_0$ going along $\tau$ to $v$ then traversing $e$ to $w$ and afterwards returning to $v_0$ along $\tau$. Again picking both orientations gives a symmetric set of generators of the free group while picking only one orientation per edge fixes a basis.
Any edge in the spanning tree corresponds to the unit, that is the class of a constant loop.

In this language, the weight function \( wt \) is a representation of \( \pi_1 \) lifted to the edges of the graph by the above correspondence. Thus, as long as the base point \( v_0 \) stays fixed, the changes of spanning tree can be viewed as a change–of–basis of \( \pi_1(\Gamma, v_0) \). If \( v_0 \) moves, say to \( v'_0 \), then, as usual, any path from \( v'_0 \) to \( v_0 \) gives an isomorphism taking \( \pi_1(\Gamma, v'_0) \) to \( \pi_1(\Gamma, v_0) \). Both types of isomorphisms will play a role later in the symmetry group actions.

### 2.1.5. Non–degeneracy and toric non–degeneracy.

We call a groupoid representation non–degenerate, if the images of the basis of the free group given by the construction above are independent unitary generators of \( \mathcal{A} \) and call it toric non–degenerate if \( \mathcal{A} \) is isomorphic to the noncommutative torus \( T_{b_1}^{b_1} \).

Notice that if \( \mathcal{A} \) is commutative and non–degenerate, then \( \mathcal{A} \cong T_{b_1}^{b_1} \), the \( C^* \) algebra of the torus of dimension \( b_1 \).

### 2.1.6. Hamiltonian and \( \mathcal{A} \) from a weighted graph.

Alternatively to starting with a groupoid representation one can also start with an \( \mathcal{A} \)–weighted graph. It is in this representation that we can understand the re–gauging groupoid \( G \).

Fix a finite connected graph \( \bar{\Gamma} \), a rooted ordered spanning tree \( \tau \) of \( \bar{\Gamma} \) such that the root of \( \tau \) is the first vertex, a unital \( C^* \) algebra \( \mathcal{A} \), and a morphism \( wt : \{ \text{Directed edges of } \Gamma \} \to \mathcal{A} \) which satisfies

1. \( wt(\overrightarrow{e}) = wt(\overleftarrow{e})^* \) if \( \overrightarrow{e} \) and \( \overleftarrow{e} \) are the two orientations of an edge \( e \).
2. \( wt(\overrightarrow{e}) = 1 \in \mathcal{A} \) if the underlying edge \( e \) is in the spanning tree.

In general, if \( wt \) is as above and it satisfies the first condition, we will call it a weight function (with values in \( \mathcal{A} \)) and if it satisfies both conditions, a weight function compatible with the spanning tree.

Fix a separable Hilbert space \( \mathcal{H}_{v_0} \). By Gel’fand Naimark representability we realize \( \mathcal{A} \subset B(\mathcal{H}_{v_0}) \) and we shall use this representation.

We shall also postulate that \( \mathcal{A} \) is minimal, which means that it is the \( C^* \)–algebra generated by the \( wt(\overrightarrow{e}) \) where \( \overrightarrow{e} \) runs through the directed edges of \( \bar{\Gamma} \). This makes the terminology of §2.1.5 applicable. Also, we see that this is again just a lift of a representation of \( \pi_1(\bar{\Gamma}, v_0) \) to the edges of \( \bar{\Gamma} \) using the spanning tree \( \tau \).

Given this data, let \( k \) be the number of vertices of \( \Gamma \). We will enumerate the vertices \( v_0, \ldots, v_{k-1} \) according to their order; \( v_0 \) being the
root. Given this data, the Hamiltonian \( H = H(\Gamma, \tau, w) \) is the matrix \( H = (H_{ij})_{ij} \in M_k(\mathcal{A}) \) whose entries are:

\[
H_{ij} = \sum_{\text{directed edges } e \text{ from } v_i \text{ to } v_j} \text{wt}(e)
\]

It acts naturally on \( \mathcal{H} := \mathcal{H}_0^k \). In this sense, the weighted graph encodes both the Hamiltonian and the symmetry algebra \( \mathcal{A} \).

In the general noncommutative case, this is not quite enough for the whole theory, as we do not recover the action of \( \mathcal{A} \) on \( \mathcal{H} \) and the connection between the action of \( H \) and that of \( \mathcal{A} \). Recall that the action of \( \mathcal{A} \) on \( \mathcal{H} = \mathcal{H}_v^k = \bigoplus_{v \in V(\Gamma)} \mathcal{H}_{v_0} \) is given on each summand \( \mathcal{H}_{v_0} \) corresponding to \( v \) by pulling back the action from \( \mathcal{H}_v \). That is, the true action is a conjugated action.

In the commutative case this is not an issue as the representation is exactly the diagonal representation.

2.1.7. Geometry in the commutative case. If \( \mathcal{B} \) is commutative (and hence also \( \mathcal{A} \)),\(^3\) then there is a geometric version of these algebras which can be understood as the spectra of a family of Hamiltonians over a base. We have the following inclusion of commutative \( C^* \) algebras \( i : \mathcal{A} \hookrightarrow \mathcal{B} \), by Gel’fand Naimark this gives us a surjection of compact Hausdorff spaces\(^4\) \( \pi : Y \to X \) where \( C(X) \simeq \mathcal{A} \) and \( C(Y) \simeq \mathcal{B} \). The correspondence is given via characters. Namely a character is a \( C^* \)–homomorphism \( \chi : \mathcal{A} \to \mathbb{C} \). The characters are by definitions the points of \( X \). Vice–versa any point \( t \in X \) determines a character \( \text{ev}_t : C^*(X) \to \mathbb{C} \) via evaluation. That is any \( f \in C^*(X) \) is sent to \( f(t) \in C \). Given a character \( \chi \) on \( \mathcal{A} \), we can lift it to a \( C^* \)–morphism \( \hat{\chi} : M_k(\mathcal{A}) \to M_k(\mathbb{C}) \) by applying it in each matrix entry.

Thus any point \( t \in X \) represented by the character \( \chi \) determines a Hamiltonian \( \hat{\chi}(H) \in M_k(\mathbb{C}) \) via \( \hat{\chi} \).

\[
(\hat{\chi}(H))_{ij} = \chi(H_{ij})
\]

Thus we get a family of Hamiltonians \( H(t) \) parameterized over the base. One can furthermore check, see [2], that \( \pi \) is a branched cover over \( \mathcal{A} \) with \( \pi^{-1}(t) = \text{spec}(H(t)) \).

2.2. Physical example: PDG and honeycomb wire networks. The PDG examples are based on the unique triply periodic CMC surfaces where the skeletal graph is symmetric and self–dual. Physically, in the P (primitive), D (diamond) and G (Gyroid) case, one starts with

\(^3\)This is for instance the case in the applications if the magnetic field vanishes.

\(^4\)Both \( \mathcal{A} \) and \( \mathcal{B} \) are unital.
a “fat” or thick version of this surface, which one can think of as an interface. A solid-state realization of the “fat” Gyroid aka. double Gyroid has recently been synthesized on the nano–scale [1]. The structure contains three components, the “fat” surface or wall and two channels. Urade et al. [1] have also demonstrated a nanofabrication technique in which the channels are filled with a metal, while the silica wall can be either left in place or removed. This yields two wire networks, one in each channel. The graph we consider and call Gyroid graph is the skeletal graph of one of these channels. The graph Hamiltonian we construct algebraically below is the tight-binding Harper Hamiltonian for one channel of this wire network. The 2d analogue is the honeycomb lattice underlying graphene. Graph theoretically the quotient graph for the honeycomb is the 2d version of that of the D surface, but as we showed, the behavior, such as the existence of Dirac points [5], is more like that of the Gyroid surface.

To formalize the situation, we regard the skeletal graph of one channel as an embedded graph $\Gamma \subset \mathbb{R}^n$. The crystal structure gives a maximal translational symmetry group $L$ which is a mathematical lattice, i.e. isomorphic to $\mathbb{Z}^n$, s.t. $\bar{\Gamma} := \Gamma / L$ is a finite connected graph. The vertices of this quotient graph are the elements in the primitive cell.

The Hilbert space $\mathcal{H}$ for the theory is $\ell^2(V(\Gamma))$, where $V(\Gamma)$ are the vertices of $\Gamma$. This space splits as $\bigoplus_{v \in V(\bar{\Gamma})} \mathcal{H}_v$ where for each vertex $v \in V(\bar{\Gamma})$, $\mathcal{H}_v = \ell^2(\pi^{-1}(v))$ where $\pi : \Gamma \to \bar{\Gamma}$ is the projection. All the spaces $\mathcal{H}_v$ are separable Hilbert spaces and hence isomorphic. Furthermore if $\vec{e}$ is a directed edge from $v$ to $w$ in $\bar{\Gamma}$ then it lifts uniquely as a vector to $\mathbb{R}^n$, which we denote by the same name. Moreover for each such vector there is a naturally associated translation operator $T_{\vec{e}} : \mathcal{H}_v \to \mathcal{H}_w$, by the usual action of space translations on functions. We also allow for a constant magnetic field $B = 2\pi \hat{\Theta}$ where $\hat{\Theta} = \sum \theta_{ij} dx_i \wedge dx_j$ is a constant 2–form given by the skew–symmetric matrix $\Theta = (\theta_{ij})_{ij}$. If $\Theta \neq 0$ then the translations become magnetic translations or Wannier operators $U_{\vec{e}} : \mathcal{H}_v \to \mathcal{H}_w$; see e.g. [8]. These operators are still unitary and give partial isometries when regarded on $\mathcal{H}$ via projection and inclusion, which we again denote by the same letter. The Harper Hamiltonian is then defined by equation (1).

Likewise $L$ acts by magnetic translations. If $\vec{\lambda}$ is a vector in $L$ then $U_{\vec{\lambda}}$ sends each $\mathcal{H}_v$ to itself and the diagonal action gives an action on $\mathcal{H}$. Since $L$ is a lattice, the representation it generates is given by $n$ linearly independent unitaries. The commutation relations among the Wannier operators amount to the fact that the representation is
a copy of $T^n_\Theta$, the noncommutative $n$–torus, see [2] or [8]. The direct
sum yields the global symmetry representation $\alpha : T^n_\Theta \to B(H)$. This
representation and $H$ by definition generate the Bellissard-Harper $C^*$–
algebra $\mathcal{B}$.

We see that this is an example of the general setup where the groupoid
representation of $\bar{\Gamma}$ is given by the $U_\mathcal{A}$. Here $\mathcal{A} = T^n_\Theta$ and the Hamiltonian
associated to the graph is the Harper Hamiltonian. If $B = 0$ then the situation is fully commutative. Notice that $\mathcal{A}$ being commu-
tative just means that the fluxes though the $L$ lattice are 0. If $\mathcal{B}$ is
commutative, this means the the fluxes cancel according to the entries
of $H$. If there are vertices with more than one edge, potentially the
situation is commutative, but not fully commutative.

3. Symmetries

In order to deal with the symmetries of the graph it is helpful to first
fix the notation as sometimes questions become subtle.

3.1. Classical Symmetries. A graph $\Gamma$ is described by a set of ver-
tices $V_\Gamma$ and a set of edges $E_\Gamma$ together with incidence relations $\partial$ where
for each edge $e$, $\partial(e) = \{v, w\}$. is the unordered set of the two vertices it
is incident to. A directed edge is given by an order on this pair. Hence
for each edge $e$ there are two ordered edges by the orders $(v, w)$ and by
$(w, v)$. We usually denote these two edges by $\overrightarrow{e}$ and $\overleftarrow{e}$. The set of all
oriented edges is called $E^\sigma_\Gamma$.

An isomorphism $\phi$ of two graphs $\Gamma$ and $\Gamma'$ is a pair of bijections
$(\phi_V, \phi_E) : V_\Gamma \to V_{\Gamma'}$ and $\phi_E : E_\Gamma \to E_{\Gamma'}$. The compatibility is
that the incidence conditions are preserved, i.e.: if $\partial(e) = \{v, w\}$ then
$\partial(\phi_E(e)) = \{\phi_V(v), \phi_V(w)\}$. Notice the $\phi$ also induces a map of ori-
ented edges, the orientation of the edge $\phi_E(e)$ given by $(\phi_V(v), \phi_V(w))$,
if the orientation of $e$ is $(v, w)$.

We will treat isomorphism classes of graphs from now on. Fixing an
isomorphism class of a graph still allows for automorphisms. These are
given as follows. Fix a representative of $\Gamma$ then an automorphism is a
pair of compatible maps $(\phi_V, \phi_E); \phi_V : V_\Gamma \to V_{\Gamma}$ and $\phi_E : E_\Gamma \to E_{\Gamma}$.

Example 3.1. Let us illustrate this for the graphs corresponding to
the PDG and honeycomb cases which are given in Figure 1; see §2.2
for details about the corresponding wire networks. We fix once and
for all an isomorphism class of these graphs and then consider their
automorphisms using the representatives given in the figure.
For the P case there is only one vertex hence $\phi_V = id$ is the only possibility. However there is an $S_3$ action permuting the three loop edges.

The D graph has the possibility of switching the two vertices and freely permuting the three edges. This gives the automorphism group $\mathbb{Z}/2\mathbb{Z} \times S_3$. The honeycomb similarly has automorphism group $\mathbb{Z}/2\mathbb{Z} \times S_3$.

For the Gyroid, there is an $S_4$ worth of potential choices for $\phi_V$. Now all these choices extend uniquely to the edges, since there is exactly one edge between each distinct pair of vertices and hence the symmetry group is exactly $S_4$.

3.1.1. Pushing forward Spanning Trees. Given a pair $(\Gamma, \tau)$ of a graph and a rooted spanning tree, we define the action of isomorphisms and automorphisms by push–forward. That is an isomorphism between $(\Gamma, \tau)$ and $(\Gamma', \tau')$ is an isomorphism from $\Gamma$ to $\Gamma'$ such that $\phi_V$ maps the root of $\tau$ to the root of $\tau'$ and $\phi$ restricted to $\tau$ is an isomorphism onto $\tau'$.

If we have not already specified a spanning tree on $\Gamma'$ we can extend any isomorphism $\phi$ from $(\Gamma, \tau)$ to it by push–forward. This means that we push–forward all the vertices and the edges of the spanning tree $\tau$ to $\Gamma'$: $E_{\tau'} := \phi_E(E_{\tau})$ and likewise push–forward the root.

In particular, $Aut(\Gamma)$ acts on the set of spanning trees of a fixed graph $\Gamma$. This action is not transitive in general and may have fixed points.

Example 3.2. In the cases of PDG and the honeycomb, it is a transitive action.

For the G graph the action is not fixed point free, there is an $S_3$ subgroup fixing a given spanning tree.

For the P graph the action is fixed point free, while for the D and the honeycomb although the action is transitive, there are again stabilizers.

For the honeycomb the group fixing a spanning tree is the $S_2 = \mathbb{Z}/2\mathbb{Z}$ interchanging the two other edges, with both vertices fixed, while in
the D case it is an $S_3$ action interchanging the edges which are not part of the spanning tree.

As an example of a non–transitive action consider the triangle graph, with one edge doubled. That is three vertices 1, 2, 3 with one edge between 1 and 2, one edge between 1 and 3 and two edges between 2 and 3.

3.1.2. Orders, Weight Functions and Isomorphisms. If there is an order on all the vertices then the isomorphisms are asked to be compatible with this order and auto– and isomorphisms can be extended by pushing forward the order.

A final piece of data on a graph, which we utilize is the $C^*$ algebra valued map $wt : E \to A$, such that $wt(\overleftarrow{e}) = wt(\overrightarrow{e})^*$. In our case of interest $A = T_0^\infty$, and even $T_0^0$ later, but for now we will keep the abstract setting.

Notice that a given weight function might not be compatible with the new, pushed–forward spanning tree, since it does not necessarily satisfy the condition (2). The idea of re–gauging is to re–establish condition (2) by passing to an equivalent, re–gauged weight function.

One way to see the failure to preserve the condition (2) of § 2.1.6 is to view the change of spanning tree as a change of basis of $\pi_1$ or rather an isomorphism of $\pi_1$s via the path–groupoid. This point of view is at the basis of the proof of Theorem 3.10 below.

3.1.3. Classical vs. extended symmetries. There is another natural choice of iso– or automorphism for graphs with weight functions. Here one would postulate that the weight functions are compatible. Weight functions naturally pull back via $\phi_E$, that is $\phi_E^* (w(e)) = wt(\phi_E(e))$. Using that $\phi_E$ is an isomorphism, one can push–forward by pulling back along $\phi_E^{-1}$.

One could call these symmetries classical symmetries of the weighted graph. These are the kinds of symmetries that were for instance considered by [3].

We will consider symmetries of the underlying graph, not of the weighted graph. The weights are taken care of by re–gauging. One way to phrase this is that we utilize an extended symmetry group which allows for phase factors at the vertices. The details are given below.

3.2. Gauging. We will now consider the relationship between the different matrices $H_\tau$ and $H_{\tau'}$ for different gauging data, which represent $H$ via different isomorphisms. Here and in the following we use the notation: $\tau = (\tau, v_0, <)$, $\tau' = (\tau', v'_0, <')$, etc.
There are basically three situations: First, $\tau = \tau'$ as rooted trees and only the order changes. Secondly, $\tau = \tau'$ but $v_0 \neq v'_0$ and thirdly, the trees just do not coincide, i.e. at least one edge is different. In the first case the isomorphisms are simply changed by permutations of the factors $H_{v_0}$. This means that the difference between the two matrix Hamiltonians is simply conjugation by $M_{\sigma}$, the standard permutation matrix. Since $v_0$ is fixed to be the first element, the permutation actually lies in the subgroup $S_{k-1} \subset S_k$ fixing the first element. $S_{k-1}$ then acts simply transitively on the orders.

In the second and third case, the situation is more complicated. Of course the second type of change is related to an action of $S_k$, but things are not that simple, since there is a change of the space that $H_{\tau'}$ acts on. If the tree moves, then we have to also change the weight functions to make them compatible with the new spanning tree.

Taking the point of view of $\pi_1$’s the first type of transformation is just a permutation of the basis. But when we move the base point, we move to an isomorphic group. In doing this, we effectively use the path groupoid and not just the fundamental group.

3.2.1. Gauging in groupoid representations. As discussed in §2.1 the Harper Hamiltonian before fixing a spanning tree can be thought of as a certain type of groupoid representation.

For such representation, we can re–gauge it to an equivalent representation by acting with any of choice automorphisms of the $H_v$, that is the group $\times_{v \in \Gamma} Aut(H_v)$. Picking an element $\phi$ in this group is the same as the assignment $v \mapsto \phi(v) \in Aut(H_v)$. The operators $U_{e} : H_v \rightarrow H_w$, where $e = (v, w)$ get re–gauged to $\phi(w)U_{e}\phi^{-1}(v)$. Again, one has to be careful with the indexing of the direct sums. Since there is no natural order, there is a natural $S_k$ action by permutations this interacts with the diagonal re–gaugings via the wreath product.

In our situation, since we have Hilbert spaces, we can look at unitary equivalences and restrict the automorphisms to be unitary. Note that the gauge group is smaller than the full group of unitary equivalences $U(H)$. Also, choosing an identification of all the isomorphic separable Hilbert spaces $H_v$ with some fixed $H_{v_0}$ we can take the re–gaugings to live in the unitary operators on $H_{v_0}$.

In this situation, the gauge group becomes $G = U(\mathcal{A})^k \wr S^k$. It acts on the orders, the weight functions and on the Hamiltonians by conjugation and permutation just as above.
3.2.2. Spanning tree re-gauging.

**Proposition 3.3.** Given two ordered rooted spanning trees $\tau$ and $\tau'$ there is a matrix $M \in M_k(\mathcal{A})$ with $MM^* = M^*M = id$ such that $MH_\tau M^* = U^\tau_{v_0v_0'}H_{\tau'}U^\tau_{v_0v_0'}$. Moreover $M$ is an element of the gauge group.

**Proof.** Consider the commutative diagram:

\[ \begin{array}{cccc}
\bigoplus_{i=1}^k \mathcal{H}_{v_0} & \xrightarrow{\bigoplus_{i} U^\tau_{v_0v_0'}} & \bigoplus_{i} \mathcal{H}_{v_i} & \xrightarrow{H} \mathcal{H} = \bigoplus_{i} \mathcal{H}_{v_i} & \xrightarrow{\bigoplus_{i} U^\tau_{v_i0}} & \bigoplus_{i} \mathcal{H}_{v_0} \\
\bigoplus_{i=1}^k \mathcal{H}_{v_0} & \xrightarrow{\bigoplus_{i} U^\tau_{v_0v_i'}} & \bigoplus_{i} \mathcal{H}_{v_i'} & \xrightarrow{\sigma} \mathcal{H} & \xrightarrow{\sigma} \bigoplus_{i} \mathcal{H}_{v_i'} & \xrightarrow{\bigoplus_{i} U^\tau_{v_i'v_0}} & \bigoplus_{i} \mathcal{H}_{v_0} \\
\end{array} \]

We see that if $i' = \sigma(i)$ and $j' = \sigma(j)$ so that $v_i' = v_j$: \[(H_{\tau'})_{i'j'} = U^\tau_{v_0v_0'}H_{v_i'v_j'}U^\tau_{v_j'v_0} \]
\[ = U^\tau_{v_0v_0'}(U^\tau_{v_0v_i'}U^\tau_{v_i'v_j'}U^\tau_{v_j'v_0})(U^\tau_{v_0v_i'}U^\tau_{v_i'v_j'}U^\tau_{v_j'v_0})U^\tau_{v_0v_0'} \]
\[ = U^\tau_{v_0v_0'}\Phi^*_\sigma(H_{\tau})_{ij}\Phi^*_j U^\tau_{v_j'v_0} \]

With $\Phi^*_\sigma = U^\tau_{v_0v_j'}U^\tau_{v_j'v_i'}U^\tau_{v_i'v_0} \in U(\mathcal{A})$. So that if $\Phi = diag(\Phi^*_\sigma)$ and $M_\sigma$ is the permutation matrix of $\sigma$ which moves the order $< \rightarrow <'$ then $M = \Phi^*M_{\sigma^{-1}}$ and $M^*M = id$. \hfill \Box

We choose to place $M$ on the left of the Hamiltonian so as to get a left action later on.

**Remark 3.4.** Unraveling the definition given in equation (2), we can express the matrix $\Phi$ as a re-gauging by the following iterative procedure. We start at the root of $\tau'$ and choose $\phi(v_0') = id$. Assume we have already assigned weights to all vertices at distance $i$ from $v_0'$ and let $w$ be a vertex at distance $i+1$. Then there a unique $v$ at distance $i$ which is connected to $w$ along a unique directed edge $\vec{e}$ of the spanning tree $\tau'$. Set $\phi(w) = wt(\vec{e})\phi(v) \in U(\mathcal{A})$. Then $\Phi = diag_{v \in \tau'}(\phi(v'))$.

Of course the form of $M$ depends on the initial choice of $\phi(v_0) = id$, which amounts to using the iso $U^\tau_{v_0v_0'}$ to pull-back the matrix. Any other choice of iso will differ by an element of $\mathcal{A}$ which is then the value of $\phi$ on $v_0$. This plays a crucial role later.

3.2.3. Commutative case. Reduced gauge group. In the commutative case, we can fix a character $\chi: \mathcal{A} \rightarrow \mathbb{C}$ and then under $\chi$ all matrices become $U(1)$ valued and all the Hilbert spaces $\mathcal{H}_v$ become identified.
with \( \mathbb{C} \). In this case, we can identify the gauge group action with an action of \( U(1)^{\times V_E} \) on \( U(1) \)-valued weight functions, using \( \lambda = \chi \circ \phi \).

For every oriented edge \( \vec{e} \) from \( v \) to \( w \) the re-gauged weights are

\[
wt'(\chi(\vec{e})) := \lambda(v) \chi(wt(\vec{e})) \bar{\lambda}(w)
\]

Notice that we have taken the indexed unordered product. If we fix an order of the vertices, then the group \( S_k \) acts on the vertices as well and the full gauge group which acts on the Hamiltonians by conjugation is the wreath product \( G = U(1) \wr S_k \).

We see that the constant functions \( \lambda \) act trivially and hence to get a more effective action we can quotient by the diagonal \( U(1) \) action and consider the reduced gauge group \( \bar{G} := G/U(1) \), where \( U(1) \) is diagonally embedded in \( U(1)^k \) and \( S_k \) acts trivially.

Abstractly \( U(1)^k/U(1) \simeq U(1)^{k-1} \), to make this explicit, we can choose a section of \( \bar{G} \rightarrow G \). Our choice \( \phi(v_0) = 1 \) is just such a choice of a section. The action of \( S_k \) on the remaining \( k-1 \) factors is then more involved, however. It is still a semi-direct product, but not a wreath product any more. This has practical relevance in the Gyroid case.

The proof of the theorem above then boils down to the fact that a rooted spanning tree uniquely fixes a unique gauge transformation as follows. We let \( \lambda(\text{root}) = 1 \) by the global gauge \( U(1) \). Now the weight on each vertex of the tree is fixed iteratively by the condition that \( \lambda wt(e) = 1 \). The whole set of weights then gives a diagonal unitary matrix and taking the product with the appropriate permutation, we obtain the matrix \( M \).

### 3.3. Re-gauging groupoid \( \mathcal{G} \), representations, cocycles and extensions

In order to keep track of all the re-gaugings and ultimately find the extended symmetries, we introduce the following abstract groupoid \( \mathcal{G} \). It has rooted ordered spanning trees \( \tau \) of \( \bar{\Gamma} \) as objects and a unique isomorphism between any two such pairs. If the two pairs coincide, the isomorphism is the identity map.

Having fixed the representation \( (\mathcal{H}, U) \), there is an induced representation \( \rho \) of \( \mathcal{G} \) which also takes values in separable Hilbert spaces. On objects it is given by \( \rho(\tau) = \mathcal{H}^{v_0}_{v_0} \), \( v_0 \) being the base point of \( \tau \). For a re-gauging morphism \( g : \tau \rightarrow \tau' \) we set \( \rho(g) = \mathcal{H}^{v_0}_{v_0} U_{v_0}^{\tau'} \) for the \( M \) of Proposition 3.3. Plugging into the definitions one checks that indeed \( \rho(g) \rho(h) = \rho(gh) \) for composable \( g \) and \( h \).

In order to find the symmetry groups, we will however need to consider only the matrix “\( M \)” part of \( \rho \). This is not a representation, but
gives rise to a noncommutative 2–cocycle and moreover, this cocycle can be lifted to the groupoid level.

3.4. **Induced structures and cocycles.** To understand the cocycle, let us first consider the “U”–part of ρ. For this we notice that there is a functor \( p : P_G \to P_{\Gamma} \) from the path space of \( G \) to that of \( \Gamma \). It is given by \( p(\tau) = v_0 \) and \( p(\tau \xrightarrow{g} \tau') = \gamma_{v_0}^\tau \), the shortest path of §2.1.2. We can now compose with \( (\mathcal{H}, U) \) and obtain \( \nu := p \circ (\mathcal{H}, U) \) on objects and morphisms. I.e. for \( g : \tau \to \tau' \) we have \( \nu(g) = U_{v_0}^\tau : \mathcal{H}_{v_0} \to \mathcal{H}_{v_0} \).

This is not a representation of \( G \), but for \( g \) as above and \( h : \tau' \to \tau'' \) it satisfies

\[
\nu(h)\nu(g) = \nu(hg)C^{-1}(h, g), \quad \text{with} \quad C^{-1}(h, g) := U_{v_0}^\tau \nu U_{v_0}^\tau \nu U_{v_0}^\tau : \pi_1(\Gamma, v_0)
\]

For the \( M \) part of \( \rho \) the relevant cocycle will actually be the inverse of \( C^- \), see also §3.4.2 below. Explicitly, \( C(h, g) = C^{-1}(h, g)^{-1} = U_{v_0}^\tau U_{v_0}^\tau U_{v_0}^\tau \). For three composable morphisms \( \tau \xrightarrow{g} \tau' \xrightarrow{h} \tau'' \xrightarrow{k} \tau''' \) one obtains the following equation for \( C \) by plugging in:

\[
C(h, g)C(k, h) = \nu(g)^{-1}\nu(h)^{-1}\nu(k)^{-1}\nu(khg) =: C(k, h, g)
\]

And if we denote conjugation of \( x \) by \( y \) with an upper left index \( yx = xy^{-1} \) to keep with standard notation [10, 11], we find the cocycle equation

\[
\nu(g)^{-1}C(k, h)C(kh, g) = C(h, g)C(k, hg)
\]

One can also lift the cocycle \( C \) to a cocycle \( l \) with values in \( \mathcal{L} \).

\[
l(h, g) = \gamma_{v_0}^\tau \gamma_{v_0}^{\tau'} \gamma_{v_0}^{\tau''} \in \pi_1(\Gamma, v_0)
\]

it satisfies the analogous equation to (8) with \( \nu \) replaced by \( p \). We have \( p(l(h, g)) = C(h, g) \).

3.4.1. **Matrix version and cocycle.** In order to do calculations it is preferable to work with a matrix representation of the groupoid action. The problem is that although the groupoid associates a matrix to each re–gauging, these matrices all act in different spaces. To make everything coherent one has to use pull–backs. Explicitly, for \( \tau \xrightarrow{g} \tau' \) we set \( Mat(g) := M_g := M \in \mathcal{A}_{v_0} \) of Proposition 3.3. If we have another regauging \( \tau' \xrightarrow{h} \tau'' \) then we cannot directly multiply the matrices \( M_g \) and \( M_h \) as they have coefficients in different algebras. We therefore
define the product\( M_h \circ_\tau M_g := U_{v_0 v_0}^\tau M_h U_{v'_0 v_0}^\tau M_g \).\(^5\) A straightforward calculation shows:

**Proposition 3.5.** \( M_h \circ_\tau M_g = C(h, g) M_{hg} \) with the same cocycle \( C(h, g) \) as above. \( \square \)

Again, by a straightforward calculation:

**Lemma 3.6.** If \( \mathcal{A} \) is commutative, then the product is independent of the choice of pull–back \( U_{v_0 v_0}^\tau \). Defining the product by using conjugation by any \( U(\gamma) \) with \( \gamma \) a contractible path from \( v_0 \) to \( v'_0 \) will give the same result. \( \square \)

**Corollary 3.7.** If the situation is fully commutative, we can use the \( \alpha(v) \) to pull back all the matrices \( M_g \) to matrices with coefficients in \( \mathcal{A} \). Then the multiplication above simply becomes matrix multiplication in \( M_k(\mathcal{A}) \). \( \square \)

3.4.2. Groupoid cocycles and extension. The data of \( \nu \) and \( C \) as well as \( p \) and \( l \) technically yield a crossed noncommutative groupoid 2-cocycle \([10–12]\). In order to get one of the standard forms of the cocycle, e.g. that of \([10]\), we will have to transform the pairs \((p, l)\) and \((\nu, C)\) a bit. It turns out that everything is more natural in the opposite groupoid \( \Gamma^\text{op} \) of the groupoid \( \Gamma \). This is because we are actually re–gauging. On the groupoid level define \( p^\text{op} : \mathcal{G}^\text{op} \times 1 \to \hat{G} \) and \( C^\text{op} : \mathcal{G}^\text{op} \times \mathcal{G}^\text{op} \to \hat{A} \)

\[
(11) \quad p^\text{op}(g^\text{op}) := \gamma^\tau_{v_0 v_0}^\tau, \quad l^\text{op}(g^\text{op}, h^\text{op}) := l(h, g)
\]

And similarly hitting the above maps with \((H, U)\) we get \( \nu^\text{op} : \mathcal{G}^\text{op} \to \hat{B} \) and \( C^\text{op} : \mathcal{G}^\text{op} \times \mathcal{G}^\text{op} \to \hat{A} \)

\[
(12) \quad \nu^\text{op}(g^\text{op}) := \nu(g)^{-1}, \quad C^\text{op}(g^\text{op}, h^\text{op}) := C(h, g)
\]

Now \( \mathcal{L} \) is a \( \mathcal{P}_\Gamma \) crossed module via the inclusion \( i : \mathcal{L} \to \mathcal{P}_\Gamma \) and the conjugation action \( \Phi : \mathcal{P}_\Gamma \times \mathcal{L} \to \mathcal{P}_\Gamma : (\gamma, l) \mapsto \gamma l \gamma^{-1} \). Analogously \( \hat{A} \) is a \( \hat{B} \) crossed module via inclusion and conjugation action.

**Proposition 3.8.** The pair \((p^\text{op}, l^\text{op})\) are an element of \( C^2(\mathcal{P}_\Gamma, \mathcal{G}, \mathcal{L}) \) that is a \( \mathcal{P}_\Gamma \)–crossed \( \mathcal{G} \) 2–cocycle with values in \( \mathcal{L} \). Likewise the pair \((\nu^\text{op}, C^\text{op})\) are an element of \( C^2(\hat{B}, \hat{A}) \).

**Groupoid extension:** By general theory, \([10,12,13]\) the noncommutative cocycle \((p, l)\) gives rise to a groupoid extension \((\Sigma, b)\) over \( \mathcal{P}_\Gamma \)

\[
(13) \quad \Sigma : 1 \to \mathcal{L} \to \hat{G} \to \mathcal{G} \to 1 \quad b : \hat{G} \to \mathcal{P}_\Gamma
\]

\(^5\)Notice that here \( U_{v_0 v_0}^\tau \) is taken to be a “scalar” that is it acts as the \( k \times k \) diagonal matrix \( \text{diag}(U_{v_0 v_0}^\tau, \ldots, U_{v_0 v_0}^\tau) : \mathcal{H}_{v_0}^k \to \mathcal{H}_{v_0}^k \).
Remark 3.9. It is this extension via $\text{Mat}$ that gives rise to the projective representation of $\text{Sym}(\Gamma)$ in the commutative case. In the non-commutative case, the geometry begins to look like a gerbe geometry. This fits with the non-commutativity being given by a 2-form $B$–field. We leave this for further study.

3.4.3. Categorical description of the Matrix Hamiltonians and re–gauging. The constructions we have presented have a more high–brow explanation. Each spanning tree $\tau$ gives a functor from $F_{\tau}: \mathcal{P}\Gamma \rightarrow \mathcal{P}_{\Gamma/\tau}$, where $\Gamma/\tau$ is result of contracting $\tau$ and is the graph with one vertex $\bullet$ and $k$ loops $l_i$. Given a functor $(\mathcal{H}, U)$ we can look at all the left Kan–extensions $\text{Lan}_\tau(\mathcal{H}, U): \mathcal{P}_{\Gamma/\tau} \rightarrow \text{Hilb}$, where $\text{Hilb}$ is the category of separable Hilbert spaces. In Particular $\mathcal{H}$ becomes just $\mathcal{H}(\bullet)$. The action of the $l_i$ is then the action of the diagonal of $\tilde{A}$ obtained by pushing forward $\mathcal{A}_{v_0}$ from a common vertex $v_0$. In the fully commutative case this coincides with the action of $\mathcal{A}$.

The re–gauging groupoid compares all the functors obtained by the different left Kan extensions.

3.4.4. Re–gaugings Induced by Graph Symmetries. If we have a symmetry, aka. automorphism, of the graph $\Gamma$, then given a fixed choice $\tau$, we can push forward both these pieces of data to $\tau'$ with $\phi$. This means that for every $H_\tau$ any automorphism $\phi$ gives rise to a re–gauging of $H_\tau$ to $H_{\tau'}$. That is we have a map $\text{Sym}(\Gamma) \times \mathcal{G}_1 \rightarrow \mathcal{G}_1$ where $\mathcal{G}_1$ are the morphisms in $\mathcal{G}$.

3.4.5. Lifts to Automorphisms. One interesting question for any given re–gauging is if there are automorphisms $\psi$ of $\mathcal{A}$ such that

$$\hat{\psi}(H_\tau) = U^\tau_{v_0 v_0} H_{\tau'} U^\tau_{v_0 v_0}$$

where, again, $\hat{\psi}$ is $\psi$ applied to the entries. This is the type of enhanced, extended symmetry we will use in the commutative case.

One way such a symmetry can arise is by a re–gauging induced by an automorphism $\phi$ is $\Gamma$. A stricter requirement that is easier to handle is that not only the matrix coefficients of the Hamiltonian transform into each other, but rather already the weight functions. This avoids dealing with sums of weights. We say a re–gauging induced by an automorphism $\phi$ of $\Gamma$ is weight liftable by an automorphism $\psi$ of $\mathcal{A}$ if $\psi(\text{wt}(e)) = \text{wt}'(\phi(e))$, where $\text{wt}'$ is the re–gauged weight function for the pushed forward spanning tree.

Theorem 3.10. Given an automorphism $\phi$ of $\Gamma$ there is at most one weight lift by an automorphism $\psi$ of the re–gauging induced by $\phi$. On
the generators $wt(\vec{e})$, $e$ not a spanning tree edge, the putative map is fixed by the condition $\psi(wt(\vec{e})) := wt'(\phi(\vec{e}))$, where $wt'$ is the re-gauged weight function.

Furthermore, the $\psi(wt(\vec{e}))$ again generate $\mathcal{A}$ and hence whether $\psi$ indeed defines an automorphism only needs to be checked on the generators $wt(\vec{e})$.

Lastly, $\psi$ is induced by a base change of $\pi_1(\bar{\Gamma})$.

Proof. Let $wt'$ be the re-gauged weights after moving from $\tau$ to $\tau'$. If an automorphism $\psi$ of $\mathcal{A}$ that lifts $\phi$ exists, then it satisfies $wt'(\phi(\vec{e})) = \psi(wt(\vec{e}))$. After fixing an orientation for each edge the $wt(\vec{e})$ generate, we see that the morphism is already fixed, since by assumptions the $wt(\vec{e})$ generate $\mathcal{A}$.

In order to show that the $\psi(wt(\vec{e}))$ are generators, we will prove the last statement first. As discussed in §2.1.4 $wt$ gives a representation $\rho$ of $\pi_1(\bar{\Gamma}, v_0)$ and $wt'$ gives a representation $\rho'$ of $\pi_1(\bar{\Gamma}, v'_0)$ if $v_0$ is the root of $\tau$ and $v'_0 = \phi(v_0)$ is the root of $\tau'$, the pushed forward spanning tree. In $\tau$ there is a canonical shortest path $p^\tau_{v_0v'_0}$ from $v'_0$ to $v_0$. Conjugating by this path gives an isomorphism $P : \pi_1(\bar{\Gamma}, v'_0) \to \pi_1(\bar{\Gamma}, v_0)$. This is in essence the definition of the path groupoid of $\bar{\Gamma}$. Let $l'^\tau(\vec{e})$ be the loop associated to $\vec{e}$ by using $\tau$ as a spanning tree, see §2.1.4, then $wt(\vec{e}) = \rho(l'^\tau(\vec{e}))$. It follows from the definition of the re-gauging that $\psi(\rho(l'^\tau(\vec{e}))) = \psi(wt(\vec{e})) = wt'(\phi(\vec{e})) = \rho'(l'^\tau'(\phi(\vec{e}))) = \rho(P(l'^\tau'(\phi(\vec{e}))))$ so that $\psi$ is induced by the chance of basis $l'^\tau(\vec{e}) \to P(l'^\tau'(\phi(\vec{e})))$ in $\pi_1(\bar{\Gamma}, v_0)$. From this it follows that the $\psi(wt(\vec{e}))$ generate. □

Corollary 3.11. If the groupoid representation is non-degenerate, so that $\mathcal{A}$ is generated by the $wt(\vec{e})$ and each non-spanning-tree edge gives a linearly independent generator, then the morphism $\Psi$ above is well-defined as a linear morphism.

If there are no relations among the generators, e.g. in the case $\mathcal{A} = \mathbb{T}^n$ the commutative algebra of the torus, then every automorphism is weight liftable, i.e. $\Psi$ from above is well-defined as an algebra homomorphism. □

We will use the corollary in §3.5 to define the enhanced symmetry groups in the commutative toric non-degenerate case.

Remark 3.12. These types of symmetries might also help to explain the somewhat mysterious approximate symmetry between the noncommutative and the commutative case found in [6]. Here the symmetry
is between two loci in the base of the variations. In the commutative case this is the base \( X \) for the family of Hamiltonians as discussed above and in the noncommutative case is the space parameterizing the background magnetic field \( B \). The two loci are the locus of degenerate Eigenvalues on the commutative side and the locus of values of \( B \) where \( \mathcal{B} \) is not the full matrix algebra. From the examples PDG and honeycomb, these two loci have exactly the same top dimension and there are further characteristic features which they have in common. These considerations would lead us too far astray in the present context, but we plan to return to them in a future paper.

3.5. Enhanced symmetries in the commutative case. We will concentrate on the commutative case in the following. One physical feature that makes the noncommutative theory more complicated is that conjugating \( H \) with elements from \( \mathcal{A} \) usually does not leave it invariant. This is of course the starting point for considering the \( \mathcal{C}^* \)-algebra \( \mathcal{B} \) which contains all these conjugates.

3.5.1. Extension. In the commutative case, \( U(\mathcal{L}) \) is a commutative group and the 2–cocycle defines a central extension \( \tilde{G} \) of \( G \) by \( U(\mathcal{L}) \). We can consider the action of this central extension, since the action of \( U(\mathcal{L}) \) commutes with the Hamiltonians, permutations and the re–gaugings in this case. If we are moreover in the fully commutative case, then by using the diagonal embedding of \( \mathcal{A} \) we can even make the cocycle take values in \( U(\mathcal{A}) \) and hence obtain the central extension.

\[
1 \to U(\mathcal{A}) \to \tilde{G} \to G \to 1
\]

Then \( \rho \) does give a groupoid representation of \( \tilde{G} \).

Remark 3.13. There is a nice geometric interpretation of this in the case of wire networks. Here the group \( U(\mathcal{A}) \) corresponds to translations along the lattice \( L \). One can identify the vertices of \( \bar{\Gamma} \) with the elements in a chosen primitive cell and likewise one can arrange the spanning tree edges to be inside this cell. When we are re–gauging, we move the base point along the spanning tree edges. After doing this several times the new root can lie outside the original primitive cell. The co–cycle then measures the displacement of the new cell relative to the old cell in terms of an element \( \lambda \in L \), more precisely it is just \( U_{\lambda} \).

3.5.2. Enhanced symmetry group. In order to find degeneracies in the spectrum, we use the characters and then look for fixed points under the induced groupoid action. Using the language of §2.1.7, given a
point $\chi \in \mathcal{A}$ we get a map $\hat{\chi} : \text{Ham}_0 \rightarrow M_k(\mathbb{C})$. There is then an induced action of the groupoid on $\hat{\chi}(\text{Ham}_0)$, by pushing forward with this character. It can now happen that $\hat{\chi}(H_\tau) = \hat{\chi}(H_\tau')$, that is $H_\tau(t) = H_\tau'(t)$, for the point $t \in X$ corresponding to $\chi$.

For each element $H(t) \in \hat{\chi}(\text{Ham}_0)$, we get its stabilizer group $\text{St}(H(t))$ under the induced groupoid action. This is the image of the transitive action of the groupoid on the fiber of $\hat{\chi}$ over $H(t)$. We can identify $\text{St}(H(t))$ with the image of that subgroupoid. If this group is not trivial, which means that the fiber is not just a point, we call this group the enhanced symmetry group of $H(t)$. It is realized by re–gaugings, that is conjugation by specific matrices which form a projective representation of the stabilizer group as we presently discuss.

3.5.3. Super–selection rules, Projective Representation and Degeneracies. If $\text{St}(H) \neq 1$ then this means that the set of all matrices $\hat{\chi}_\rho(g)$ for $g \in \text{St}(H(t))$, where we identified $g$ with its defining element in $\tilde{G}$, all commute with the Hamiltonian $H(t)$ and hence each one and all of them together give super–selection rules. This of course is already a great help in finding the spectrum.

Since $\rho$ is only a groupoid representation of $\tilde{G}$, we get that $\hat{\chi}_\rho$ is a representation of a an extension of $\text{St}(H(t))$. If we are in the fully commutative case this extension is central and gives rise to a projective representation of $\text{St}(H(t))$.

(16) $1 \rightarrow U(1) \rightarrow \tilde{\text{St}}(H(t)) \rightarrow \text{St}(H(t)) \rightarrow 1$

Here we pulled back with the diagonal embedding, i.e. $U(1)$ is embedded as scalars, viz. diagonal matrices.

In order to apply the general arguments of representation theory, we will be interested in the class of this extension. These extensions are classified up to isomorphism by $H^2(\text{St}(H(t)), U(1))$ [14, 15].

We give a brief definition of this cohomology group, as it is important for our calculations (see e.g. [16]). Let $G$ be a group and $A$ be an Abelian group, which we also write multiplicatively. Set $C^i(G, A) := \text{Map}(G^\times, U(1))$ these are the $i$–th cochains. There is a general differential $d : C^i \rightarrow C^{i+1}$ with $d^2 = 0$. We will need the formulas for it on 1– and 2– cochains. If $\lambda \in C^1(G, A)$ then $d\lambda(g, h) = \lambda(g)\lambda(h)\lambda(gh)^{-1}$ and if $c \in C^2(G, A)$ then $dc(g, h, k) = c(h, k)c^{-1}(gh, k)c(g, hk)c(g, h)^{-1}$. Set $Z^2(G, A) := \ker(d : C^2(G, A) \rightarrow C^3(G, A))$ and $B^2(G, A) := \text{Im}(d : C^1(G, A) \rightarrow C^2(G, A))$. Notice that an element $c \in C^2$ is in $Z^2$ precisely means that $c$ satisfies the cocycle condition (9) in the Abelian

\footnote{We consider $A$ to be a $G$–module with the trivial action.}
case, where the conjugation action is trivial. Now $B^2(G, A) \subset Z^2(G, A)$ and $H^2(G, A) := Z^2(G, A) / B^2(G, A)$.

What this means is that we can move to an isomorphic extension by using a rescaling $\lambda \in C^1(St(H(t)), U(1))$. Another interesting concrete question is if a given homology class $[c]$ can be represented by a cocycle in a subgroup of $A$. This is especially interesting if the subgroup is finite. In our concrete calculations for the Gyroid, we will use for instance $\mathbb{Z}/2\mathbb{Z}$ and this will lead us to consider double covers.

In general if we identify that the projective action of $St(H(t))$ is isomorphic to an action of a finite group extension $\tilde{St}(H(t))$, then we can use this representation to decompose $C^k$ into its isotypical decompositions with respect to this group action. If the group is non–Abelian, then there is a chance that some of the irreducible representations in the decomposition are higher dimensional, which implies degeneracies of the order of these dimensions. Again this is present for the Gyroid.

3.5.4. Geometric lift of the groupoid action. In order to understand the (projective) group action, geometrically in the commutative case, one lifts the action on the Hamiltonians to an action on the underlying geometric space. We will now for concreteness fix $A = \mathbb{T}^n$, that is the groupoid representation is commutative, toric non–degenerate, as is the case in all crystal examples we consider: PDG, Bravais and Honeycomb.

Finding lifts then means that one considers the commutative diagram

\[
\begin{array}{ccc}
T^n & \xrightarrow{H_t} & \hat{\chi}(Ham_0) \\
\psi_t' \downarrow & & \downarrow \phi_t' \\
T^n & \xrightarrow{H_t} & \hat{\chi}(Ham_0)
\end{array}
\]

where the dotted morphism is the lift to be constructed and $H_t$ is the map $t \mapsto H_t(t) := \hat{\chi}(t)$ if $\chi$ is the character corresponding to $t$.

The existence of these lifts is not guaranteed in general, and indeed there are examples of re–gaugings that cannot be lifted. A non–liftable example can e.g. be produced from the cube graph obtained from the Gyroid graph by quotienting out by the the simple cubic lattice, see [2]. We will show that all lifts stemming from automorphisms of the underlying graph do lift.

Looking at the diagram (17), one consequence of this action is that it lets us pinpoint Hamiltonians with enhanced symmetry group. Using Corollary 3.11 and translating it to the geometric side, we obtain
Proposition 3.14. Let \((\bar{\Gamma}, \text{wt})\) be a toric non–degenerate weighted graph. In the commutative case the automorphism group of \(\bar{\Gamma}\) lifts via the gauging action to an automorphism group of \(\mathbb{T}^n\). That is we get a morphism \(\text{Aut}(\bar{\Gamma}) \to \text{Aut}(\mathbb{T}^n)\).

If a point \(t \in T^n\) is a fixed point of a lift of an element \(g \in \mathcal{G}\), then, the re–gauging is an enhanced symmetry for the corresponding Hamiltonian, that is \(\hat{\chi}(\rho(g))\) commutes with the Hamiltonian \(H_{\tau}(t)\). □

Summarizing these results:

Theorem 3.15. If \((\bar{\Gamma}, \text{wt})\) is commutative and toric non–degenerate, then a stabilizer sub–group \(G_t\) of \(t \in T^n\) under the induced action of \(\text{Aut}(\bar{\Gamma})\) on \(T^n\) leads to an enhanced symmetry group \(\text{St}(H(t))\) for the Hamiltonian \(H(t)\). This group also has a projective representation via the matrices \(\hat{\chi}(\rho(g))\). □

We can exploit the representation theory of this group to get information about degeneracies.

Example 3.16. For commutative toric non–degenerate groupoid representations of symmetric graphs the re–gaugings by re–orderings are always representable via an automorphism of the graph. If \(\sigma \in S_{k-1}\) permutes the vertices of the spanning tree leaving the root fixed, then the re–gauging lifts as the reordering of the generators and possibly taking \(\ast\) of them. The matrices are just the usual permutation matrices of \(S_{k-1} \subset S_k\) acting on the last \(k-1\) copies of \(\mathbb{C}\) in \(\mathbb{C}^k\).

Remark 3.17. In the commutative case, the representation of \(\pi_1(\bar{\Gamma}, v_0)\) factors through its Abelianization \(H_1(\bar{\Gamma})\).

4. Calculations and Results for Wire Networks

In this paragraph, we perform the calculation for the PDG and honeycomb graphs of Figure 1. These correspond to wire networks as reviewed in §2.2. In all these situations Theorem 3.15 applies. The upshot of the following calculations together with the analysis of [5] is:

Theorem 4.1. In all the examples PDG and honeycomb, all the fixed points come from fixed points of the semi–classical action. Moreover the fixed points, stabilizer groups, their extensions and the decomposition into irreps for the case of the Gyroid are given in Table 2.

For the calculations, we note that we are in the fully commutative case and hence Corollary 3.7 applies. Furthermore the graphs all have transitive symmetry groups, so that we only have to calculate for one
source $\tau$ and can then transport the results by push–forward to any other.

4.1. Gyroid. The graph $\bar{\Gamma}$ in the Gyroid case is the full square. It has symmetry group $S_4$. With the Gyroid weights, the graph is faithful and hence the action can be lifted to an action on the torus. It acts transitively on all ordered spanning trees. Such a spanning tree is fixed by specifying a root and the order. The subgroup of $S_3$ acts transitively on all orders. The matrices of this subgroup action are just the permutation matrices acting on the last 3 copies of $C$ in $\mathbb{C}^4$ and the lift of the $S_3$ action on the generators $A, B, C$ of $T^3$ is given by the permutation action.

We fix an initial rooted spanning tree and order as in Figure (3).

4.1.1. Action on $T^n$. The action of $S_4$ on $T^3$ is fixed once we know the action of the generators $(12), (23)$ and $(34)$.

The action of $(23)$ is graphically calculated in Figure 2, from which one reads off $\Psi((23))(A, B, C) = (A^*, C^*, B^*)$. Here $(A, B, C)$ is the notation for the initially chosen basis of $T^3$.

In the graphical calculation, we first write down the graph together with the initial spanning tree and order. We then push–forward the spanning tree and the order. For this we keep the vertices and edges as well as the weights fixed. We then (if necessary) give the re–gauging parameters by writing them next to the respective vertices and (if necessary) perform the re-gauging. Finally we move the vertices and edges, so that they coincide with their pre–images to read off the morphism on the generators given by Theorems 3.10 and 3.15.

A similar calculation shows that $\Psi((34))(A, B, C) = (B^*, A^*, C^*)$. A consequence is that the cycle $(234) = (23)(34)$ acts as $\Psi((234))(A, B, C) = \Psi((23))(B^*, A^*, C^*) = (B, C, A)$ and is the cyclic permutation.
The action of (12) is more complicated as the root is moved. For this we calculate graphically, see Figure 3, and read off $\Psi$ as: $(A, B, C) \mapsto (A^*, B^*, ACB)$.

This allows us to compute fixed points and stabilizer groups. We will first concentrate on non–Abelian stabilizer groups. There are only two fixed points under the full $S_4$ action and these are $(1, 1, 1)$ and $(-1, -1, -1)$. The group $A_4$, the subgroup of all even permutations, is the stabilizer group of the two points $(i, i, i)$ and $(-i, -i, -i)$. One can readily check that these are the only non–Abelian stabilizer groups. The other possibility would be $S_3$, but a short calculation shows that anything that is stabilized by any $S_3$ subgroup is stabilized by all of $S_4$.

4.1.2. Representations. We collect together the matrices $M$ needed for further calculation. Again, we fix our initial ordered rooted spanning tree as before.

Using short hand notation, the matrix for the re–gauging induced by the transpositions (12), (13), (14) from the initial spanning tree to the pushed forward one are

$$\rho_{12} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} A, \rho_{13} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} A^*, \rho_{14} = \begin{pmatrix} 0 & B \\ 0 & C^* \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}$$

The calculation for $\rho_{12}$ can be read off from Figure 3. For this we read off the matrix $\Phi$ from the re–gauging parameter and the matrix $M_\sigma$ is...
given by the permutation we are considering. The other calculations are similar. All other transpositions, viz. those not involving 1, simply yield permutation matrices as there is no re–gauging involved. It is convenient to also have the following matrices as a reference:

\[
\rho_{(12)(34)} = \begin{pmatrix} 0 & 1 & & \\ 1 & 0 & & \\ & B & & \\ & & A & \end{pmatrix}, \quad \rho_{(14)(23)} = \begin{pmatrix} & C^* & & B \\ & & & 1 \\ 1 & & & \\ & & A & \end{pmatrix}
\]

and finally

\[
\rho_{(123)} = \begin{pmatrix} 0 & 0 & 1 & & \\ 1 & 0 & 0 & & \\ & 0 & A & & \\ & B & & \end{pmatrix}
\]

4.1.3. The point \((0, 0, 0)\). At \((0, 0, 0)\), the matrices \(\rho_{12}, \rho_{23}, \rho_{34}\) give the usual representation of \(S_4\) on \(\mathbb{C}^4\). As is well known this representation decomposes into the trivial representation and an irreducible 3–dim representation. This means that there is an at least 3–fold degenerate Eigenvalue \(\lambda\). Since the trace of \(H\) is zero, we also know that the Eigenvalues satisfy \(\mu = -3\lambda\). Plugging in \((1, 1, 1, 1)\), which spans the trivial representation, we see that \(\mu = 3\) and \(\lambda = -1\).

4.1.4. The point \((\pi, \pi, \pi)\). In this case, the matrices \(\rho_{12}, \rho_{23}, \rho_{34}\) only give a projective representation. As one can check \(\rho_{12}\rho_{23}\rho_{12} = -\rho_{13}\) while \(\rho_{23}\rho_{12}\rho_{23} = \rho_{13}\) for instance. Define the 1–cocycle \(\lambda\) by \(\lambda(\sigma) = -1\) if 1 appears in a cycle of length > 1 and 1 else. So that \(\lambda((12)) = \lambda((13)) = \lambda((123)) = -1\) while \(\lambda((23)) = \lambda((24)) = \lambda((234)) = 1\). Then one calculates that \(\tilde{\rho} := \rho \circ \lambda\) has a trivial cocycle \(c\) and thus \(\rho\) is isomorphic to a true linear representation of \(S_4\). Checking the characters, one sees again that in this case the irreducible components of \(\tilde{\rho}\), which also commute with \(H\) are again the one–dimensional trivial representation and the 3–dimensional standard representation. The trivial representation is spanned by \((-1, 1, 1, 1)\). The Eigenvalues are then readily computed to be 1 with multiplicity 3 and -3 with multiplicity 1.

**Remark 4.2.** We would like to remark that the choice of \(\lambda\) amounts to choosing a different gauge for the root vertex, namely \(-1\) instead of 1.

**Remark 4.3.** Notice that already in this case, even though there is no projective extension, our enhanced gauge–group is necessary. Without it there would only be an \(S_3\) action, those elements which involve no
re–gauging. This smaller symmetry group is, however, not powerful enough to force the triple degeneracy, as $S_3$ has no irreducible 3–dim representation.

4.1.5. The point $(\pi/2, \pi/2, \pi/2)$ and $(-\pi/2, -\pi/2, -\pi/2)$. These points are similar to each other. We will treat the first one in detail. Again, we have only a projective representation of $A_4$ aka. the tetrahedral group $T$. Namely, $\rho_{(12)(23)}\rho_{(13)(24)} = -i\rho_{(14)(23)}$. Again we can scale by a 1–cocycle $\lambda$. This time $\lambda(id) = 1, \lambda((ij)(kl)) = i, \lambda(ijk) = 1$ if $1 \not\in \{i, j, k\}, \lambda((ijk)) = i$ if $1 \in \{i, j, k\}$. The resulting representation $\tilde{\rho} = \rho \circ \lambda$ is then still a projective representation, but is it a representation of the unique non–trivial $\mathbb{Z}/2\mathbb{Z}$ extension of $A_4$, which goes by the names $2T, 2A_4, SL(2, 3)$ or the binary tetrahedral group. This group is well known. It is presented by generators $s$ and $t$ with the relations $s^3 = t^3 = (st)^2$. In $SL(2, 3)$ (that is the special linear group of $2 \times 2$ matrices over the field with three elements $\mathbb{F}_3$), one can choose $s = \begin{pmatrix} -1 & -1 \\ 0 & -1 \end{pmatrix}$ and $t = \begin{pmatrix} -1 & 0 \\ -1 & -1 \end{pmatrix}$.

For $2A_4$ using a set theoretic section $\wedge$ of the extension sequence

\[ 1 \longrightarrow \mathbb{Z}/2\mathbb{Z} \longrightarrow 2A_4 \xrightarrow{\wedge} A_4 \longrightarrow 1 \]

and $z$ as a generator for $\mathbb{Z}/2\mathbb{Z}$, we can pick $s = \hat{z}(123), t = \hat{z}(234)$ as generators. Now we can check the character table, Table 1, and find that the representation $\tilde{\rho}$ over the complex numbers decomposes as the sum of two irreducible two–dimensional representations $\chi_5 \oplus \chi_6$. In fact, these are the two representations into which the unique real irreducible 4–dimensional representation of complex type splits over $\mathbb{C}$.

The explicit computation for the representation

\[
\tilde{\rho}(s) = -\lambda((123))\rho_{(123)} = \begin{pmatrix} 0 & 0 & -i & 0 \\ -i & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}
\]

\[
\tilde{\rho}(t) = -\lambda((234))\rho_{(234)} = -\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}
\]

is as follows. Suppose the $\tilde{\rho} = \bigoplus_{i=1}^{7} a_i\rho_i$, where $\rho_i$ is the irrep with character $\chi_i$. Now $tr(id) = 4, tr(-1) = -4$ , using the character table this implies that the coefficients $a_1 = a_2 = a_3 = a_7 = 0$ and furthermore $(\star) a_4 + a_5 + a_6 = 2$. We furthermore have that $tr(s) = -1$ so that

\end{table}

\(a_4 + \omega a_5 + \omega^2 a_6 = −1\) which together with (*) implies that \(a_4 = 0, a_5 = a_6 = 1\). This fixes the decomposition into irreps. As a double check one can verify that the rest of the equations are also satisfied.

So indeed we find that \((\pi/2, \pi/2, \pi/2)\) is a point with two Eigenvalues with degeneracy 2. It is not hard to find (e.g. using the results of §4.1.6) that these Eigenvalues are ±\(\sqrt{3}\).

The analysis of the complex conjugate point \((-\pi/2, −\pi/2, −\pi/2)\) is analogous.

We would briefly like to connect these results to [5]. There it was shown that these four points are the only singular points in the spectrum and that the two double crossing points are Dirac points.

4.1.6. Super–Selection Rules and Spectrum Along the Diagonal. To illustrate the power of the super–selection rules we consider the action of the cyclic group generated by \((234)\). One can easily see that the fixed
point set in the $T^3$ is the diagonal $t = (a, a, a)$. The matrices $\hat{\chi}\rho$ actually give a *bona fide* representation of $\mathbb{C}^4$. This is the representation of $C_3$ given by cyclicly permuting the last three factors of $C$. The action decomposes into irreps as follows: $\mathbb{C}^4 = \text{triv} \oplus \text{triv} \oplus \omega \oplus \bar{\omega}$. Where $\omega$ is the 1--dimensional representation given by $\rho((123)) = \omega = \exp(2\pi i/3)$. The two trivial representations are spanned by $v_1 = (1, 0, 0, 0)$ and $v_2 = (0, 1, 1, 1)$ while the representation $\omega$ is spanned by $w = (0, 1, \omega, \bar{\omega})$ and $\bar{\omega}$ by $\bar{w}$.

Although we cannot extract information about the degeneracies from this it helps greatly in determining the Eigenvalues, since there are two irreps with multiplicity one each giving a unique 1--dimensional Eigenspace for the Hamiltonian. Hence we immediately get two Eigenvalues. Plugging $w$ and $\bar{w}$ into $H(t)$ one reads off

\begin{equation}
\lambda_1 = \omega \exp(ia) + \bar{\omega} \exp(-ia) \quad \lambda_2 = \bar{\omega} \exp(ia) + \omega \exp(-ia)
\end{equation}

The sum of the two trivial representations gives a 2--dimensional isotypical component. Therefore, we have to diagonalize $H$ inside this Eigenspace. It is interesting to note that at the special points it is exactly this flexibility that is needed in order to allow for crossings.

To determine the two remaining eigenvalues $\lambda_3$ and $\lambda_4$, we apply $H$ to $\vec{v} = xv_1 + yv_2 = (x, y, y, y)$. The eigenvalue equation $H \cdot \vec{v} = \lambda \vec{v}$ leads to the equations $3y = \lambda x$ and $x + y(\exp(ia) + \exp(-ia)) = \lambda y$, Fixing $x = 3$ this gives the quadratic equation $\lambda^2 - 2 \cos(a)\lambda - 3 = 0$ which has the two solutions

\begin{equation}
\lambda_{3,4} = \cos(a) \pm \sqrt{\cos^2(a) + 3}
\end{equation}

This gives the spectrum along the diagonal which is given in Figure 4. The calculation only involves the classical symmetries without re--gauging.
In [3] the authors also assert that numerically they only found singular points in the spectrum along the diagonal. The fact that the arising candidates for Dirac points are indeed such points and the analytic proof that indeed there are no other singular points in the spectrum is contained in [5].

4.2. The P case. There is nothing much to say here. There is only the root of the spanning tree which is unique. The $S_3$ action permutes the edges and their weights. This yields the permutation action on the $T^3$. There is no nontrivial cover and the Eigenvalues remain invariant.

4.3. The D case. Here things again become interesting. Permuting the two vertices, we obtain eight fixed points if $a, b, c \in \{1, -1\}$. The matrix for this transposition is $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. This gives super-selection rules and we know that $v_1 = (1, 1)$ and $v_2 = (-1, 1)$ are Eigenvectors. The Eigenvalues being $1 + a + b + c$ and $-(1 + a + b + c)$ at these eight points.

We can also permute the edges with the $S_4$ action. In this case the $S_3$ action leaving the spanning tree edge invariant acts as a permutation on $(a, b, c)$. The relevant matrices however are just the identity matrices and the representation is trivial. The transposition $(12)$, however, results in the action $(a, b, c) \mapsto (\bar{a}, \bar{a}b, \bar{a}c)$ on $T^3$, see Figure 3. So to be invariant we have $a = 1$, but this implies that $\rho_{12}$ is the identity matrix. Invariance for $(13)$ and $(14)$ and the three cycles containing 1 are similar. But, if we look at invariance under the element $(12)(34)$ we are lead to the equations

$$a = \bar{a}, b = \bar{a}c, c = \bar{a}b$$

This has solutions $a = 1, b = c$, for these fixed points again we find only a trivial action. But for $a = -1, b = -c$ these give rise to the diagonal matrix $\text{diag}(1, -1)$ and hence Eigenvectors $e_1 = (1, 0)$ and $e_2 = (0, 1)$, but looking at the Hamiltonian, these are only Eigenvectors if it is the zero matrix $H(a, b, c) = 0$. Indeed the conditions above imply $1 + a + b + c = 0$.

Similarly, we find a $\mathbb{Z}/2\mathbb{Z}$ group for $(13)(24)$ and $(14)(23)$ yielding the symmetric equations $b = -1, a = -c$ and $c = -1, a = -b$. These are exactly the three circles found in [6]. Going to bigger subgroups we only get something interesting if the stabilizer group $G_t$ contains precisely two of the double transposition above. That is the Klein four group $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$. The invariants are precisely the intersection points of the three circles given by $a = b = -1$ and $c = 1$ and its cyclic permutations.
These are three lines of double degenerate Eigenvalue 0. These are not Dirac points since there is one free parameter and hence the fibers of the characteristic map of [5] are one dimensional which implies that the singular point is not isolated.

4.4. The honeycomb case. This is very similar to the D story. The vertex interchange renders the fixed points \(a = \pm 1, b = \pm 1\) which have Eigenvectors \(v_1, v_2\) as above and Eigenvalues \(1 + a + b\) and \(-(1 + a + b)\) respectively. The irreps of the \(C_3\) action are \(\text{triv} \oplus \omega\).

As far as the edge permutations are concerned the interesting one is the cyclic permutation \((123)\) which yields the equations

\[a = \bar{b}, b = \bar{b}a\]

for fixed points. Hence \(a^3 = 1\). We get non-trivial matrices at the points \((\omega, \bar{\omega})\) and \((\bar{\omega}, \omega)\). At these points \(e_1, e_2\) are Eigenvectors with Eigenvalue 0 and \(H = 0\), since \(1 + a + b = 1 + \omega + \bar{\omega} = 0\). They are exactly the Dirac points of graphene.

5. Conclusion

By considering re-gaugings, we have found the symmetry groups fixing the degeneracies of the PDG and honeycomb families of graph Hamiltonians. The symmetries we used were those induced by the automorphisms of the underlying graphs. In our specific examples, all the graphs were highly symmetric, and hence had large automorphism group. Here we stress that our symmetries are extended symmetries and not just the classical ones. The most instructive and interesting case is the action of the binary tetrahedral group giving rise to the Dirac points in the Gyroid network. Note that as dimension-0 objects, the Dirac points for the Gyroid are codimension-3 defects in \(T^3\), rather than codimension-2 defects in \(T^2\) as for the honeycomb lattice, which describes graphene. Nevertheless, one may expect that they too lead to special physical properties.

There are several questions and research directions that tie into the present analysis.

It would be interesting to find concrete examples of lifts of re-gaugings either in the noncommutative case or in the case of re-gaugings not induced by graph symmetries. One place where we intend to look for the former is in the noncommutative case of PDG and the honeycomb as we aim to probe the noncommutative/commutative symmetry mentioned in Remark §3.12.

We are furthermore interested in how these symmetries behave under deformations of the Hamiltonian and if they are topologically stable. A
physically important type of deformations are those corresponding to periodic (in space) lattice distortions that describe crystals with lower spatial symmetry than those considered here. Such distortions may occur for instance during synthesis of the structure [1]. Codimension-3 Dirac points, such as those of the Gyroid network, are especially interesting in this respect: they can be viewed as magnetic monopoles in the parameter space [18] and as such are expected to be topologically stable. This makes the physics associated with such points immune to periodic lattice distortions.

Finally it seems that on the horizon there are connections between our theory and two other worlds. The first being quiver representations in general and the second being cluster algebras. The connection to the first is inherent in the subject matter, while the connection to the second needs some work. The point is that in our transformations, we change several variables at a time. Nevertheless, the re–gauging groupoid can be viewed as a sort of mutation diagram. We plan to investigate these intriguing connections in the future.

Acknowledgments

RK thankfully acknowledges support from NSF DMS-0805881 and DMS-1007846. BK thankfully acknowledges support from the NSF under the grants PHY-0969689 and PHY-1255409. Any opinions, findings and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the National Science Foundation. Both RK and BK thank the Simons Foundation for support.

Parts of this work were completed when RK was visiting, the IHES in Bures–sur–Yvette, the Max–Planck–Institute in Bonn and the University of Hamburg with a Humboldt fellowship. He gratefully acknowledges their support. BK acknowledges the hospitality of the DESY theory group where finishing touches for this article were made. Both RK and BK thank the Institute for Advanced Study where this version was written.

We also wish to thank Sergey Fomin for a short but very valuable discussion.
