**Abstract**

The aim of the present study was to predict the potential of visible and near infrared (Vis/NIR) Spectroscopy in estimating the amount of lycopene in intact tomato. Eight tomato varieties from loose and cluster type were selected and harvested at commercial ripening stage for the study. The tomato cultivars were prepared after 3 days storage at 18°C and 80% Relative Humidity (RH) before they were subjected to visible and near infrared (Vis/NIR) spectroscopy measurements. For the visible and near infrared (Vis/NIR) spectroscopy measurements four tomato fruits from each variety were prepared as appropriate by separating of clusters, removal of attached stems and assigning a number to each of the tomato fruits. Accordingly, the spectral measurements were done on intact tomato fruits. The visible and near infrared (Vis/NIR) spectroscopy combined with multivariate calibration method such as principal component analysis (PCA) and partial least-squares (PLS) has showed a reasonable prediction performance. The established PLS model at full spectral range (380 – 1700 nm) was with correlation coefficient ($r$) = 0.90 and standard error of prediction (SEP) = 0.65 mg/100g for lycopene. However, the best model for prediction was obtained when the spectral range was limited to the visible range (380 – 950 nm), correlation coefficient ($r$) = 0.92 and standard error of prediction (SEP) = 0.58 mg/100g. Although HPLC is the most accepted method of analysis, Vis/NIR spectroscopy measurement combined with multivariate techniques has the potential to estimate lycopene in intact tomato fruits.

**INTRODUCTION**

Lycopene is the most abundant carotenoid pigment principally responsible for the characteristic deep red color of ripe tomato fruits and tomato products. Recently, a lot of attention has been paid to its biological and physicochemical properties, especially related to its effect as a natural antioxidant (Anantha narayan and Choudhari, 2007; Barba et al., 2006; Qiu et al., 2006; Rao, 2007; Maguer and Shi, 2000), with a singlet oxygen physical quenching rate constant almost twice as high as that of β-carotene and more than ten times higher than that of α-tocopherol (Di Mascio et al., 1989; Ali and Rao, 2007; Pol et al., 2004; Shi et al., 2003).

A number of analytical procedures have been developed and applied for the determination of antioxidants in fresh tomato and tomato products (Gomez-Romero et al., 2007) in a destructive and non-destructive way including electronic tongue (Rudnitskaya et al., 2001), colorimeter, electronic nose (Berna et al., 2002), acoustic firmness sensor (AFS), near infrared spectroscopy (NIR) (Peirs et al., 2003; Yong et al., 2005; Baranska et al., 2006), nuclear magnetic resonance (NMR) (Gladdeny and Alexanderz, 1996), NIR-FT- Raman spectroscopy (Schulz et al., 2005), Fourier transform infrared spectroscopy (FTIR), hyperspectral imaging (Berna, 2006), etc.

However, the analytical methods used for lycopene are rather complicated (Barba et al., 2006), and not all analytical methods available for carotenoid analysis in food products are suitable for lycopene rich foods due to its low solubility in some of the solvents employed, as in the case of methanol and due to the fact that use of other...
solvants may interfere with the HPLC mobile phase applied for carotenoid separation.

Furthermore, the instability of lycopene during processes of extraction, handling, and elimination of organic solvents makes the sample preparation for lycopene an extremely delicate task, often requiring successive and complex procedures to ensure that all the carotenoids are extracted (Barba et al., 2006; Maguer and Shi, 2000; Xu et al., 2006).

Therefore, evaluation of the potential of the non-destructive Vis/NIR reflectance spectroscopy in determination of lycopene content in tomato fruits was importantly considered in this study.

MATERIALS AND METHODS
Experimental Design and Plant Materials
A total of eight tomato varieties, all harvested at commercial ripening stage were selected for the study and prepared after 3 days storage at 18 °C and 80% RH before subjected to Vis/NIR spectroscopy measurements. The tomato varieties included were four loose tomato cultivars (Growdena, Brodena, DRW 75-93 and Excelsior) and four cluster types (Tricia, Clotilde, Bonaparte and Plaisance). For the Vis/NIR Spectroscopy measurements, four tomato fruits from each cultivar were prepared as appropriate by separating of clusters, removal of attached stems and assigning a number to each of the tomato fruits. The spectral measurements were done on intact tomato fruits. Finally, HPLC analyses were carried out on same fruits for comparison.

Vis/NIR Spectroscopy Instrumentation
The spectra were acquired in the wavelength range between 380 nm and 1700 nm. The spectrophotometer (Corona Fibre VISNIR 1104-400, ZEISS, Germany) worked with a single-beam diode array (polychromator) and two sensors (Si, Hamamatsu S 3904 (380-950 nm, 3 nm/diode) and an In Gas array (950-1700 nm, 6nm/diode)). The light source for Vis/NIR (380-1700 nm) could be used both in the visible and near infrared region. The light source consisted of a 9W, 5V stabilized halogen lamp which was directed to the fruit, placed on a black holder (Figure 1). The reflected light was captured by bundled detecting fibers under an angle of 45 degrees to avoid specular reflection and was guided towards the grating polychromator. The light source and spectrophotometer were switched on one hour prior to the acquisition of the spectra.

A reflectance spectrum was taken at approximately two equidistant positions on the equator of each tomato with the help of CORA software for windows 98/NT 4.0/2000. The spectra acquired on the spectrophotometer were corrected for the dark current response of the detector. Each reflectance spectrum was divided by a white reference spectrum recorded on a BaSO4 disc. Furthermore, each measured spectrum was the average of 100 individual optical scans with 2 nm increments. For further calculations the average spectrum of the two sides, which means a total of 200 scans was used for data processing.

Statistical Analysis
Multivariate techniques (PCA and PLS) were also used to analyze the NIR spectra and correlate the NIR spectra with the HPLC reference measurements. The Unscramble version 9 software (CAMO AS, Trondheim, Norway) was used to build multivariate calibration models based on partial least-squares (PLS). The calibration models were validated by means of cross validation, where a small set of randomly selected observations (leave-one-out) was left out to construct the model and is used afterward for validation purposes. This procedure was repeated until all samples have been used for validation. The accuracy of PLS calibration models was calculated as the standard error of prediction (SEP).

\[ SEP = \sqrt{\frac{1}{I_p} - \sum_{i=1}^{I_p} \frac{(Y_i - \bar{y_i} - bias)^2}{I_p}} \]

Where,
- \(Y_i\) is the predicted value of the \(i^{th}\) observation,
- \(y_i\) is the measured value of the \(i^{th}\) observation &
- \(I_p\) is the number of observations in the validation.

RESULTS AND DISCUSSION
In this study the use of Visible/Near infrared reflectance spectroscopy (Vis/NIR) was evaluated for predicting the lycopene concentration of tomatoes. The same tomato
cultivars analyzed by Vis/NIR spectroscopy were measured by HPLC for comparison. The objectives were to establish relationships between non-destructive Vis/NIR spectral predictions of lycopene and HPLC measured values of lycopene. Intact tomato fruits were measured by reflectance in a spectral range of 380–1700nm. The average spectrum (relative reflectance vs. wavelength) was given for each cultivar (Figure 2). A large diversity between the spectra of the cultivars was observed as clearly shown in the Figure 2.

As it can be observed from Figure 2, there are differences in reflectance between cultivars for the whole spectral range but a remarkable difference is noticed between 644 nm and 908 nm. To see more clearly differences between spectra, a principal component analysis (PCA) was performed. The calibration models are developed by partial least square regression.

Sci. Technol. Arts Res. J., July–Sep 2012, 1(3): 17–23

The average lycopene content of tomato cultivars (Table 1) ranged from 2.5 to 7 mg/100 g (fresh weight basis). This result was in closest values (2.62–6.29 mg/100g fresh weight) which were reported by Baranska et al. (2006) for tomato fruit and various tomato products. However, the mean range obtained in this particular study was relatively lower when compared with those reported (6 to 13 mg/100g wet basis) for tomato breeding selections by Halim et al. (2006).

The coefficient of variation (RSD) for replicated HPLC assays was varying between 5.4 to 27.8% for fresh tomato samples depending on cultivar. Although higher value RSD of HPLC measured values seems to have an impact in the uncertainty of the PLS prediction, the overall result shows comparable estimation of lycopene content in tomatoes among the analytical techniques.

Table 1: Cross-validation results using PLS models for lycopene content in tomato cultivars in the visible, NIR and full wavelength range.

| Element | Slope | Offset | Correlation (r) | RMSEP | SEP | Bias |
|---------|-------|--------|-----------------|-------|-----|------|

** Not predicted in the NIR range (Outliers), * Relative Standard Deviation in percentage

The variability in lycopene content between the cultivars was analyzed by the principal component analysis (PCA) based on the visible, NIR and full spectral ranges. The score plot based on concentration in the visible range which is presented in Figure 3 showed good separation of cluster and loose tomatoes. The first two principal components PC1 and PC2 explained 71% and 23% of the total variance respectively. Conversely, the score plot based on NIR spectral ranges shows no well separation of the two tomato types as presented in Figure 4. Based on the NIR spectral ranges PC1 and PC2 explained 92% and 7% of the total variance. In this study the score plot based on the full spectral ranges were also analyzed and the first two principal

components explained 80% and 12% of the total variance respectively.

The PLS prediction result for lycopene in the visible spectra is presented in Figure 5. In this figure, the ordinate and abscissa axes respectively represent the predicted and measured values of lycopene in tomato. A summary of the results that show the performance of the model in the different spectral ranges (Vis, NIR and full range) is also presented in Table 2.

The PLS model can predict the lycopene content of tomato in visible, Vis/NIR and NIR spectral ranges with a correlation coefficient ($r$) of 0.92, 0.90 and 0.82 respectively. A reasonable model was obtained by using the full spectral range ($r = 0.90$, RMSEP = 0.64, SEP = 0.65, bias = -0.012) and the NIR wavelength range ($r = 0.82$, RMSEP = 0.87, SEP = 0.88, bias = 0.028). However, the best model was obtained when the spectral range was limited to 380 – 950 nm ($r = 0.92$, RMSEP = 0.57, SEP = 0.58, bias = -0.011) for lycopene (Table 2 and Figure 5). The wavelength range (380 - 950 nm) which is in the visible spectra seems more convenient for prediction of lycopene in tomato. It seems true that relatively higher spectral ranges are disturbed by CO$_2$ absorption as explained by Baranska et al. (2006). In general, the multivariate calibration model PLS had the potential to estimate the lycopene component concentrations in the different cultivars and the most estimate prediction was based on the visible spectra, which means the color of the tomatoes. Obviously measurement of color is closely related to visual perception (Shewfelt et al. 1988). Also the PCA analysis showed that the loose and cluster tomatoes could be separated from each other based on the visible spectra.

This can lead to the conclusion that Vis/NIR spectroscopy has allowed for rapid, simple and accurate determination of lycopene in tomatoes with minimal sample preparation. The result suggests the potential of Vis/NIR spectroscopy for determining the status of lycopene in a non-destructive way. From this study it can be generalized that this technique has very promising results but more measurements should be performed on a large range of tomato cultivars.

CONCLUSION

The study has evaluated the non-destructive Vis/NIR reflectance spectroscopy measurement of lycopene in the same tomato cultivars at different spectral ranges. The Vis/NIR spectroscopy combined with multivariate calibration method PCA and PLS has the potential to estimate the concentration of lycopene in tomatoes. With this technique, a reasonable prediction performance was achieved from the established PLS model for lycopene at full spectral range (380 –1700 nm), $r =0.90$ and SEP=0.65 mg/100g. However, the best model was obtained when the spectral range was limited to the visible range (380–950 nm), $r = 0.92$ and SEP=0.58 mg/100g. Therefore, it can lead to the conclusion that, although HPLC technique is a widely accepted method of choice, Vis/NIR spectroscopy can be used for rapid, simple and accurate determination of lycopene in tomatoes.
with minimal sample preparation. However, more measurements should be performed on a large range of tomato cultivars and/or on other related fruits such as watermelon.
