ABSTRACT

Objectives Social activities such as ‘eating-with-others’ can positively affect the ageing process. We investigated the gender-specific association between eating arrangements and risk of all-cause mortality among free-living older adults.

Setting A representative sample from the Elderly Nutrition and Health Survey in Taiwan during 1999–2000.

Participants Some 1894 participants (955 men and 939 women) who aged ≥65 and completed eating arrangement question as well as confirmed survivorship information.

Primary and secondary outcome measures Eating arrangements, health condition and 24-hour dietary recall information were collected at baseline. We classified eating arrangements as the daily frequency of eating-with-others (0–3). Survivorship was determined by the National Death Registry until the end of 2008. Cox proportional-hazards regression was used to assess the association between eating-with-others and mortality risk.

Results Overall, 63.1% of men and 56.4% of women ate with others three times a day. Both men and women who ate with others were more likely to have higher meat and vegetable intakes and greater dietary quality than those who ate alone. The HRs (95% CI) for all-cause mortality when eating-with-others two and three times per day were 0.42 (0.28 to 0.61), 0.67 (0.52 to 0.88) in men and 0.68 (0.42 to 1.11), 0.86 (0.64 to 1.16) in women, compared with those who ate alone. Multivariable HRs (95% CI) adjusted for sociodemographic, nutritional and ‘activities of daily living’ covariates were 0.43 (0.25 to 0.73), 0.63 (0.41 to 0.98) in men and 0.68 (0.35 to 1.30), 0.69 (0.39 to 1.21) in women. With further adjustment for financial status, HR was reduced by 54% in men who ate with others two times a day. Pathway analysis shows this to be dependent on improved dietary quality by eating-with-others.

Conclusions Eating-with-others is an independent survival factor in older men. Providing a social environment which encourages eating-with-others may benefit survival of older people, especially for men.

INTRODUCTION

Social engagement, such as interpersonal relations (eg, contact and transactions with friends), exchange of information and receiving and providing emotional support, is a key component of healthy ageing, besides avoiding disease and maintaining physical and cognitive functions.1 However, opportunities to interact are frequently reduced after retirement because of factors such as loss of physical capacity, loss of mobility and solitary living.

The word ‘Meal’ means the event of eating and what is eaten. For this reason, social interaction is considered one of the criteria for a meal.2 Numerous countries offer nutritional programmes, such as congregate meals or meals-on-wheels programmes, to encourage eating in a social setting.3 The inverse correlation between eating-with-others and risk of depression has been studied extensively.4–7 Additionally, eating alone can be analysed as a separate risk factor from living alone with regard to depression or depressive symptoms.5 6 Eating-with-others can potentially improve dietary quality, variety and energy intake through social facilitation.8 9 Depression and poor dietary quality increase the risk of chronic disease and mortality in older adults.10 11 Solitary eating has been associated with a higher risk of mortality among small cohorts of elders in Botswana and the USA.12 13 But, it is unclear whether the daily frequency of eating-with-others is associated with survivorship.
Gender is also a factor in the quality of older people’s lives; for example, women frequently exhibit more health-seeking behaviour.\textsuperscript{14, 15} Yet men face higher risks of depression after widowhood than do women.\textsuperscript{16} Exploring the gender-specific associations between solitary eating and mortality among older adults is potentially of public health value.

Providing simple, achievable steps for healthy ageing can prolong life, maintain quality of life over an extended duration and limit physical deterioration, all of which are beneficial to public health. The purpose of this study was, therefore, to evaluate whether the daily frequency of eating-with-others is associated with all-cause mortality in a representative, free-living, Taiwanese cohort of older men and women.

SUBJECTS AND METHODS

Participants

Participants aged 65 and over were recruited from the elderly Nutrition and Health Survey in Taiwan (NAHSIT Elderly) during 1999–2000. The details of the survey design and sampling method have been published elsewhere.\textsuperscript{17} In total, 1937 older people completed face-to-face interviews with trained interviewers. We excluded 40 participants with incorrect identification or incorrect identity numbers and those who did not provide relevant or required information. After which 1894 participants (955 men and 939 women) remained in the study. Trained interviewers collected data on sociodemographics, dietary habits and intake, and disease history. All participants signed informed consent forms prior to being interviewed. This project was approved by the ethics committees of the National Health Research Institute and Academia Sinica, Taiwan.

Eating arrangement

Eating arrangements were assessed by asking participants whether they usually ate breakfast, lunch and dinner with others. Their responses were recorded as one of the following four options: eat alone, eat with spouse, eat with children or relative(s) and eat with friend(s) or neighbour(s). We then classified the eating arrangements as eating-with-others 0 (eat alone), 1, 2, 3 times a day.\textsuperscript{18} Information was also obtained about the person responsible for meal preparation.

Dietary assessment

Information on frequency of dietary intake was collected using a validated Simplified Food Frequency Questionnaire.\textsuperscript{19} Dietary quality and nutritional intake were measured through 1-day 24-hour dietary recall. The dietary quality was evaluated using the Dietary Diversity Score (DDS), which is based on the consumption of a half serving of the following six food groups daily: grains, meat, fish or eggs; dairy; vegetables; fruits and oil or fat. The DDS ranges from 0 to 6, with a higher score representing higher dietary quality. The method of nutrient intake calculation is described elsewhere.\textsuperscript{16}

Other variables

Participants were also asked how frequently they cooked or aided with cooking (excluding ready-to-eat meals), and their responses were recorded as never, sometimes, often or usually. Participants were then asked how many people they lived with. The response ‘0’ was defined as living alone.

Health-related quality of life was measured by a 36-item Short Form (SF-36) in a validated traditional Chinese version. A total of eight dimensions of health were included, such as physical functioning, role limitations due to physical problems, mental health, role limitations due to emotional problems, social function, bodily pain, vitality and general health. The score was calculated by the norm-based scoring system ($\mu=50$, $\sigma=10$) and standardised. Higher scores indicated a better quality of life.\textsuperscript{20}

Disability was evaluated by activities of daily living (ADL) which included nine questions about self-care task difficulty in an older adult’s daily life. We used bioelectrical impedance analysis to measure muscle mass. The Skeletal Muscle Mass Index was used to determine sarcopenia status, calculated with the following equation:\textsuperscript{21}

$$
(0.401 \times (\text{height}^2/\text{resistance}) + (3.825 \times \text{gender}) - (0.071 \times \text{age}) + 5.102)/\text{height}^2 \text{ where height is measured in metres, resistance in Ohms and age in years; men=1 and women=0.}
$$

The Charlson Comorbidity Index was used to assess multimorbidity.\textsuperscript{22} Cognitive function was assessed by a validated Short Portable Mental Status Questionnaire in Chinese which included 10 questions about orientation in time and place, personal history, long-term and short-term memory and calculation. More than or equal to three erroneous responses were regarded as cognitive impairment.\textsuperscript{23}

Outcome ascertainment

National Death Registry data were obtained from Taiwan’s Ministry of Health and Welfare. We linked the NAHSIT dataset to the National Death Registry dataset using the participant ID to determine survival rates. Follow-up time was calculated from date of interview to date of death or until 31 December 2008.

Statistical analysis

Categorical variables and continuous variables were presented as n (%) or mean±SEs. $X^2$ and analysis of variance were used to determine the association between eating arrangements and baseline characteristics for categorical or continuous variables, respectively. The Cox proportional-hazards regression model was used to evaluate the association between daily frequency eating-with-others and risk of all-cause mortality. Since the interaction between eating arrangements and gender was significant ($p=0.0093$), we used gender-specific analyses. Additional factors were age, education level, marital status, region, and mortality among older adults is potentially of public health value.
living arrangement, body mass index (BMI), DDS, cooking frequency, appetite status, ADL and self-rate financial status. All data analyses were performed using SAS V.9.2 and SUDAAN V.9.0 to adjust for the design effect of sampling.

To explore the pathways which might connect eating-with-others to survival, we have considered the intermediates of dietary quality (DDS), physical functioning, mental health and general health. The first linkage, using continuous variables, has been assessed by Pearson’s partial correlation coefficients. The second linkage to risk of mortality, as coefficients, has been assessed by the Aalen additive hazards model.21

RESULTS
In total, 63.1% of men and 56.4% of women ate with others three times a day. For both genders, those who ate with others were more likely to be younger, married, better financial status, living with others and less cooking than were those who ate alone. Men who ate alone had significantly higher ADL (p=0.004) and cognitive impairment (p=0.005) than those who ate with others (table 1).

Table 2 presents the dietary quality and food intakes for daily frequency of eating-with-others by gender. Those who ate alone had a poor dietary quality (DDS ≤3), compared with those who ate with others three times daily. Men who ate alone ate less meat (1.02 vs 1.30 times/day) and vegetables (1.90 vs 2.47 times/day) than did those who ate with others three times a day (p<0.05). Women who ate with others three times a day tended to eat more meat (1.13 vs 0.81 times/day), seafood (0.99 vs 0.70 times/day), eggs (0.38 vs 0.23 times/day) and vegetable intake (2.52 vs 2.09 times/day) than did those who ate alone (p<0.05). Further, women who ate alone had lower fat (24.7 vs 28.9 g/1000 kcal/day) intakes, but higher carbohydrate (155 vs 144 g/1000 kcal/day) intakes compared with those who ate with others (p=0.05). Regarding meals, around 58%–60% of men and 68%–74% of women prepared meals by themselves when eating alone. Men were more likely to eat out when eating-with-others one time a day compared with women.

Men who ate with others two times per day have significantly high physical functioning compared with other groups (p=0.044). For women, who ate with others one time per day had higher physical functioning (50.7 vs 45.2) and role limitations due to physical problem (51.4 vs 46.1) compared with those who ate alone (table 3).

Table 4 presents the association between daily frequency eating-with-others and risk of all-cause mortality by gender. In the crude model, the HRs (95% CI) of risk of all-cause mortality for who ate with others two or three times a day were 0.42 (0.28 to 0.61), 0.67 (0.52 to 0.88) in men and 0.68 (0.42 to 1.11), 0.86 (0.64 to 1.16) in women compared with those who ate alone, respectively. When adjusted for age, education, marital status, region, living arrangement, cooking, appetite status, ADL, DDS and BMI, the HRs (95% CI) were 0.43 (0.25 to 0.73), 0.63 (0.41 to 0.98) for men and 0.68 (0.35 to 1.30), 0.69 (0.39 to 1.21) for women who ate with others two or three times a day. With further adjustment for financial status, the risk of mortality is reduced by 54% (HR 0.46, 95% CI 0.28 to 0.77) and 34% (HR 0.66, 95% CI 0.43 to 1.02) for men who ate with others two or three times a day.

The pathway analyses are shown in figure 1. For men, there are significant positive associations between eating-with-others frequency and dietary quality (DDS) (p=0.006) as well as mental health (p=0.0009). In turn, better dietary quality (p<0.0001) is associated with less mortality risk, as are physical functioning (p<0.0001) and general health (p=0.007). For women, eating-with-others is not associated with any of dietary quality, physical functioning, mental health or general health; however, dietary quality (p=0.0004) and physical functioning (p<0.0001) are inversely associated with mortality risk, while mental health (p=0.043) is positively associated.

DISCUSSION
This study explored the gender-specific associations between eating arrangement and risk of mortality by observing a population-representative older adult cohort with a 10-year follow-up in an Asian country. Eating-with-others was inversely associated with risk of mortality, more evident in men than in women.

Food intake when eating-with-others
Eating-with-others has numerous beneficial effects on health. A randomised controlled trial at a Dutch nursing home found that family-style meals that included the presence of others increased the energy intake and reduced the prevalence of malnutrition. Those who ate with others are more than those who ate alone. Social eating may stimulate intake through extension of meal duration and improved ambiance.8 The presence of others in the household did not affect energy intake, but the presence of others during mealtime did, with an average of 114 calories more per meal than those who ate alone.25 Eating socially also improved dietary quality and diversity.7,9 However, the present study shows that after control for dietary quality in the model, eating-with-others and mortality remain associated. A possible reason for this is that solitary eating is often associated with depression,4-6 in turn associated with mortality. However, there may be value in solitude itself which would be an alternative interpretation of the difference we have found in mortality risk reduction between eating two times and three times a day with others by men.

Eating-with-others and mortality
Our findings are consistent with several studies from Western countries. The Nutrition Screening Initiative checklist, a tool for malnutrition screening and awareness in older adults in the USA, asks questions regarding solitary eating. A cohort study with 581 community-dwelling older adults, who ate more than 17 meals alone per week,

All data weighted for unequal probability of sampling design by SUDAAN. Categorical variables are presented as n (%), and continuous variables are presented as mean±SE. ANOVA and χ² were used for continuous and categorical variables to test difference between the groups by gender. ANOVA: analysis of variance; MET, metabolic equivalent of task.
Table 2  Food, nutrient intakes and daily frequency of eating-with-others by gender

| Daily frequency for eating-with-others | Men | Women | p Value | Men | Women | p Value |

*p<0.05; **p<0.01; ***p<0.001.
†Women were not adjusted for activities of daily living in the models since it is highly correlated with cooking frequency.

Data were weighted for unequal probability of sampling design by SUDAAN and estimated HR (95% CI) by using the Cox proportional-hazards model.

Model 1: adjusted for age.
Model 2: adjusted for age, education (illiterate, primary school, high school and above), region (Hakka, mountains, Eastern Taiwan, Penghu, Northern Taiwan 1–3, Central Taiwan 1–3, Southern Taiwan 1–3), live alone (live alone, live with others), cook frequency (never, sometimes, often, frequently), marital status (married, bereaved, other), appetite status (good, fair, poor), Dietary Diversity Score (≤3, 4, 5, 6), activities of daily living and body mass index (<18.5, 18.5–23.9, 24.0–26.9, ≥27 kg/m²).

Model 3: model 2 plus adjusted self-rate financial status (more than enough, just enough, not enough).

In the present study, men who ate with others had a lower risk of mortality than did those who ate alone for several probable reasons. Men who ate with others had better dietary quality and a higher vegetable intake than those eating alone. We also found that men who ate alone were more likely to eat out, not prepare meals by themselves and frequently skip meals than did women. A Japanese cohort study discovered that men who ate alone were more likely to be underweight and skip meals and less likely to eat fruits and vegetables.9 Underweight older adults with poor dietary quality and low fruit and vegetable intakes have been associated with a higher risk of mortality.10 26 Furthermore, in our study, eating out is often associated with high-fat foods with poor quality. Men who were solitary eaters had low carbohydrate, protein, dietary fiber and other nutrient intakes, but a higher fat intake than those who ate with others, although the differences were non-significant. Compared with Japan, in our study, men had a higher rate of solitary eating, but were more likely to be unmarried or live separately from their spouse. We found that the eating companionship of men who ate with others was usually their spouse or children rather than friends or neighbors (table 1). Men who were alone ate 0.33 fewer meals per day than did those who ate with others (table 1). Men who ate alone had a lower probability of eating most of their meals at home, which could be related to their lower dietary quality and lower fruit and vegetable intakes.9

It is also possible that what has been observed as a link between eating habits and mortality is part of a bigger picture of the role of marriage and men living with a partner. It has been documented that men who live with a female partner live longer than those who do not.38 This could be for any one or more of several reasons which include not eating alone and gender.

Pathways from eating-with-others to survival

For men but not women, pathway analyses indicate that dietary quality, assessed as dietary diversity, provides a potential connection between the social aspect of eating-with-others and survival (Figure 1). This underscores the likely basic importance of nutritional factors in lifelong health, but draws attention to the social as well as the biomedical role of food in health. For men, on pathway analysis, eating-with-others is associated with better mental health. Since pathway analysis requires that all independent variables are continuous, this may have resulted in an absence of a significant direct association of eating-with-others with mortality due to its frequency not being linearly related to mortality; this contrasts with the survival analyses by Cox regression (Table 4). In addition, by pathway analysis, each of physical functioning and general health are themselves important in the prediction of mortality risk in men. It remains conceivable that the dietary quality that men achieve, irrespective of eating-with-others, plays a role in each of physical functioning and general health, which is evident in this population.10 20

In the case of women, dietary quality directly and favourably predicts survival, but this connection is not

Figure 1  Gender-specific pathway analysis for the associations of eating-with-others and all-cause mortality. All values are presented as β coefficients with their p values (p<0.05 are highlighted in bold). (A) men; (B) women. DDS, Dietary Diversity Score.
found to be dependent on eating-with-others. Perhaps women can achieve the biomedical benefit of survival through diet without the need for its social function. In addition, women have a more favourable survival with better physical functioning. Somewhat surprisingly, better mental health is unfavourably associated with survival, although this is weakly significant. It is possible that confounders that have not been considered in this pathway analysis might account for this mental health association with mortality in older women. For example, in devoting themselves to the care of others or in dealing successfully with a relative socioeconomic disadvantage in widowhood, a sense of well-being may obtain, while health adversity supervenes.

Limitations

There are some limitations to this study. First, since the study participants were elderly, it can be expected that a change in their eating arrangements would take place through time as family and health circumstances change. Given that this is a single point survey (1999–2000), varied follow-up times may alter the findings. However, we have performed analyses with several follow-up times varied follow-up times may alter the findings. However, we have performed analyses with several follow-up times (<2, <4, <6 and 6 years) or the exclusion of events in the first and second years (data not shown). For men, the point estimates for HRs eating-with-others two times a day are consistently <1.00. But for women, low HRs of 0.15 are seen for eating-with-others one time a day in the first 2 years of observation, although not beyond. This does not change our conclusions with the 10-year survival analysis. Second, the association may be affected by the duration of time spent eating alone or eating-with-others, which was not considered. Third, in Taiwanese society, older people are more likely to live with and depend on their families, so the culturally specific nature of this study may limit its applicability elsewhere. The study should be considered within a Taiwanese (of perhaps a broader Asian) context. As with cohort studies in general, there may have been confounders not considered which might have explained the associations presented. The study itself, however, has sought to consider the circumstances of eating which are usually neglected in the exploration of food and nutrient health relationships. The pathway analyses are an attempt to encompass more of the explanatory models for these relationships by way of inclusion of physical, mental and general health. The gender differences which are now recognised here and in other reports for the respective health roles of dietary quality on the one hand, and with whom the food is consumed on the other, are a challenge to more gender comprehensive public health policy.

CONCLUSIONS

Eating socially may benefit survival in elderly men through the adjunct of dietary quality; it is also positively associated with men’s mental health. For women, dietary quality is associated with survival advantage which is not apparently dependent on eating-with-others. The relative gender advantage in longevity that women have in this population is not adequately explained in the present study, except that they are likely to be the ones who eat with men who benefit from this social role of food. Thus, for men and women, the provision of a healthy social environment which increases social interactions should improve health outcomes.
