ABSTRACT
With the increasing computational power of current supercomputers, the size of data produced by scientific simulations is rapidly growing. To reduce the storage footprint and facilitate scalable post-hoc analyses of such scientific data sets, various data reduction/summarization methods have been proposed over the years. Different flavors of sampling algorithms exist to sample the high-resolution scientific data, while preserving important data properties required for subsequent analyses. However, most of these sampling algorithms are designed for univariate data and cater to post-hoc analyses of single variables. In this work, we propose a multivariate sampling strategy which preserves the original variable relationships and enables different multivariate analyses directly on the sampled data. Our proposed strategy utilizes principal component analysis to capture the variance of multivariate data and can be built on top of any existing state-of-the-art sampling algorithms for single variables. In addition, we also propose variants of different data partitioning schemes (regular and irregular) to efficiently model the local multivariate relationships. Using two real-world multivariate data sets, we demonstrate the efficacy of our proposed multivariate sampling strategy with respect to its data reduction capabilities as well as the ease of performing efficient post-hoc multivariate analyses.

1 INTRODUCTION
Scientists frequently simulate multiple physical variables/attributes at the same time in their computational models. The resulting multivariate simulation data is analyzed to understand the variable relationships and how they interact to influence the simulated physical phenomenon. However, with increasing data size, it is becoming computationally prohibitive and challenging to analyze and visualize such high-dimensional simulation data.

A popular and effective strategy to address these challenges is to reduce the data size by sampling important features of the data while data still resides in the memory [24]. Instead of storing the high-resolution data sets, the corresponding sampled data is stored and subsequently used for various post-hoc analyses. Different flavors of sampling algorithms exist in literature [4, 5, 20] which can selectively sample different data properties. However, most of these algorithms primarily target univariate data. To perform traditional multivariate analyses such as correlation studies between variables and joint multivariate queries across different variables directly on the sampled data, it is important to preserve the variable relationships while sampling the data. Using the univariate sampling methods to sample the multivariate datasets can potentially fail to preserve the important inter-variable relationships, and the subsequent post-hoc multivariate analyses can become unreliable. Further, given the correlation existing across the variables, it is not necessary to explicitly store all the variables. Therefore, it is possible to achieve much larger data reduction for multivariate datasets if we consider the variable relationships while sampling the data.

In this paper, we propose a multivariate sampling strategy to preserve and utilize the original multivariate relationships to facilitate higher data reduction as well as enable an efficient post-hoc exploration workflow. To efficiently model the complex global non-linear multivariate relationships, we use a locally piece-wise linear model [15, 22] by first partitioning the spatial domain. In this regard, we propose variants of different partitioning schemes (regular and irregular), especially adapted for multivariate data. The local linear relationship for each partition is modeled using Principal Component Analysis (PCA). Using PCA, we extract the correlations among the variables and proceed to achieve data reduction by selecting an optimal number of uncorrelated variables. We further reduce the data footprint by sampling the spatial domain in that uncorrelated variable space. PCA also provides the means to perform uncertainty quantification that can be controlled by the user as an error-tolerance.

To demonstrate the efficacy of our proposed strategy, we apply it on a two-dimensional ocean simulation data set with 75 variables and a three-dimensional hurricane data set with 13 variables. We used three different partitioning schemes and two popular sampling algorithms to highlight its compatibility with existing sampling and partitioning methods. To summarize, the main contribution of our work is threefold:

1. We formulate a sampling strategy for large-scale multivariate data which utilizes the intrinsic redundancy of the variables and the spatial dimensions to achieve larger data reduction.
2. We facilitate various post-hoc multivariate analyses directly on the reduced/sampled data, without the need to reconstruct the high-resolution scalar fields for all the variables.
3. We propose multivariate relationship-aware spatial domain decomposition schemes to extract the locally linear models.

2 RELATED WORK
Sampling-based Data Analysis: Data sampling methods have been widely used in the visualization community to reduce the size of large-scale data sets in order to facilitate timely execution of various visualization and analysis activities. To enable interactive visualization of large-scale cosmology simulation data, Woodring et al. [23] proposed a stratified random sampling approach. Nguyen and Song [17] incorporated centrality-driven clustering information during random sampling. Using the ideas of entropy maximization, Biswas et al. [4, 5] recently proposed in situ data-driven sampling schemes that preserve important data features along with their gradient properties. For scattered datasets, Rapp et al. [29] proposed a blue noise preserving sampling method to identify representative subset of points. However, these sampling methods are primarily targeted for univariate data fields or a very specific derived property of the multivariate data. For instance, Dutta et al. [7] recently proposed a pointwise mutual information based approach for multivariate sampling to identify regions with high mutual information among the variables. In this paper, we preserve the overall variable relationships to enable more generic multivariate analyses directly on the sampled data.
Multivariate Data Analysis: This is an important area of research in the scientific visualization community. To visualize multivariate relationships across the spatial domain, Sauber et al. [23] analyzed the correlation coefficients among the variables in local neighborhoods. Correlation analysis was also extended to enable different query-driven methods for multivariate data [3]. Gosnik et al. [10] improved multivariate query-driven analysis by using various statistical models. To identify interesting regions in multivariate data, Jänicek et al. [13] adapted different local statistical measures quantifying variable information. For large-scale multivariate simulation data, Hazarika et al. [12] proposed copula functions [11] to model variable relationships in situ along with different statistical distribution models to reduce storage footprint. For a more extensive review of multivariate data analysis and visualization research, readers can refer to Wong et al. [25] and Fuchs et al. [9].

3 Method

Overview: Fig 3 provides a high-level illustration of our proposed strategy. To efficiently model the multivariate relationships using locally linear models, the spatial domain is first decomposed into smaller partitions using three different partitioning schemes. Next, for each partition, we apply PCA and sampling algorithms to reduce the overall storage footprint of multivariate data while preserving the variable relationships. Finally, we perform different post-hoc multivariate analyses directly on the reduced/sampled data.

In this paper, we first introduce the concept of PCA and its properties for multivariate relationship modeling in subsection 3.1. In subsection 3.2, we discuss the different sampling algorithms for spatial data reduction. Despite being the first step in our workflow, we leave the detail discussion of the multivariate partitioning schemes to subsection 3.3, after certain notations and concepts related to PCA have been explained in subsection 3.1. The various post-hoc analyses are covered in Section 4.

3.1 Variable Dimension Reduction using PCA

Multivariate data comprises of multiple interrelated variables with different degrees of association among them. The central idea of PCA is to project these variables to a new set of uncorrelated variables/dimensions, called principal components (PC’s), which are ordered in such a way that the first few retain most of the variation in all of the original variables. This property of PCA is useful to quantitatively decide how many dimensions (PCs) to store to capture a given fraction of the variation of the original data. We apply this dimensionality reduction property of PCA to identify the number of PC’s to store for individual partitions of the data.

As illustrated in Fig. 3, consider a partition with N datapoints and d variables. Let X (d x N matrix) denote the multivariate data in this partition. Then X can be expressed by the following linear combination,

\[ X = WC_q + \mu + \varepsilon \]  

where, the new basis C_q (q x d matrix) represents the top q PC’s that capture the maximum variation of X. W (N x q matrix) represents the projections of the original N datapoints onto these q orthogonal directions and \( \mu \) represents the d-dimensional mean vector of X. \( \varepsilon \) is the residual error associated with the loss of dimensions (i.e., \( q < d \)). When number of PC’s \( q = d, \varepsilon = 0 \). Therefore, given W, C_q and \( \mu \), we can approximate the original multivariate data \( X \) using Equation 1. Eigen decomposition of the covariance matrix of \( X \) (i.e, \( \frac{1}{N-1}X^T X \)) gives the full \( d \times d \) PC matrix \( C_{full} \) (aka. eigen vectors) and their corresponding explained variances \( EV \) (aka. eigen values). The first q PC’s in \( C_{full} \) makes up the matrix \( C_q \). The transformed data \( W \) is obtained as follows:

\[ W = (X - \mu)C_q^T \]  

where, \( C_q^T \) is the transpose of \( C_q \).

Error Quantification: An advantage of using PCA to reduce variable dimensions is that we can estimate a threshold on the reconstruction error of the original variables in the post-hoc analysis phase. This is because in PCA maximizing variance is equivalent to minimizing the residual error \( \varepsilon \) of reconstructing the original data back. This relationship between explained variance of the PC’s with the residual error (least-square error) is given as,

\[ \text{Explained Variance Ratio} = 1 - \frac{\varepsilon^2}{\|X\|^2} \]  

where, \( \varepsilon^2 = \|X - (WC_q + \mu)\|^2 \) is the squared norm of the residual error. The term \( \frac{\varepsilon^2}{\|X\|^2} \) corresponds to the normalized residual error corresponding to the original data and is inversely proportional to the percentage of variance captured by the PC’s. For each partition, given the desired maximum variance required to preserve, we can decide the optimal number of PC’s \( q \) (\( q < d \)) to store.

3.2 Spatial Data Reduction using Sampling Algorithms

After reducing the variable dimensions from \( d \) to \( q \) using PCA, we next decide how many datapoints to retain out of \( N \) using sampling algorithms on the uncorrelated variable. In our work, to obtain consistent samples for all variables, we apply the sampling algorithms only on the scalar field of the first PC, which captures the maximum variation of the original multivariate data. This helps us to efficiently perform post-hoc multivariate analyses on the sampled data. Depending on the analysis requirements, different state-of-the-art sampling algorithms can be utilized to perform spatial data reduction. In this work, we consider the following two distinct flavors of sampling algorithms commonly used for scientific data sets.

(S1) Random Sampling: Random sampling is a popular sampling technique for data summarization because the sampled data points preserve the original data distribution along with statistical properties like mean, standard deviation etc. It can also be readily combined with other importance-based sampling methods to induce randomness in the samples.

(S2) Feature-based Sampling: Scientific data sets often contain important low-frequency data features which can get eliminated with random sampling. Recently, Biswas et al. [5] proposed an importance sampling algorithm using the idea of entropy maximization to preserve important local data features in the sampled data.
While SLIC based partitioning schemes have been common for univariate data, recently, Jiang et al. [14] proposed a method, called axis-aligned partitions. SLIC, on the other hand, can produce superpixels for load-balancing. For a real-world application, we consider the Hurricane Isabel data set, we demonstrate the properties of the two sampling algorithms. As can be seen in Fig. 2, with random sampling, each data point has an equal probability of being picked, irrespective of the data features. Whereas, feature-based sampling algorithm (Fig. 2) puts more emphasis on the intrinsic data features (i.e., hurricane eye).

3.3 Partitioning Schemes

Variable relationships and their degree of association often vary across different regions of the spatial domain. Decomposing the spatial domain and applying PCA on individual partition data helps to efficiently model the non-linear and complex multivariate relationships using multiple locally linear models [15,22]. An important distinction to make here is that these partitions are different from the implicit simulation partitions for load-balancing. For a real-world application, we can partition the individual per-node data to model the overall multivariate data.

(P1) Regular Block-wise Partitioning: This is a very widely used partitioning scheme where the spatial domain is decomposed into equal sized (non-overlapping) blocks of user-defined dimensions. This scheme does not take into consideration the data properties while segmenting the space. This can lead to sub-optimal partitions for performing local data analysis.

(P2) Multivariate K-d Tree Partitioning: K-d tree is a more data-centric partitioning scheme which follows a top-down subdivision scheme to recursively partition the domain till a desired data property is met for the partitions [8, 18]. In this work, to obtain partitions whose multivariate data can be appropriately modeled using PCA, we design a new terminating criterion. Under this new criterion, we calculate the local PCA of each partition (subsection 3.1). The decision to further sub-divide the partition depends on whether q PC’s can capture $p\%$ of the variance in the original multivariate data of the partition. If this criteria is not satisfied for a partition, we further sub-divide the current partition till either the criterion is met or the size of the partition has reached the minimum dimension set for a partition. The parameters $q$ and $p$ are user-defined and can be appropriately set depending on the application requirements.

(P3) Multivariate SLIC Partitioning: Simple Linear Iterative Clustering (SLIC) is a clustering-based data partitioning scheme [1, 27]. The partitioning schemes discussed above (P1 and P2) produce axis-aligned partitions. SLIC, on the other hand, can produce irregular shaped partition, more in tuned with the data properties. While SLIC based partitioning schemes have been common for univariate data, recently, Jiang et al. [14] proposed a method, called superPCA to extend SLIC for multivariate data. They perform SLIC based partitioning on the scalar field of the first PC, which captures maximum variance of the original data. Applying local PCA models on these irregular partitions help us to better model the overall multivariate relationship of the data in a local region.

In Fig. 3, we show the results of these partitioning schemes along with the number of PC’s required for each partition to capture 99% variance of a 75 variable ocean simulation data (Fig. 3a). The number of PC’s required for each partition is visualized using a categorical colormap. It can be clearly seen that not all the regions require the same number of PC’s to retain the multivariate relationship of the data. Fig. 3b and Fig. 3c highlight that the data-centric partitioning schemes like P2 and P3 try to have a more intelligent decomposition of the spatial domain as compared to a regular partitioning scheme. To sum up the discussion in this section, for each spatial partition, using our proposed sampling strategy, we reduce the size of the multivariate simulation data and store the reduced form instead of the original high-resolution data. The reduced multivariate data for a partition comprises of the full PC matrix $C_{full}$, explained variances $EV$, the mean vector $\mu$, and the sampled transformed data $W_s$ as represented by the orange blocks in Fig. 3.

4 Multivariate Post-hoc Analysis

To demonstrate how to perform various multivariate analyses directly on the reduced data, we experimented on two different multivariate datasets. Our first data set is a 2-dimensional $(720 \times 360)$, 75-variable ocean biogeochemistry (Ocean-BGC) data set generated using the MPAS-O [16,21,24] (Model for Prediction Across Scale Ocean) and the E3SM [19] (Energy Exascale Earth System Model) simulations. Our second dataset is a 3-dimensional $(250 \times 250 \times 50)$, 13-variable Hurricane Isabel data set, simulating the impact of hurricanes on the coastal regions of the United States. In this section, we cover three different types of multivariate analyses.

Multivariate Reconstruction: For the sampled data points, we can reconstruct the full multivariate vector using the reduced data form of the respective partitions. By applying Eq. 1 on the transformed data samples $W_s$, we can reconstruct their original variable values, i.e., $X_t = W_s C_{full} + \mu$. Since we tried to maximize the variance of the multivariate data (which is inversely proportional to the residual error of reconstruction using Eq. 3), we also get a bound on the multivariate reconstruction error. Table 1 shows the results of data reduction and reconstruction error for the two data sets. For each partition, we store the number of PC’s required to capture 99.9% variance of the data. Using Eq. 3 this is equivalent to a normalized reconstruction error-bound of 0.001 (i.e., $\frac{1}{\sqrt{M}}$ in Section 3.1). This is reflected in the fourth column of Table 1 where the average normalized reconstruction error across the partitions are under the estimated error-bound of 0.001.

| Data Details | Partition Scheme | Reduced Size (MB) | Norm Per MV Error | Min Var RMSE | Max Var RMSE |
|--------------|------------------|-------------------|------------------|-------------|-------------|
| Ocean BGC (75 Var) | Res: 720 x 360 | K-d Tree | 253.9 | 0.00095 | 0.0317 | 0.024 |
| Size: 416 MB | SLIC | 242.2 | 0.00088 | 0.0315 | 0.019 |
| Isabel (13 Var) | Res: 250 x 250 x 50 | K-d Tree | 15.4 | 0.00090 | 0.0099 | 0.015 |
| Size: 283.4 MB | SLIC | 15.3 | 0.00085 | 0.0097 | 0.010 |

Table 1: Results of data reduction and reconstruction errors for the 3 different partitioning schemes, keeping similar average partition sizes for each datasets and a sampling rate of 5%.
is lower than regular partitioning. On the other hand, they also tend to have more storage footprint than regular partitions because of the additional overhead of storing partition information.

**Multivariate Query-driven Analysis:** Query-driven analysis is a class of very efficient data analysis and visualization methods for large-scale data. For multivariate data, queries are vectors in the original variable space that specify desired values for different variables. Given such a set of multivariate queries \( Q \), we can identify the samples that satisfy \( Q \) without having to reconstruct the multivariate vectors for all the samples. For each partition, we convert \( Q \) to the corresponding orthogonal dimensions using the multivariate data summaries, i.e., \( W_Q = (Q - \mu)C_{D}^{-1/2} \) (using Eq. 2). We then calculate the distance between these low-dimensional query vectors \( W_Q \) and the transformed samples \( W_s \). By coloring the samples based on the query distance, we can visualize the regions that satisfy the query.

In Fig. 4, we show the results for a multivariate query of pressure=\(-1000\)Pa, temperature=\(0^\circ\)C, and wind velocity=\(20\)ms\(^{-1}\). This generally corresponds to the wall surrounding the eye of the hurricane. Fig. 4a shows the multivariate distance of this query on the original multivariate scalar field. Fig. 4b shows the query distance on the sampled data points. The distance values were normalized for both the cases. In Fig. 4c, by overlaying the two results, we can qualitatively verify that the query distance measured in the PC space for the samples match with the ground-truth multivariate data.

**Correlation Analysis:** Understanding the correlation between different variables is a very important analysis objective for multivariate data. Same set of variables can exhibit varying degrees of correlation across different regions of the spatial domain. Many univariate data reduction approaches do not preserve this relationship information in their approaches which can lead to unreliable multivariate analyses. In our proposed method, we store the full PC matrix \( C_{D} \) and their explained variances \( \text{EV} \), which are respectively the eigenvectors and the eigenvalues of original covariance matrix. Therefore, the full covariance matrix can be reconstructed using \( \text{Cov} = C_{D} \text{EV} C_{D}^{-1} \), where \( \text{EV} \) is a diagonal matrix whose diagonal elements are the eigenvalues \( \text{EV} \). The corresponding correlation matrix (Pearson’s coefficient) can then be computed using \( \text{Cor} = D^{-1} \text{Cov} D^{-1} \), where \( D \) is a diagonal matrix of the standard deviations (square root of the diagonal of \( \text{Cov} \)).

Fig. 5 shows the result for correlation analysis between average \( NO_3 \) and Fe concentration in the Ocean-BGC data set. Fig. 5a shows the original correlation between the two variables for different partitions, created using the SLIC partitioning scheme. The corresponding reconstructed correlation values of the sampled data points are shown in Fig. 5b. By comparing the two figures, we can see that the sampled data points correctly represent the original correlation information between the two variables.

## 5 Evaluation and Discussion

Apart from the results discussed so far in the paper, we performed different experiments to evaluate our proposed multivariate sampling strategy and to understand the impact of different factors. Here is a brief outline of our observations from these experiments:

### 5.1 Effect of Partition Schemes
Not only the size, but also the shape of the partition plays an important role in modeling the multivariate relationship. We observed that for a particular partitioning scheme, the average variable reconstruction error increases with increasing partition sizes. This is mainly because, for bigger spatial partitions, the variable relationships are often complex and non-linear. As a result, linear models like PCA are not good at capturing their multivariate properties.

### 5.2 Effect of Sample Rate and Algorithm
The rate of sampling the data using different sampling algorithms also play an important role in the quality of post-hoc analysis as well as the overall storage footprint of the data summaries. More samples essentially help get better reconstruction results, however at the cost of more storage size. The sampling algorithm can also effect the quality of the analysis results. Among the two sampling algorithms used in the paper, \( S1 \) preserves the overall data distribution, whereas, \( S2 \) is more tailored towards preserving the important features in the data. Depending on the requirement of analysis, users can decide a flavor of sampling algorithm for their implementation, or even combine the results of multiple algorithms.

## 6 Conclusion and Future Work

In this paper, we have proposed a sampling strategy which utilizes and preserves the variables relationships, while reducing the storage footprint of multivariate simulation data. The global multivariate relationship is captured using multiple local PCA models across the spatial domain, which is decomposed using different multivariate relationship-aware partitioning schemes. We showed how various multivariate analysis and visualization tasks can be performed directly on the sampled data without the need to reconstruct the high-resolution scalar fields. In future, we plan to extend this strategy for temporal multivariate data sets by using incremental PCA models. We also plan to deploy this sampling strategy for in-situ data reduction of multivariate data in large-scale simulation models.
