Abstract

We investigate the non-self-averaging properties of the dynamics of Ising, 4-state Potts and 10-state Potts models in single-cluster Monte Carlo simulations on quenched ensembles of planar, trivalent ($\Phi^3$) random graphs, which we use as an example of relevant quenched connectivity disorder. We employ a novel application of scaling techniques to the cumulative probability distribution of the autocorrelation times for both the energy and magnetisation in order to discern non-self-averaging. Although the specific results discussed here are for quenched random graphs, the method has quite general applicability.
1 Introduction

The effect of quenched, typically bond, disorder on the critical behaviour of spin systems has been a subject of interest for many years \cite{1}, both because of its own intrinsic interest and the prevalence of disordered systems in nature. The Harris criterion states \cite{2} that the critical behaviour of a pure system will be unchanged by the introduction of weak quenched bond disorder if the specific-heat exponent of the pure system, $\alpha_p$, is less than zero. By the same token if $\alpha_p$ is greater than zero the disordered system will not be governed by the pure fixed point, but rather a new disordered fixed point. The borderline, $\alpha_p = 0$, constitutes a marginal case which requires more careful investigation for each specific case.

As was emphasised in \cite{3}, a pure fixed point is usually characterised by a gaussian distribution of renormalised couplings around the fixed point Hamiltonian which tends to a delta function in the thermodynamic limit, whereas a disordered fixed point might be expected to be characterised by some other distribution which tended to a finite width in the thermodynamic limit \cite{4}. For a fixed point with a finite width distribution of couplings a measurement of the density of an extensive thermodynamic quantity such as the energy $E$, magnetisation $M$, specific heat $C$ or magnetic susceptibility $\chi$, would be different on each sample because of the different disorder realizations. Such behaviour is called non-self-averaging.

This non-self-averaging behaviour for an observable $X$ (such as $E$, $M$, $C$, or $\chi$ above) can be characterised by examining the normalised variance

$$R(X) = \frac{[X^2]_{av} - [X]_{av}^2}{[X]_{av}^2},$$

where $[\ldots]_{av}$ denotes an average over the disorder realizations \cite{3, 4, 5}. If $R(X) \to 0$ as $N \to \infty$, where $N$ is the number of lattice sites, then we have self-averaging, whereas if $R(X) \to c$, with $c$ a constant, we have non-self-averaging. Self-averaging systems may in turn be divided into strongly self-averaging systems where $R(X) \sim N^{-1}$, which is the typical behaviour off criticality and at pure fixed points and weakly self-averaging systems where $R(X) \sim N^\kappa$ with $-1 < \kappa < 0$, which has been observed for the case of irrelevant quenched disorder at criticality \cite{4}. For self-averaging systems measurements on a single large system are sufficient, whereas for non-self-averaging systems measurements on different realizations of the disorder must be carried out in order to obtain reliable ensemble averages.

In this paper we will be concerned with quenched connectivity disorder, which has received rather less attention than quenched bond disorder. The possible influence of quenched geometrical disorder (connectivity, aperiodicity, \ldots) on the universality properties of statistical mechanical systems in general has been explored by Luck \cite{6} who arrived at a criterion rather similar in spirit to the Harris criterion for the (ir)relevance of such disorder. He noted that if $B(\Omega)$ was the number of bonds in a region $\Omega$ and $\Sigma(\Omega) = \sum_{<ij> \in \Omega} J_{i,j}$ was the sum of bond values in that region then, although both these quantities scaled as the volume $N$ of the region $\Omega$, one had

$$\Sigma(\Omega) - J_0 B(\Omega) \sim N^\phi,$$

where $J_0$ was the limiting value as $N \to \infty$ of $\Sigma(\Omega)/B(\Omega)$ and $0 \leq \phi < 1$ was a fluctuation (or

\footnote{As we note in the sequel, the presence of such a finite width distribution, and hence non-self-averaging, is not a hard and fast indicator of new, random fixed points since Poissonian random lattices still display pure critical behaviour even though they also display non-self-averaging properties.}
wandering) exponent. The geometrical fluctuations were found to be relevant if
\[
\phi > \frac{1 - \alpha}{2 - \alpha}.
\] (3)

Although explicit calculations of \( \phi \) have not been carried out for models with quenched connectivity disorder, simulations have shown that it appears to be remarkably difficult to escape from pure fixed points with such disorder, in contrast to the case of bond disorder. A prime example of this generic behaviour is Poissonian (or Voronoi) random lattices, which have been shown to display the pure critical exponents for the 3D Ising model \( ^7 \) to a very high degree of accuracy. Numerous other systems with quenched connectivity disorder show similar, pure critical behaviour \(^8\). However, the quenched connectivity disorder manifested by an ensemble of planar, trivalent random graphs, which we denote \( \Phi^3 \) graphs for brevity, \( does \) appear to give rise to new disordered fixed points \(^9\). The exponents of the Ising and \( q \leq 4 \) state Potts models, which already possess continuous transitions on flat 2D lattices, are altered and the first-order transition of higher state Potts models is softened to a continuous transition \(^9, 10\) on the \( \Phi^3 \) graphs.

The \( \Phi^3 \) graphs in question are precisely those generated in a simulation of pure 2D quantum gravity, though in that case one has an annealed ensemble in which the connectivities fluctuate. For such an annealed ensemble of \( \Phi^3 \) graphs the KPZ formula \(^11\) shows how the conformal weights of operators in spin models living on the graphs are transformed from their flat 2D lattice values. The KPZ formula \emph{per se} thus applies to systems in which the spins are fluctuating on the same time-scale as the connectivity. One can, however, obtain predictions for the critical exponents of spin models living on an quenched ensemble of such graphs \(^12\), which is what we are considering here, by taking a quenched limit in the KPZ formula \(^12, 13, 14\). In this limit one finds that the flat lattice conformal weight \( \Delta \) is transmuted to a new quenched weight
\[
\tilde{\Delta}_{\text{quenched}} = \frac{\sqrt{1 + 24\Delta} - 1}{4},
\] (4)

which may then be used to determine the critical exponents \( \alpha \) and \( \beta \) for the quenched ensemble\(^12\).

To date investigations of non-self-averaging behaviour in the presence of quenched disorder have concentrated exclusively on static quantities such as the susceptibility, rather than the dynamical properties described by the autocorrelation times for various observables. In this paper we study the non-self-averaging properties of autocorrelation times for the energy and the magnetisation in the presence of quenched (in our case connectivity) disorder. We consider the Ising, \( q = 4 \) and \( q = 10 \) state Potts models on quenched ensembles of \( \Phi^3 \) random graphs, since the simulations of \(^9\) provided strong evidence for new, disordered fixed points in all these cases.

In the next section we briefly recall the models studied and describe the Monte Carlo simulations performed. The results of the autocorrelation analyses are presented in Sec. 3, and in Sec. 4 we close with a summary and a few concluding remarks.

---

2 In which the connectivity disorder is frozen in.
3 It is only fair to remark that the analysis of the data in \(^9\), on which the current paper is also based, only lend rather weak support to these predictions.
2 The Model and Simulations

As in [9] we use the standard definition of the $q$-state Potts model partition function and energy

$$Z_{\text{Potts}} = \sum_{\{\sigma_i\}} e^{-\beta E}; \quad E = -\sum_{\langle ij \rangle} \delta_{\sigma_i \sigma_j}; \quad \sigma_i = 1, \ldots, q,$$

(5)

where $\beta = J/k_B T$ is the inverse temperature in natural units, $\delta$ is the Kronecker symbol, and $\langle ij \rangle$ denotes the nearest-neighbour bonds of the random $\Phi^3$ graphs (without tadpoles or self-energy bubbles) with $N$ sites. We consider the cases $q = 2$ and $4$ with $N = 500, 1000, 2000, 3000, 4000, 5000,$ and $10000$ which in the pure model exhibit second-order phase transitions, and the case $q = 10$ with $N = 250, 500, 1000, 2000, 3000, 5000,$ and $10000$ which in the pure model undergoes a first-order phase transition.

The simulations were carried out using the Wolff single-cluster update algorithm [15]. For each lattice size we generated 64 independent graphs using the Tutte algorithm [16], and performed 500K equilibration sweeps followed by up to 10 million measurement sweeps in order to obtain 500K independent measurement sweeps for each lattice size. The runs were carried out at several $\beta$ values near the transition point and time series of the energy $E$ and the magnetisation

$$M = (q \max\{n_i\} - N)/(q - 1)$$

recorded for each graph. In what follows the per-site quantities are denoted by $e = E/N$ and $m = M/N$, the thermal averages on each individual graph by $\langle \ldots \rangle$ and the quenched average over the different graphs by $[\ldots]_{\text{av}}$. From the time series of $e$ and $m$ it is straightforward to compute in the finite-size scaling (FSS) region various quantities at nearby values of $\beta$ by standard re-weighting [7] techniques.

To estimate the statistical (thermal) errors for each of the 64 realizations, the time-series data was split into bins, which were jack-knifed [18] to decrease the bias in the analysis of re-weighted data. The final values are averages over the 64 realizations which will be denoted by square brackets $[\ldots]_{\text{av}}$, and the error bars are computed from the fluctuations among the realizations. Note that these errors contain both the average thermal error for a given realization and the theoretical variance for infinitely accurate thermal averages which is caused by the variation over the random graphs.

From the time series of the energy measurements we computed by re-weighting the average energy, specific heat, and energetic fourth-order cumulant, as discussed in more detail in [3]. Similarly, we derived from the magnetisation measurements the average magnetisation, susceptibility, and magnetic cumulants and also evaluated mixed quantities involving both the energy and magnetisation. However, it is the dynamical aspects of the simulations which are our principal concern here and these are characterised by the autocorrelation functions and the associated integrated autocorrelation times $\hat{\tau}$. It is now customary when discussing single-cluster algorithm simulations [19] to convert the $\hat{\tau}$ thus obtained by multiplying with a factor $f = n_{\text{flip}}(\langle C \rangle)/N$ to a standardised scale where, on the average, measurements are taken after every spin has been flipped once. This allows a fair comparison with, e.g., Metropolis simulations.

When one has quenched random disorder this procedure is not unique due to the average over realizations $[\ldots]_{\text{av}}$, since one can take either $[\hat{\tau}]_{\text{av}} \equiv [f \cdot \hat{\tau}]_{\text{av}}$ or $[f]_{\text{av}} \cdot [\hat{\tau}]_{\text{av}}$. We have presented the raw data and both variations in Tables 1–6 for both the energy and magnetisation for $q = 2$, 4, and 10 where it can be seen that the differences between the two averaging prescriptions are rather small, so for all practical purposes they can be considered to be equivalent. For definiteness in the scaling analysis we take $[\hat{\tau}]_{\text{av}} \equiv [f \cdot \hat{\tau}]_{\text{av}}$. In Tables 1–6 the minimum value

\[4\text{Where } n_i \leq N \text{ denotes the number of spins of “orientation” } i = 1, \ldots, q \text{ in one lattice configuration.}\]
of $\tau \ (= f \cdot \hat{\tau})$ for the various realizations is denoted by $\tau_{\text{min}}$ and the maximum by $\tau_{\text{max}}$. The standard deviation $\Delta \tau$ and its scaled form, $\Delta \tau/|\tau|_{\text{av}}$, are also tabulated.

3 Results for Autocorrelation Times

The integrated autocorrelation times for each random-graph realization are obtained by blocking techniques. These are (necessarily) measurements at the simulation points which are chosen close to a finite-size scaling sequence of $\beta$-values but not with high precision since these are a priori estimates based on the results on smaller lattices. For higher accuracy one would have to redo the simulations using the knowledge of the infinite-volume estimates of $\beta_c$ or the locations of the maxima of $C$, $\chi$, etc. obtained from the present batch of runs and presented in [9]. As a consequence of this choice of measurement points it can be seen in the sequel that one or two data points lie rather far from the general trend.

Looking at the behaviour of the autocorrelation times for each $q$ in turn, we can see that the autocorrelation times for $q = 2$ stay roughly constant with increasing system size for both the energy and the magnetisation. For the energy we obtain values in the range $3 - 4$, and for the magnetisation in the range $1 - 2$. These results are obtained with the cluster update for general $q$-state Potts models where the new spin direction $s_{\text{new}}$ for a cluster is chosen randomly from $s_{\text{new}} \in [1, q]$. Picking the old value, $s_{\text{new}} = s_{\text{old}}$, would not change anything. Hence for $q = 2$ the autocorrelation time can be reduced by a factor of 2 by requiring that the spin direction of the cluster flips rather than is chosen randomly.

For $q = 4$ the autocorrelation times are also still reasonably small, covering a range $12 - 18$ for the energy and a range $7 - 10$ for the magnetisation. However, here a scaling with system size is now clearly observable and fits to the standard finite-size scaling ansatz

$$[\tau]_{\text{av}} = a N^{z/D} \quad (6)$$

give for the energy $\ln a = 2.283(82)$ and $z/D = 0.064(10)$ with $\chi^2/\text{dof} = 1.28$ or a goodness-of-fit parameter $Q = 0.28$, if the $N = 500$ and $N = 1000$ graphs are omitted. For the magnetisation the fit through all available graph sizes yields $\ln a = 1.554(95)$ and $z/D = 0.074(13)$ with $\chi^2/\text{dof} = 1.01$ or $Q = 0.41$. The data along with the fits are shown in Fig. 1. Note that the estimates of $z/D$ on the random graphs are considerably smaller than for regular lattices [20] where $z/D = 0.876(11)/2 = 0.438(6)$ for the integrated autocorrelation time of the energy, using the Swendsen-Wang cluster-update [1]. In fact, since the Li-Sokal bound [21] guarantees for regular lattices that $\tau_e \geq \text{const} \times C$ and the specific heat $C$ diverges on regular lattices at criticality like $L(\ln L)^{-3/2}$, we see that (as was noted in [20]) this actually must be an underestimate. It should be emphasised that for quenched (or annealed) gravity graphs the singularity of the specific heat is predicted to be weakened; hence we are not a priori in contradiction with the suitably generalised Li-Sokal bound.

For $q = 10$, where one would expect on regular lattices for both autocorrelation times a pronounced exponential increase with system size due to the first-order nature of the transition, the first point to note is that here on $\Phi^3$ graphs the values are very large by comparison with the Ising and $q = 4$ Potts model measurements discussed above, falling into the range $60 - 500$ for the energy and $40 - 350$ for the magnetisation. The increase of $[\tau]_{\text{av}}$ with system size, however,

\[5\] In two dimensions the difference between the dynamical critical exponent of the Wolff single-cluster and Swendsen-Wang cluster algorithm, if any, is empirically extremely small.
is consistent with a power-law scaling behaviour rather than the exponential increase of a first-order transition. If we omit the two smallest graph sizes with \( N = 250 \) and \( N = 500 \) we obtain from fits of the energy autocorrelations the estimates \( \ln a = -1.44(29) \) and \( z/D = 0.829(35) \) with \( \chi^2/\text{dof} = 1.97 \) or \( Q = 0.12 \). Fits of the magnetisation autocorrelations yield \( \ln a = -3.49(44) \) and \( z/D = 1.019(54) \) with \( \chi^2/\text{dof} = 1.00 \) or \( Q = 0.39 \). The data and the quality of the fits can be inspected in Fig. 2.

For quenched, random systems not only the scaling behaviour of the average \([\tau]_{\text{av}}\) is of interest but also the properties of the whole probability density \( P(\tau) \). Since we have only few (= 64) events for sampling this density it is numerically (and mathematically) more sensible to consider the cumulative probability distribution \( F(\tau) = \int_0^\tau P(\tau') d\tau' \), with the obvious relation \( dF(\tau)/d\tau = P(\tau) \).

In Figs. 3 and 4 we have plotted the cumulative distribution of the scaled \( \tau \) at the simulation point in the \( q = 4 \) model for both the energy and the magnetisation. It is clear from the graphs that the distribution is slightly broadening with increasing lattice size, rather than sharpening. For self-averaging measurements one would expect the curves to tend to a step function, since the underlying probability density of \( \tau \) would tend to a delta-function in such a case. One can therefore conclude that the measurements of \( \tau \) in the simulations provide strong evidence for non-self-averaging behaviour in the \( q = 4 \) model. This statement can be made more quantitative by considering similar to eq. (1) the ratio of the width of the probability density, the standard deviation \( \Delta \tau \), and the average value, \([\tau]_{\text{av}}\), which sets the scale. As this is a property of the quenched randomness here we tacitly assume that the thermal noise of the estimates of \( \tau \) for a given realization can be neglected which, in view of our extremely high statistics, is justified.

The plot of \( \Delta \tau/[\tau]_{\text{av}} \) in Fig. 5 shows that the relative widths of the densities of both the energy and the magnetisation stay roughly constant with increasing system size, thus clearly demonstrating the lack of self-averaging. Another way to demonstrate this property graphically is to plot the probability distribution \( F \) against the scaled variable \( \tau/[\tau]_{\text{av}} \). If the density is non-self-averaging with \( \Delta \tau/[\tau]_{\text{av}} = \text{const} \) one expects to see in such a plot data collapse onto a single master-curve. As can be seen in Figs. 6 and 7 this is indeed the case for both the energy and the magnetisation.

For \( q = 2 \) the corresponding plots look very similar and are not reproduced here. More interesting is the qualitatively different case of the \( q = 10 \) Potts model, because here the first-order transition on regular lattices is softened to a second-order transition for quenched, random graphs. Here the plots of the cumulative distributions in Figs. 8 and 9 again clearly exhibit the broadening with increasing lattice size just as for \( q = 4 \), rather than sharpening. Therefore it is even more impressive to observe that reploting the data versus the scaled variable \( \Delta \tau/[\tau]_{\text{av}} \) still produces well-defined master curves for both the energy and magnetisation as can be seen in Figs. 10 and 11. The scaling of \( \Delta \tau/[\tau]_{\text{av}} \) as a function of system size looks slightly more scattered than for \( q = 4 \) (recall that the effective statistics per graph is smaller by about one order of magnitude compared with the \( q = 4 \) model), but also here it is safe to claim that \( \Delta \tau/[\tau]_{\text{av}} \) stays roughly constant with increasing system size. One can therefore conclude that the measurements of \( \tau \) in the simulations provide strong evidence for non-self-averaging behaviour in the \( q = 10 \) model as well.
4 Conclusions

Our previous analysis of the static properties of simulations of the Ising and $q = 4, 10$ state Potts models on $\Phi^3$ graphs showed that the quenched connectivity disorder they possessed altered the exponents of models with a continuous transition on a regular lattice, and softened the first-order transition of the $q = 10$ model to a continuous transition.

The analysis of the autocorrelation times discussed here shows that these models display another property that is often associated with a disordered fixed point with a distribution of couplings, namely, non-self-averaging. One must, however, be a little careful in using non-self-averaging as a diagnostic for distinguishing pure and random fixed points: the Ising model on a 3D Poissonian random lattice has been shown to have the standard critical exponents to a very high degree of accuracy, but nonetheless still displays non-self-averaging of both static and dynamical properties [7].

Whatever the circumstances in which non-self-averaging appears the analysis here shows that it is also manifest in the autocorrelation times of the systems in question and amenable to a quantitative scaling analysis. Although we have only discussed the Ising and $q = 4, 10$ state Potts models on $\Phi^3$ random graphs here, it is clear that the idea of looking at $P(\tau)$ and its scaling properties to discern non-self-averaging is generally applicable.

Figure 1: The data points and fits to $[\tau]_{av} = aN^{z/D}$ for both the energy and magnetisation in the $q = 4$ state Potts model.
Figure 2: The data points and fits to $[\tau]_{av} = a N^{z/D}$ for both the energy and magnetisation in the $q = 10$ state Potts model.
Figure 3: The cumulative distribution function for the energy autocorrelations in the $q = 4$ Potts model. The system size is *increasing* as the curves move to the right.
Figure 4: The cumulative distribution function for the magnetisation autocorrelations in the $q = 4$ Potts model. Again, the system size is increasing as the curves move to the right.
Figure 5: A plot of $\Delta \tau / [\tau]_{av}$ for both the energy and magnetisation. Given the caveat in the text regarding the simulation points this is clearly tending to a constant for increasing system size.
Figure 6: The scaled cumulative distribution function for the energy autocorrelations in the $q = 4$ Potts model showing the good data collapse.
Figure 7: The scaled cumulative distribution function for the magnetisation autocorrelations in the $q = 4$ Potts model showing a similar data collapse to the energy case.
Figure 8: The cumulative distribution function for the energy autocorrelations in the $q = 10$ Potts model. The system size is increasing as the curves move to the right.
Figure 9: The cumulative distribution function for the magnetisation autocorrelations in the $q = 10$ Potts model. Again, the system size is increasing as the curves move to the right.
Figure 10: The scaled cumulative distribution function for the energy autocorrelations in the $q = 10$ Potts model showing the data collapse.
Figure 11: The scaled cumulative distribution function for the magnetisation autocorrelations in the $q = 10$ Potts model.
