Chronic mucocutaneous candidiasis (CMC) is a primary immunodeficiency characterized by persistent or recurrent skin and mucosal surface infections with Candida species. Different gene mutations leading to CMC have been identified. These include various heterozygous gain-of-function (GOF) mutations in signal transducer and activator of transcription 1 (STAT1) that are not only associated with infections but also with autoimmune manifestations. Recently, two STAT1 GOF mutations involving the Src homology 2 (SH2) domain have been reported, while so far, over 50 mutations have been described mainly in the coiled coil and the DNA-binding domains. Here, we present two members of a Dutch family with a novel STAT1 mutation located in the SH2 domain. T lymphocytes of these patients revealed STAT1 hyperphosphorylation and higher expression of STAT1 target genes. The clinical picture of CMC in our patients could be explained by diminished production of interleukin (IL)-17 and IL-22, cytokines important in the protection against fungal infections.

Keywords: chronic mucocutaneous candidiasis, signal transducer and activator of transcription 1, Src homology 2 domain, heterozygous mutation, gain-of-function mutation

Abbreviations: CMC, chronic mucocutaneous candidiasis; anti–dsDNA, anti-double stranded DNA; STAT1, signal transducer and activator of transcription 1; SH2, Src homology 2; CMV, cytomegalovirus; ANA, antinuclear antibodies; SSA, Sjögren’s-syndrome-related antigen A (Ro); CENP-B, centromere protein B; MFI, mean fluorescence intensity; PBMC, peripheral blood mononuclear cells; ELISA, enzyme-linked immunosorbent assay; HKCA, heat-killed Candida albicans; PMA, phorbol 12-myristate 13-acetate; I, ionomycin; qRT-PCR, quantitative reverse transcription polymerase chain reaction.
INTRODUCTION

Patient 1 (II-4) (Figures 1A,B) is a 24-year-old female who presented at age of 1 with a Streptococcus haemolyticus jaw abscess, with recurrent oral and esophageal Candida albicans infections from the age of 6 onward and an episode of Staphylococcus aureus pneumonia and cytomegalovirus (CMV) pneumonia at age of 7 years. At age of 8, she developed hypothyroidism, and there were serologic signs of celiac disease, without clinical relevance. Moreover, additional immunological analysis revealed the presence of antinuclear antibodies (ANA) in high titer (1:5,120), anti-Sjögren’s-syndrome-related antigen A (Ro), and anti-centromere protein B autoantibodies (anti-CENP-B). At the age of 20, she developed autoimmune hemolytic anemia. Over the past years, the clinical picture has been dominated by recurrent oral and esophageal C. albicans infections for which she was repetitively treated with antifungal therapies. To prevent recurrence of C. albicans infections, she is currently treated with prophylactic

| Patient (age) | Clinical features | Laboratory findings |
|---------------|-------------------|---------------------|
| I-1 (50)      | Recurrent mucosal candidiasis, culture-negative frontal-lobe brain abscess, aortic valve replacement | ANA+, anti-CENP-B+, anti-thyroglobulin+ | lupus anticoagulant+ |
| II-3 (25)     | Recurrent mucosal candidiasis, ulcerative stomatitis and esophagitis, photosensitivity, skin lesions | ANA+, anti dsDNA+, anti-gliadin antibodies+, lupus anticoagulant+ |
| II-4 (24)     | Recurrent mucosal candidiasis, ulcerative stomatitis and esophagitis, vaginal ulcers, hypothyroidism, hemolytic anemia | ANA+, anti-SSA+, Anti-CENP-B+, anti-gliadin IgA/IgG+ |
| II-5 (13)     | Recurrent mucosal candidiasis, ulcerative stomatitis and esophagitis, Staphylococcus aureus pneumonia | Anti-gliadin IgG+ |

FIGURE 1 | (A) Family pedigree of patients. Symbols in black indicate individuals with the same genetic defect and arrow signs indicate the patients enrolled in this study. (B) Table showing clinical data of all four affected individuals. (C) Sanger DNA sequencing chromatogram of mutated STAT1 gene. (D) Evolutionary conservation of p.Val653 among species. (E) Three-dimensional structure of phosphorylated STAT1 protein with the mutation (Val653Ile), the phosphorylation site (pTyr701), and the target DNA indicated.
antifungal therapy (fluconazole 200 mg once daily). Moreover, she has experienced oral and vaginal ulcers which were found negative for bacterial, fungal, and viral microbes as determined by culture and/or PCR of oral and vaginal swabs and tissue biopsies from vaginal ulcers. Because of these ulcers, which were assumed to be autoimmune manifestations related to chronic mucocutaneous candidiasis (CMC), various immunosuppressive therapies have been initiated over time, including steroids, azathioprine, hydroxychloroquine, and mycophenolate mofetil, all with little benefit. She has recently started treatment with adalimumab [anti-tumor necrosis factor (TNF)-α 40 mg every other week, which resulted in complete resolution of oral and vaginal ulcers after three subcutaneous injections. After three months of treatment, there is still no recurrence of oral and/or vaginal ulcers, whereas no increased incidence of infectious complications was reported while using anti-TNF-α treatment.

Peripheral blood total CD3+ T lymphocyte numbers [1.63 × 10^9/l (reference value: 0.7–2.1 × 10^9/l)], CD4+ T lymphocyte numbers [0.6 × 10^9/l (reference value: 0.3–1.4 × 10^9/l)], CD8+ T lymphocyte numbers [0.84 × 10^9/l (reference value: 0.2–0.9 × 10^9/l)], total CD19+ B lymphocyte numbers [0.16 × 10^9/l (reference value: 0.1–0.4 × 10^9/l)], and CD16+ CD56+ NK cell numbers [0.1 × 10^9/l (reference value: 0.1–0.4 × 10^9/l)] were within the normal reference ranges. Immunoglobulin levels were also found to be within normal limits [IgG 10.5 g/l (reference value: 7.0–16.0 g/l), IgA 1.24 g/l (reference value: 0.76–3.91 g/l), and IgM 1.12 g/l (reference value: 0.45–2.30 g/l)]. The patient was negative for autoantibodies against interleukin (IL)-17A, IL-17F, and IFN-γ.

After immunization with a polysaccharide vaccine against Streptococcus pneumonia (Pneumovax), IgG antibody concentration to all 16 serotypes (1, 3, 4, 5, 6B, 7F; 8, 9V, 14, 15B, 18C, 19A, 19F, 20, 23F, and 33F) measured increased when compared to pre-vaccination concentrations and for 12 serotypes the post-immunization concentrations reached values above 1 μg/ml, which is indicative of a normal response to polysaccharide immunization.

Patient 2 (1-1) (Figures 1A,B) is the 50-year-old father of patient 1, with a medical history including aortic valve replacement at age 29 and surgical and antibiotic treatment for a culture-negative, frontoloboal brain abscess at age 33. He presented for the first time at our outpatient clinic at the age of 49 because of very severe C. albicans infection in the oral cavity and esophagus. At that time, he had already suffered from recurrent oral and esophageal fungal infections for years, for which he was treated with antifungal therapies by his general physician. Microbiological analysis revealed a fluconazole-resistant C. albicans and treatment with posaconazole 400 mg once daily was initiated with prompt clinical improvement. Subsequently, prophylactic posaconazole 200 mg once daily has been prescribed. At the time of first analysis, also autoimmune hypothyroidism with positivity for antithyroglobulin antibodies, ANA and lupus anticoagulant were detected. Peripheral blood total CD3+ T lymphocyte numbers [1.06 × 10^9/l (reference value: 0.7–2.1 × 10^9/l)], CD4+ T lymphocyte numbers [0.5 × 10^9/l (reference value: 0.3–1.4 × 10^9/l)], CD8+ T lymphocyte numbers [0.52 × 10^9/l (reference value: 0.2–0.9 × 10^9/l)], total CD19+ B lymphocyte numbers [0.35 × 10^9/l (reference value: 0.1–0.4 × 10^9/l)], and CD16+ CD56+ NK cell numbers [0.16 × 10^9/l (reference value: 0.1–0.4 × 10^9/l)] were within the normal reference range. Immunoglobulin levels were also found within normal limits [IgG 12.9 g/l (reference value: 7.0–16.0 g/l), IgA 1.65 g/l (reference value: 0.76–3.91 g/l), and IgM 0.8 g/l (reference value: 0.45–2.30 g/l)]. The patient was negative for autoantibodies against IL-17A, IL-17F, and IL-22.

Sanger sequencing from all affected individuals in the family revealed a novel heterozygous signal transducer and activator of transcription 1 (STAT1) mutation in exon 22 at c.1957G>A, while genetic testing for mutations in 276 other known genes involved in primary immunodeficiency was negative (Table S1 in Supplementary Material). The nucleotide base change we identified has not been reported as single nucleotide polymorphism (the Human Gene Mutation Database, the National Center of Biotechnology Information, the ExAC database, the 1000G database, and the Ensembl database). The identified mutation results in replacement of a highly conserved valine at position 653 (vertebrate Phylop100 score 3.798 and SiPhy score 19.656) (Figures 1C,D; Table S2 in Supplementary Material) into isoleucine [p.(Val653Ile)] within the Src homology 2 (SH2) domain of STAT1. The mutation is exposed on the outer surface of the molecule and within the vicinity of the phosphorylation site (Figure 1E; Video S1 in Supplementary Material). The Val653Ile mutation is predicted to hardly affect the overall structure of STAT1 and was predicted as “tolerated” by the Sort Intolerant From Tolerant algorithm (score 0.58). However, Val653Ile was predicted as “possibly damaging” by the Polymorphism Phenotyping v2 (PolyPhen-2, score 0.919), the mutation was speculated as “disease causing” from the Mutation Taster and was scaled in Combined Annotation Dependent Depletion algorithm with a score of 14.99, which suggests potential deleteriousness.

To evaluate the immunological phenotype associated with this mutation, STAT1 phosphorylation was studied by flow cytometry of fresh whole blood samples from patient 1 and an age-gender-race-matched healthy control. After stimulation with interferon (IFN)-α (10^5 IU/ml; PeproTech, London, UK), IFN-β (10^5 IU/ml; tebu-bio, Le-Perray-en-Yvelines, France), IFN-γ (10^5 IU/ml; R&D systems, Abingdon, UK) for 30 min, or IL-6 (100 ng/ml; R&D systems) for 15 min, cells were fixed and permeabilized with permeabilizing reagent (Phospho-Epitope Exposure kit; Beckman Coulter). All samples were stained with CD3 (APC-conjugated antihuman CD3; BD Biosciences, USA) and Fluor® 488-conjugated phospho-STAT1 Tyr701 antibodies (Cell Signaling Technology, MA, USA). The levels of STAT1 phosphorylation in the CD3+ T lymphocytes from the patient were higher than the levels observed in the healthy control after stimulation with IFNs (Figure 2A) or IL-6 (data not shown). To study the kinetics of STAT1 phosphorylation in more detail, time-course stimulation experiments were performed with fresh whole blood samples from patients 1 and 2 along with age-gender-race-matched healthy controls. The patients clearly displayed higher levels of STAT1 phosphorylation, yet the phosphorylation levels of both the patients and controls normalized over time (Figure 2B).

Because we found a higher basal level of phosphorylated STAT1 (pSTAT1) in patient 1 (Figure S1 in Supplementary Material), we established T lymphocyte cultures to reduce the
Fig. 2 | STAT1 phosphorylation evaluated by intracellular staining flow cytometry after stimulation with IFN-α, IFN-β, or IFN-γ. (A) Histograms showing MFI of phosphorylated STAT1 (pSTAT1) in CD3+ T lymphocytes (in fresh whole blood) of patient P1 and healthy control (HC1) after stimulation with IFN-α, IFN-β or IFN-γ for 30 min. (B) Kinetics of STAT1 phosphorylation in CD3+ T lymphocytes (in fresh whole blood) of the two patients and two healthy controls after stimulation with IFN-α, IFN-β, or IFN-γ. (C) Kinetics of STAT1 phosphorylation in T lymphocyte cultures from both patients and healthy controls. HC, healthy control; P, patient; US, unstimulated; MFI, mean fluorescence intensity.

Confounding effects of exposure of both patients to different pathogens and therapies. Long-term T lymphocyte cultures were expanded from peripheral blood mononuclear cells (PBMC) of both patients and two age-gender-race-matched healthy controls in RPMI-1640 medium (Lonza, Basel, Switzerland), containing 10% heat inactivated human serum and antibiotics (2% penicillin and streptomycin; Cambrex BioWhittaker, Verviers, Belgium) in the presence of Phytohemagglutinin (1 μg/ml; Sigma-Aldrich,
MO, USA), IL-2 (25 IU/ml; Novartis, Basel, Switzerland), IL-15 (12.5 ng/ml; BioLegend, CA, USA), and γ-irradiated (40 Gy) allogeneic PBMC and EBV-negative B lymphocytes. After 2 weeks of culturing, T lymphocyte cultures (purity>90%) from both patients and healthy controls were analyzed for STAT1 phosphorylation in a manner similar to the whole blood samples. IFN stimulation resulted in higher generation of pSTAT1 in the T lymphocyte cultures from patients compared to healthy controls (Figure 2C). Stimulation of T lymphocyte cultures with IL-6 (100 ng/ml) yielded comparable results on pSTAT1 as IFN-γ (data not shown). T lymphocytes from the patients and healthy controls displayed similar levels of total STAT1 protein [determined by flow cytometry using a PE-conjugated STAT1 antibody (BD Biosciences; data not shown)]. STAT3 phosphorylation was also evaluated after stimulation with IL-6 (100 ng/ml) or IL-21 (200 ng/ml; Life Technologies, MA, USA) but did not differ between patients and healthy controls (data not shown).

To assess the effect of the STAT1 mutation on cytokine production, PBMC of both patients and five race-matched healthy controls were freshly prepared and stimulated with heat-killed C. albicans [heat-killed Candida albicans (HKCA): 10^6 cells]. Supernatants were collected, and levels of cytokines were measured by enzyme-linked immunosorbent assay (R&D systems). Cells were also stimulated with phosphorl 12-myristate 13-acetate (PMA) (81 nM) and ionomycin (I) (1.3 μM; eBioscience, CA, USA) as positive control. PBMC from both patients produced IL-6 and IL-1β levels comparable to that of healthy controls, while PBMC from patient 1 did not produce IFN-γ when stimulated with HKCA (Figure 3A). In contrast to PBMC from healthy controls, PBMC from the patients hardly increased IL-17A, IL-17F, and IL-22 production upon stimulation with PMA-I or HKCA (Figure 3A). STAT1 downstream target genes were also measured in T lymphocyte cultures. Due to limited T lymphocyte numbers in these cultures, only one time-point of stimulation (24 h) with three different stimuli [IFN-γ (10^5 IU/ml), IL-6 (100 ng/ml), and IL-27 (200 ng/ml; R&D systems)] was examined. CXCL9, CXCL10, and CD274 (PD-L1) mRNA expression levels were determined by real-time quantitative Taqman PCR in each sample on the basis of six replicates. Strikingly high mRNA levels were observed after IL-27 activation (P < 0.001) (Figure 3B).

**BACKGROUND**

Chronic and/or recurrent fungal infections may be predominant manifestations in primary immunodeficiencies, especially in inherited T lymphocyte defects. Various syndromes have been identified that present with recurrent fungal infections, for example, autosomal dominant (AD) hyper-immunoglobulin E syndrome, autosomal recessive autoimmune polyendocrine syndrome type I, and Mendelian susceptibility to mycobacterial diseases. AD-CMC is a rare and severe immunodeficiency that presents with severe mucocutaneous fungal infections, autoimmune phenomena, cerebral aneurysms and increased risk of oropharyngeal, and esophageal cancer (2–4). In the last decade, various heterozygous gain-of-function (GOF) mutations in STAT1 were found to be responsible for AD-CMC. So far, GOF mutations were described in the coiled-coil domain and the DNA-binding domain of STAT1, and in the past year, the GOF mutations c.1885C>T (p.H629Y) and c.1973G>A (p.N658S) involving the SH2 domain were described (5–7). Chronic and/or recurrent mucocutaneous fungal infections with predominantly C. albicans are the major infectious complications in patients with STAT1 GOF mutations and generally arise in infancy or childhood. However, more than half of the patients encounter bacterial infections, with lower respiratory tract infections most frequently observed. Cutaneous viral infections are also described in about one third of patients (6, 8). In addition, many patients with GOF mutations in STAT1 develop autoimmune manifestations. Autoimmune thyroid disease is reported in 22% of patients. Cerebral aneurysms and cancers are among the most severe complications that are found more frequently and at younger age in these patients when compared to the general population (6, 8).

**DISCUSSION**

The mutation identified in our patients is located in the STAT1 SH2 domain resulting in recurrent mucocutaneous C. albicans infections, which is one of the clinical hallmarks of CMC. The other two family members who carry the same STAT1 mutation but were not included in this study also suffered from recurrent mucocutaneous candidiasis (Figure 1B). In addition to fungal infections, patient 1 showed an atypical susceptibility to a wide range of pathogens, as she experienced S. haemolyticus jaw abscess, S. aureus pneumonia, and CMV pneumonia. Lower respiratory tract bacterial infections can be found in about half of patients with STAT1 GOF mutations. However, based on previous reports, CMV pneumonia was described in only 1% of patients. Patient 2 also encountered an intracranial abscess for which surgical and antibiotic treatments were required. Although the pathogenic microorganism could not be isolated, invasive deep-seated abscesses are uncommon for patients with STAT1 GOF mutations (6). Apart from CMC, atypical features of infections including invasive bacterial infections were also described in other patients carrying a STAT1 GOF mutation in the SH2 domain (5–7). Both patients 1 and 2 enrolled in this study developed a variety of autoimmune phenomena that were displayed in both clinical and laboratory analyses.

In response to various kinds of infections, STAT1 receives signals from the cell surface receptors and is subsequently phosphorylated at Tyr701. The SH2 domain carries the pTyr701-binding site and accordingly plays an important role in forming a firm cross-linkage dimerization between each STAT1 monomer. The dimers then accumulate in the nucleus, inducing transcription of genes (9). The mutation here described within the SH2 domain of STAT1 results in enhancement of STAT1 phosphorylation both upon stimulation with IFN-α/β and IFN-γ, despite the suggestion that the SH2 domain may not necessarily be required for STAT1 activation by IFN-α/β (10). Moreover, this mutation may possibly affect molecule dimerization due to its specific location within the STAT1 molecule.

We performed STAT1 phosphorylation analysis of both patients by flow cytometry, which revealed enhancement of
STAT1 phosphorylation, while total STAT1 protein was equally measured in T lymphocytes of both patients and healthy controls. After stimulation with cytokines, STAT1 phosphorylation in the T lymphocytes of both patients reached higher levels compared to the healthy controls. In contrast to previous reports studying mutations in other STAT1 domains (11–13), we found no clear prolonged STAT1 phosphorylation in the T lymphocytes from the patients. The difference in the mutated domain of STAT1 could possibly be the cause of different phosphorylation characteristics. Apart from elevated pSTAT1 induction, we also noticed a higher basal pSTAT1 level in peripheral blood T lymphocytes from patient 1. Stimulation of fresh whole blood from patient 2 yielded comparable results, although this patient showed no elevated basal level of pSTAT1 when compared to healthy controls. However, after re-evaluation in established T lymphocyte cultures, the elevated basal pSTAT1 level previously noted in the whole blood analysis of patient 1 disappeared. Due to the fact that patient 2 received prophylactic antifungal therapy while patient 1 did not at the time of analysis, recurrent exposure of patient 1 to Candida antigens could have caused the
CONCLUDING REMARKS

The novel Val653Ile mutation, located in the SH2 domain of STAT1 found in this family does not clearly result in an impaired STAT1 dephosphorylation rate, as was found in patients with GOF mutations in the other domains. However, significantly enhanced STAT1 phosphorylation in these patients results in higher expression of the STAT1 target genes CXCL9, CXCL10, and CD274 (PD-L1). Moreover, this mutation is associated with the impairment of immune cells to produce IL-17A, IL-17F, and IL-22. The clinical symptoms of CMC could, therefore, be explained by diminished Th17 responses that are crucial for confronting fungal antigens.

ETHICS STATEMENT

This study was approved by the Medical Ethics Committees of Erasmus MC with ethics approval number MEC 2013-026. Clinical data and blood samples of patients with novel STAT1 mutation and healthy controls were collected after written informed consent was obtained.
