Electrical and thermoelectrical transport in Dirac fermions through a quantum dot

Tomosuke Aono

(Dated: September 3, 2012)

We investigate the linear conductance and the thermopower through a quantum dot between two electrodes of Dirac fermions with a pseudogap Anderson model using the non-crossing approximation. When the Fermi level is at the Dirac point, the conductance shows a valley, where the thermopower changes its sign. The conductance shows a peak when the Fermi level away from the Dirac point, where the impurity moment changes sharply, indicating a transition between an asymmetric strong coupling Kondo state and a localized moment state. The thermopower changes its sign in the vicinity of the peak. The magnitude of the thermopower can be more than $k_B/\epsilon$.

Electron transport in graphene is currently under active investigation. Graphene-based quantum dot (QD) structure is fabricated and the Coulomb blockade effect is observed in semiconductor QD systems, it is known that the Coulomb interaction in the QD induces a magnetic moment, leading to the Kondo effect. The Kondo effect in graphene has been intensively discussed from the view of the magnetic impurity problem in massless Dirac fermions. A recent experiment shows the Kondo effect can be induced by lattice vacancies. The Kondo effect is expected to be observed in another representative Dirac fermions, the surface states of the topological insulator. A single Dirac cone appears on the surface of three dimensional topological insulators. Several theoretical studies on the Kondo effect in this system have been developed.

The Kondo problem in massless Dirac fermions is an important part of the pseudogap Kondo problem, where the density of states of conduction electrons is a significant part of the pseudogap Kondo problem. In this system have been developed. In graphene, the Coulomb interaction is strong enough, three fixed points control the electronic states in the system, namely the local moment (LM) fixed point, the asymmetric strong coupling (ASC) or frozen impurity fixed point, and the valence fluctuation (VFI) fixed point located in between. The Kondo problem in graphene has been studied as a tunable pseudogap Kondo problem, where the transition can be controlled by external gate voltages. Recently the Kondo effect found in Ref. has been analyzed using a pseudogap Anderson model.

In addition to electric transport, thermoelectric transport in nano-structures has been actively investigated. For instance, the measurement of the thermopower can reveal the electron-hole asymmetry in a system. The thermopower under the Kondo effect has been examined in QD systems. In the QD system, its measurement clarifies the formation of the Kondo resonant state.

We investigate electric and thermoelectric transports through a QD between two electrodes of Dirac fermions. The tunneling coupling between the QD and the electrode is proportional to $\omega$. We show how this pseudogap coupling controls electronic states of the system and the transport properties. In addition, we show how the impurity quantum phase transition influences those properties. To this end, we study the conductance, the thermopower and the impurity magnetic susceptibility based on a pseudogap Anderson model using the non-crossing approximation (NCA).

Model.— We consider a system consisting of a QD and two electrodes with the Dirac fermions, as shown in the inset of Fig. (1a). We treat the case of a single Dirac cone with the chemical potential $\mu_i (i = L, R)$, and focus on the zero bias voltage limit, $\mu_L \rightarrow \mu_R$, setting $\mu_L = 0$. The position of the Dirac point from the Fermi level is denoted by $-\mu_0$.

The Hamiltonian of Dirac fermions in the lead $i$, $H^{(i)}_0$ is given by

$$H^{(i)}_0 = \int \frac{d^2k}{(2\pi)^2} \langle \Psi^\dagger_i(k) \Psi^\dagger_i(k) \rangle M(k) \left( \frac{\Psi_i(k)}{\Psi_0(k)} \right) \tag{1}$$

with $M(k) = \left( \begin{array}{cc} -\mu_o & k_F k e^{-i\theta} \\ k_F k e^{i\theta} & -\mu_o \end{array} \right)$, where $\Psi_i(k)$ are the annihilation operators of Dirac fermions, $v_F$ is the Fermi velocity, $k = (k \cos \theta, k \sin \theta)$ with $k = |k|$ and $\theta$ stands for the azimuth angle of $k$ from the $x$ axis. The indexes $a$ and $b$ refer to (pseudo) spin indexes. For a single Dirac cone system, those are the spin indexes; $a = \uparrow$ and $b = \downarrow$. For graphene, $a = (A, s)$ and $b = (B, s)$ with the two sublattices $A$ and $B$, which play the role of the pseudo spin, and the spin index $s = \uparrow$, $\downarrow$ around the $K$ and $K'$ points.

The QD has a single energy level $E_g$ controlled by a
gate voltage. The Hamiltonian for the QD is given by
\[
H_0 = \sum_{i=1, R} \int d\omega \omega c_{\sigma i}^\dagger(\omega)c_{\sigma i}(\omega),
\]
where \(c_{\sigma i}(\omega)\) is the annihilation operator for an electron in the lead \(i\) with the pseudo spin index \(\sigma\) at the energy \(\omega\). The tunneling Hamiltonian \(H_T\) is given by
\[
H_T = \sum_{i, \sigma} \int d\omega \sqrt{\Gamma(\omega)}d_{\sigma i}^\dagger c_{\sigma i}(\omega) + \text{h.c.}
\]
We have disregard the difference between the spin and pseudo spin indexes, both are now represented by \(\sigma\). The tunneling coupling between the dot and electrodes is \(\Gamma(\omega) = \alpha(\omega + \mu_0)\) with \(\alpha = \frac{\sqrt{V_s^2}D}{2\gamma t}\) \([10, 23, 24]\). It is necessary to introduce an energy cut-off \(D\), and then it is convenient to rewrite \(\Gamma(\omega)\) in the form:
\[
\Gamma(\omega) = \Gamma_0 \left| \frac{\omega + \mu_0}{D} \right|
\]
with \(\Gamma_0/D = \alpha\). The pseudogap Anderson model with \(H = H_0 + H_T + H_0\) is analyzed below.

We consider the infinite \(U\) model. This corresponds to the asymmetric pseudogap Anderson model \([27, 29, 30]\). We use the auxiliary boson technique \([37, 42]\), where \(d_{\sigma} = b^{\dagger}f_{\sigma},\ b\) is a boson operator and \(f_{\sigma}\) is a fermion operator; \(b^{\dagger}b + \sum_{\sigma} f_{\sigma}^\dagger f_{\sigma} = 1\) should be satisfied. Then we adopt the NCA \([37, 40]\) to calculate the local density of states of the QD and other quantities. To perform the numerical calculations, we evaluate the Green functions on the range of \(|\omega| \leq 10D\) and introduce the Lorentzian cut-off in the pseudogap coupling: \(\Gamma_L(\omega) = \Gamma(\omega) \cdot D^2/(\omega^2 + D^2)\). The convergence of the NCA equations is monitored by the unity of the spectral functions for \(f_{\sigma}\) and \(b\), and the relation on the total occupancy in the QD \([39]\), which are satisfied typically with the accuracy of less than 0.1%.

The conductance \(G\) and the thermopower \(S\) are given by \(G = e^2I_0(T)\) and \(S = -I_1(T)/(eT I_0(T))\) with
\[
I_n(T) = -2/e \int d\omega \omega^n \frac{\partial f(\omega)}{\partial \omega} \Gamma(\omega) \text{Im} A^*(\omega),
\]
where \(f(\varepsilon)\) is a Fermi-Dirac function, \(f(\omega) = 1/[\exp(\varepsilon/k_B T) + 1]\), and \(A(\omega)\) is the retarded Green function for electrons in the QD \([33, 43]\). The impurity magnetic susceptibility \(\chi(\omega)\) is given by \(\chi(\omega) = \int_{-\infty}^{\infty} d\varepsilon e^{i(\varepsilon + \alpha + \theta)} M(t)\) with \(M(t) = i\theta(t)[[\tilde{M}(t), \tilde{M}(0)]]\), and \(\tilde{M} = g\mu B/2 (f_{\uparrow} f_{\downarrow} - f_{\downarrow} f_{\uparrow})\). The static susceptibility \(\chi = \chi(0)\) is evaluated using NCA \([38]\). We set \(g\mu B = 1\) and \(k_B = 1\) below.

**Undoped system.**— Let us first consider \(G\) and the occupation number in the QD, \(n_d\), when the Fermi level is at the Dirac point; \(\mu_0 = 0\). It has been shown that for this case, the Kondo temperature \(T_K = 0\) \([8, 13, 25]\). In Fig. (a), \(G\) and \(n_d\) are plotted as a function of the gate voltage \(E_g\). The plot of \(G\) shows a valley; \(G \propto |E_g - E_g| + G_m\) with the minimum conductance \(G_m\) at the cusp, where \(E_g = E_g^\ast\). Out of the valley, \(G\) decreases monotonically, consisting of double peaks. In the valley, \(n_d\) changes gradually. This means the system is in the VFI regime.

In Fig. (b), the density of states of the QD, \(\rho_d(\omega) = (-1/\pi)\text{Im} A(\omega)\), is plotted. At \(E_g = E_g^\ast\), \(\rho_d(\omega)\) shows a narrow and singular peak at the Fermi level, \(\omega = 0\). The appearance of such a distinct peak has been discussed \([13, 28, 29]\). In spite of this sharp peak of \(\rho_d(\omega)\), \(G\) remains small because \(\Gamma(\omega)\) suppresses the peak height.
function of \((E_g - E_{g}^{*})/T\) for several temperatures. The curves of \(G\) resemble one another. This means the peak width of the double peaks depends linearly on \(T\). The curves of \(S\) are also close to each other; \(S \propto (E_g - E_{g}^{*})/T\), and \(S\) changes the sign at \(E_{g}^{*}\). This means \(E_{g}^{*}\) gives the boundary between electron-like and hole-like transport, This is in agreement with the fact that \(E_{g}^{*}\) locates in the VFI regime. Note that the magnitude of \(S\) can be large, which is more than \(k_B/e \approx 76 [\mu V/K]\).

The above results of \(G\) and \(S\) are explained largely by the shape of \(\rho_d(\omega)\). When \(U = 0\),

\[
\rho_d(\omega) = -\frac{1}{\pi} \text{Im} \frac{1}{\omega - E_g + i\Gamma(\omega)/D}.
\]

To adjust the QD level shift due to \(U\), we replace \(E_g\) with \(E_g - E_{g}^{*}\). When \(U = 0\), the peak width of \(\rho_d(\omega)\) is smaller than \(T\), since \(D/\Gamma_0 > 1\). It is valid for the present model. Then \(\rho_d(\omega)\) can be approximated by a Dirac delta function, \(\rho_d(\omega) \approx \delta(\omega - (E_g - E_{g}^{*}))\), so that \(G\) is determined by the remaining part of the integrand in Eq. (6). \(\omega|f'(\omega)|\). This factor explains \(G \propto |E_g - E_{g}^{*}|\) and the width of the double peak structure. The line shape of \(S\) is explained as follows: \(I_1(T) \propto |E_g - E_{g}^{*}|(E_g - E_{g}^{*})\) near \(E_g = E_{g}^{*}\), resulting in \(S \propto (E_g - E_{g}^{*})/T\). The magnitude of \(S\) can be the order of \(k_B/e\) since \(f'(\omega)\) is finite when \(|E_g - E_{g}^{*}| \sim T\).

Doped system.— Next we consider the case when the Fermi level is away from the Dirac point; \(\mu_0 \neq 0\). Since \(\Gamma(\omega)\) is finite at \(\omega = 0\), the Kondo effect is active. As a result a clear sign of the transition between the ASC and LM states will appear by tuning external voltages.

In Fig. 3, \(G\) and the impurity moment \(T\chi\) are plotted as a function of \(\mu_0\). The values of \(E_g\) are indicated in the figures; two of them are below \(E_{g}^{*}\), and two of them above \(E_{g}^{*}\). In three of them, \(G\) shows a sharp peak. The peak height is about \(2e^2/h\). This result is in contrast with the one in Fig. 1(a). When \(\mu_0\) is negative and large, \(T\chi\) is almost zero. This means that the impurity is screened by the Kondo effect. This corresponds to the ACS state. As \(\mu_0\) increases, \(T\chi\) increases sharply, where the system moves to the LM state. The sharp peak of \(G\) appears at the boundary of the transition of those two states. The Kondo temperature \(T_K\) can be defined through \(T\chi\); \(T_K(\chi(T_K)) = 0.0701 [44, 45]\). Here we adopt this definition of \(T_K\) and draw a line in Fig. 3(b) at \(T\chi = 0.07\). Since \(T_K\) depends on \(\mu_0\), \(T_K(\mu_0) = T\) at the intersection of the line and the curves. The peak structure of \(G\) can be associated with the transition at \(T \sim T_K\). Thus \(G(\mu_0)\) brings a clear evidence of the transition between the ASC and LM states.

In Fig. 3, \(G\) and \(S\) are plotted as a function of \(\mu_0\) when \(E_g/\Gamma_0 = -0.48\) at several temperatures. As the temperature increases, \(G\) decreases monotonically. This can be understood by the suppression of the Kondo effect.

FIG. 2. (color online) Temperature and gate voltage dependence of conductance \(G\) (a), and thermopower \(S\) (b) when \(\mu_0 = 0\). The gate voltage \(E_g\) is scaled as \((E_g - E_{g}^{*})/T\), where \(E_{g}^{*}\) is the gate voltage at the cusp of \(G\).

FIG. 3. Conductance \(G\) (a), and impurity moment \(T\chi\) (b) versus shift of the Fermi level away from the Dirac point \(\mu_0\) at \(T/\Gamma_0 = 1.0 \times 10^{-4}\). For a free 1/2 spin, \(T\chi = 1/4\). The values of \(E_g\) are indicated in the figures. The dotted line in (b) indicates \(T_K(\chi(T_K)) = 0.07\).
FIG. 4. (color online) Conductance $G$ (a), and thermopower $S$ (b) versus $\mu_0$ for several temperatures and $E_F/\Gamma_0 = -0.48$. Inset (a): $\rho_4(\omega)$ for $\mu_0 = 0$ (blue) and $\mu_0 = 1.2 \times 10^{-2}$ (red), where the dip of $S$ appears, at $T/\Gamma_0 = 4.0 \times 10^{-3}$.

due to the temperature. In the vicinity of the peak of $G$, $S$ changes its sign. In the ASC state, the Kondo resonant state locates above the Fermi level, whereas in the LM state, the impurity level is below the Fermi level. Thus the sign change of $S$ reflects the transition between two states.

We add two comments on the results of $S$. First, around $\mu_0 = 0$, $S$ changes the sign for low temperatures, and this change disappears for high temperatures [40]. In this case, a dip of $\rho_4(\omega)$ induced by the pseudogap crosses the Fermi level as shown by the blue line in the inset of Fig. (b). This dip is symmetric around $\omega = 0$. The asymmetry of the dip becomes evident as $\omega$ is away from zero. At low temperatures, the crossing of the dip at the Fermi level results in the change the sign of $S$. At high temperatures, where the asymmetry of $\rho_4(\omega)$ is captured, $S$ remains negative. Second, around $\mu_0/\Gamma_0 = 1.2 \times 10^{-2}$, a clear dip in $S$ appears for high temperatures. This is the place where $\rho_4(\omega)$ shows the critical sharp peak as in Fig. (1b), at $\omega = -\mu_0$.

We have shown that $S$ can be more than $k_B/e$, which is dissimilar to the conventional Kondo system [38]. The figure of merit, $ZT = S^2GT/\kappa$, where $\kappa$ is the thermal conductivity, describes the efficiency of thermoelectric materials [32], and it can be calculated using the Landauer formula approach, where $\kappa = \left[I_2(T) - I_1(T)^2/I_0(T)^2\right]/T$ [33, 43]. Within the present model, $ZT \geq 1$, for wide range of parameter values of $T$, $E_g$, and $\mu_0$, and sometimes $ZT$ becomes more than 10. Thus the pseudogap Kondo system is interesting not only from the point of view of the impurity quantum phase transition, but also for its thermoelectric properties.

In summary, we have investigated the conductance and the thermopower through a QD between Dirac fermions. The pseudogap tunneling coupling between the QD and electrodes suppresses the conductance for doped electrodes. For doped electrodes, the conductance shows a peak structure which signifies the transition between the ASC and LM states. The thermopower can be more than $k_B/e$ for both doped and undoped cases.
