Hermon and Hutchcroft have recently proved the long-standing conjecture that in Bernoulli\((p)\) bond percolation on any nonamenable transitive graph \(G\), at any \(p > p_c(G)\), the probability that the cluster of the origin is finite but has a large volume \(n\) decays exponentially in \(n\). A corollary is that all infinite clusters have anchored expansion almost surely. They have asked if these results could hold more generally, for any finite energy ergodic invariant percolation. We give a counterexample, an invariant percolation on the 4-regular tree.

1 Introduction

This short paper gives a negative answer to the following recent question on invariant bond percolations on nonamenable transitive graphs. We refer the reader to [23] for background, but will briefly recall the basic definitions and motivations after the question.

**Question 1** (Hermon and Hutchcroft, Question 5.5 in [17]). Let \(G\) be a nonamenable unimodular transitive graph, and let \(\omega\) be an ergodic invariant bond percolation process. Apply an \(\epsilon > 0\) of Bernoulli noise to \(\omega\) to get a new invariant percolation configuration \(\omega'\); i.e., we take the symmetric difference of \(\omega\) and a Bernoulli\((\epsilon)\) bond percolation.

(A) If \(\omega'\) has infinite clusters, must these infinite clusters have anchored expansion?

(B) Is the probability that the origin lies in a finite cluster of \(\omega'\) of size at least \(n\) exponentially small?

A bounded degree infinite graph \(G = (V,E)\) is called nonamenable if the boundary-to-volume ratio \(|\partial_E K|/|K|\) stays above some \(c > 0\) for every finite subset \(K \subset V(G)\) of the vertices, where \(\partial_E K\) is the set of edges with one endpoint in \(K\) the other in \(K^c\). As a relaxation of this property, the graph is anchored nonamenable, or in other words, it has anchored expansion, if

\[
\iota_o^* := \inf \left\{ \frac{|\partial_K|}{|K|} : o \in K \subset V(G) \text{ connected finite sets} \right\} > 0
\]

holds for some (and then, for any) anchor \(o \in V(G)\).

An invariant bond percolation on an infinite transitive graph \(G\) is just a random subset of the edges whose distribution is invariant under the automorphism group of \(G\). Some standard examples, beyond Bernoulli\((p)\) bond percolation [10], are the free or wired infinite volume FK\((p,q)\) random cluster models [20], random interlacements [24], the edges spanned by the open vertices of any

Finite-energy infinite clusters without anchored expansion

Gábor Pete  Ádám Timár

Abstract

Hermon and Hutchcroft have recently proved the long-standing conjecture that in Bernoulli\((p)\) bond percolation on any nonamenable transitive graph \(G\), at any \(p > p_c(G)\), the probability that the cluster of the origin is finite but has a large volume \(n\) decays exponentially in \(n\). A corollary is that all infinite clusters have anchored expansion almost surely. They have asked if these results could hold more generally, for any finite energy ergodic invariant percolation. We give a counterexample, an invariant percolation on the 4-regular tree.
invariant site percolation model (e.g., the Ising model \[18\], or the super-level sets of an invariant height function, such as the discrete Gaussian Free Field \[14, 5\]), or processes obtained by local modifications of the above (such as factor of iid percolations \[21\]). The references given here are somewhat ad hoc; we have tried to give papers that focus on these processes on transitive graphs beyond \(\mathbb{Z}^d\).

That the subcritical phase of most of the above processes is well-behaved in the sense that correlations and/or cluster sizes decay exponentially fast on any transitive graph is relatively well-understood by now \[1, 16, 15\]. In the supercritical phase, we need a truncation, such as a conditioning on the cluster of the origin to be finite. And, the results are more subtle: even for Bernoulli percolation on amenable transitive graphs such as \(\mathbb{Z}^d\), because of the vanishing boundary-to-volume ratio, the cluster size does not have an exponential decay; on the other hand, with some non-trivial ways to measure the size of the boundary, one can sometimes get an exponential decay for that, which is still very useful; see \[19, 22, 6\]. For non-amenable transitive graphs, the need for a subtle definition does not arise, but the proofs are still harder. Hermon and Hutchcroft \[17\] have only recently proved the long-standing conjecture that for Bernoulli\((p)\) bond percolation on any nonamenable transitive graph \(G\), at any \(p > p_c(G)\), the answer to Question 1 (B) is affirmative.

The notion of anchored expansion was first explicitly defined by Benjamini, Lyons and Schramm in \[8\]; more general anchored isoperimetric inequalities appeared implicitly in \[25\], explicitly in \[22\]. The motivation is the obvious theoretical and practical interest in the robustness of large-scale geometric properties of transitive graphs under reasonable random perturbations. Infinite clusters in Bernoulli percolation on transitive graphs cannot satisfy any non-trivial isoperimetric inequalities, but often satisfy the weaker anchored counterparts, which still have implications, e.g., on the behavior of random walk on the cluster: anchored \((2 + \epsilon)\)-dimensional isoperimetry implies transience \[25\], while anchored non-amenability implies an on-diagonal heat kernel decay of \(p_n(x, x) \leq \exp(-cn^{1/3})\) and positive speed of escape \[26\]. The connection between anchored isoperimetry and supercritical exponential decay was pointed out by the first author \[13, 22\]: a positive answer to Question 1 (B) implies a positive answer to question (A) for Bernoulli percolation, and more generally, for any independent perturbation of an invariant process.

The proof of property (B) by Hermon and Hutchcroft \[17\] seemed to use quite mildly the independence in Bernoulli percolation, hence it was reasonable to hope that the argument could generalize to any finite energy ergodic invariant percolation, like most of the models mentioned above. Instead of defining here this “finite energy” condition precisely (also called uniform insertion and deletion tolerance; see \[23, \text{Section 12.1}\]), let us just assume a stronger version, as given by Question 1: the process is an independent perturbation of an invariant process. However, even in this setting, we will show that the answer to (A), and hence also to (B), is negative:

**Theorem 2.** There exists an invariant percolation on the 4-regular tree with the property that for \(\delta, \epsilon > 0\) small enough, after adding a Bernoulli\((\epsilon)\) set of edges and removing a Bernoulli\((\delta)\) set of edges, conditioned on the component of a fixed vertex to be infinite, the cluster has no anchored expansion almost surely.

Of course, this counterexample leaves it open whether standard finite energy invariant percolations, such as the FK random cluster model and the other models mentioned above, satisfy the properties in Question 1.

We assume that the reader is familiar with the notion of unimodular random rooted graphs; see \[2, 7, 23\] for background. We recall the definition for the case of regular graphs, because it will
be needed at one point of the proof which is not standard.

Consider an element of the form \((G, o; \alpha)\), where \(G\) is a connected locally finite graph, \(o\) is a distinguished vertex (root), and \(\alpha\) is a subset of the edges \(E(G)\), which can also be thought of as a mark on certain edges. Say that two such objects are equivalent, if there is a rooted graph isomorphism that takes one of them to the other and preserves the marks. Call the set of these equivalence classes \(\mathcal{G}_*\). In notation we will not distinguish between the equivalence class and a particular element representing it. Also, one may have more than one type of marks given, say \(\alpha\) and \(\beta\), in which case it will be convenient to list them all after the semicolon and write the element of \(\mathcal{G}_*\) as \((G, o; \alpha, \beta)\). Now, let \(\mu\) be a probability measure on \(\mathcal{G}_*\), and suppose that \(G\) is regular \(\mu\)-almost surely. Then we call \(\mu\) (or the random graph that it samples) unimodular, if for a uniformly chosen neighbor \(x\) of \(o\), the doubly rooted graph \((G, o, x; \alpha)\) has the same distribution as \((G, x, o; \alpha)\). See [7] for the equivalence of this definition and the more usual one, and also for the more general (nonregular) case, where a rebias by the degree of the root is needed.

2 Construction of one component in an invariant percolation

Let \(\mathcal{C}\) be the canopy tree of degrees 1 and 4, a standard example of a unimodular random tree (see, e.g., [23, Chapter 14]), and a building block of many unimodular counterexamples [11, 12, 3]. Call the set \(\mathcal{L}_0\) of leaves level 0, and the set \(\mathcal{L}_i\) of vertices at distance \(i\) from \(\mathcal{L}_0\) level \(i\). For every \(v \in \mathcal{L}_i\) and \(j \geq 0\) there is a unique vertex \(w \in \mathcal{L}_{i+j}\) at distance \(j\) from \(v\). Call this vertex the \(j\)-grandchild of \(v\), and also say that \(v\) is a \(j\)-grandchild of \(w\).

Fix \(p_i = 4^{-i}\) for \(i \in \mathbb{N}\). For every vertex \(v\) of \(\mathcal{C}\), where \(v \in \mathcal{L}_i\), define a Bernoulli\((p_i)\) random variable \(\xi_v\), and let all the \(\xi_v\) be independent from the others. For \(x \in \mathcal{L}_0\), define

\[ m(x) := \max \{ i : \xi_w = 1 \text{ for the } i\text{-grandparent } w \text{ of } x \}. \]

For every \(x \in \mathcal{L}_0\), define a finite ternary tree \(T_x\) of depth \(m(x)\) starting from root \(x\) (that is, \(x\) has degree 3 in \(T_x\), every vertex at distance at most \(m(x) - 1\) has degree 4, and every vertex at distance \(m(x)\) has degree 1). Let the \(T_x\) be all disjoint from each other and from \(\mathcal{C}\), apart from \(x\). Say that a \(y \in T_x\) has type \(i\) if \(m(x) = i\). Define the tree \(\mathcal{C}^+ := \mathcal{C} \cup \bigcup_{x \in \mathcal{L}_0} T_x\). Note that if we are only given \(\mathcal{C}^+\), we can still identify \(\mathcal{C}\) with probability 1. (Starting from an arbitrary leaf \(x\) of \(\mathcal{C}^+\), take the first vertex \(y\) separating \(x\) from infinity such that there is a subgraph of \(\mathcal{C}^+\) that is isomorphic to \(\mathcal{C}\) and has \(y\) as a leaf.) Extend the definition of \(T_v\) to every \(v \in V(\mathcal{C})\) as the graph induced by the union of \(\{v\}\) and all the finite components of \(\mathcal{C}^+ \setminus \{v\}\).

The tree \(\mathcal{C}\) can be turned into a unimodular random graph by picking the root to be a vertex in \(\mathcal{L}_i\) with probability proportional to \(3^{-i}\). Using the fact that \(\mathbb{P}(m(x) > i) < 4^{-i}\) holds for any \(x \in \mathcal{L}_0\), we have \(\mathbb{E}(|T_x|) = \mathbb{E}(\sum_{i=0}^{m(x)} 3^i) < \infty\), hence we can conclude that \((\mathcal{C}^+, o)\) is also unimodular with a suitably chosen random root \(o\); see Subsection 1.4 in [11].

3 Construction of the invariant percolation

Now we first construct an invariant percolation \(\mathfrak{F}\) on the 4-regular tree \(\mathcal{T}\) where the component of a fixed root has the same distribution as the unimodular random graph that we constructed earlier. (It is tempting to apply [9], where a general such construction is given, but we will use a different argument because we want some extra properties to hold regarding the location of the components with respect to each other. Also, in our case all degrees of the unimodular graph are 1 or 4, making
Figure 1: Without the loops at the leaves, this is a copy of the tree $C^+$, with the edges of $C^+ \setminus C$ shown in turquoise. The vertices $v$ of $C$ with $\xi_v = 1$ are also colored turquoise. Together with the loops (where triples of loops are symbolized by the “double-petals”), this is $C^{++}$, whose colored covering tree, with the turquoise edges removed, is the invariant percolation $\omega$ on the 4-regular tree.

It is easier to represent it as an invariant percolation.) Moreover, we will do it so that the components of the percolation will be isomorphic to each other: we first sample $C^+$, and then fit infinitely many pairwise disjoint copies of this sample into $T$ in such a way that these copies cover every vertex of $T$. We will then use $F$ to define $\omega$, the invariant percolation of Theorem 2.

Fix a random instance of $(C^+, \circ) =: (T_0, \circ)$.

Consider the 4-regular tree $T$. We will show that there exists a subgraph $F \subset T$ with the property that every component of $F$ is isomorphic to $T_0$, and moreover, every non-singleton component of $T \setminus E(\mathfrak{F})$ is a 3-regular tree $R$ with the property that for every $x_1, x_2 \in V(R)$ and $\mathfrak{F}$-components $F_{x_i}$ of $x_i$ ($i = 1, 2$), the $(F_1, x_1)$ and $(F_2, x_2)$ are rooted isomorphic. Starting from $T_0$, we will add edges, some of them marked to belong to $F$ and some of them not (so they will belong to $T \setminus E(\mathfrak{F})$). We will denote the $\mathfrak{F}$-component of a vertex $x$ by $F_x$ and its component in $T \setminus E(F)$ by $R_x$. In particular, $F_\circ = T_0$.

Let $L$ be the set of leaves in $T_0$, and let $T_1 := T_0 \cup \bigcup_{v \in L} R_v$, where the $R_v$ are pairwise disjoint 3-regular trees with one vertex being $v$ and all other vertices being outside of $T_0$. Define $T_2 := T_1 \cup \bigcup_{v \in L} \bigcup_{w \in V(R_v), w \neq v} F_w$, where every $(F_w, w)$ is rooted isomorphic to the $(F_v, v)$ where $w \in V(R_v)$. Similarly, define $T_{2n+1}$ to be $T_{2n}$ with a new 3-regular tree attached to every leaf of $T_{2n}$. Define $T_{2n}$ from $T_{2n-1}$ by attaching a new tree $F_w$ to every new vertex $w$ of each of these 3-regular trees, such that if $R$ is such a 3-regular tree and the vertex of it that is contained in $T_{2n-2}$ is $v$, then $(F_w, w)$ is rooted isomorphic to the $(F_v, v)$. The limit of the $(T_n, \circ)$ is a 4-regular rooted tree $(\mathfrak{T}, \circ)$. Every $F_x$ is isomorphic to $T_0 = F_\circ$, hence we can identify the canopy subgraph of it (which is preserved by any automorphism of $F_x$ almost surely); call it $\text{Can}_x$. Let $\mathfrak{F} := \bigcup_x F_x$. Finally we are ready to define the percolation process

$$\omega := \bigcup_x (R_x \cup \text{Can}_x)$$

as the union of edges that either belong to a canopy copy or to a regular tree copy.

Consider the decorated rooted random graph $(\mathfrak{T}, \circ; \omega, \mathfrak{F})$ (here $\omega$ and $\mathfrak{F}$ are viewed as decorations).

**Proposition 3.** The decorated rooted random graph $(\mathfrak{T}, \circ; \omega, \mathfrak{F})$ is unimodular. In particular, $\omega$ and $\mathfrak{F}$ are invariant percolations on the 4-regular tree. Moreover, $\omega$ is ergodic.
Proof. Consider the following simple modification of $C^+$: add 3 oriented loop-edges to every leaf (as in Figure 1), and call the set of all these loop-edges $O$. Call the result $C^{++}$; so it is a 4-regular random graph. Then $(C^{++}, o; C, O)$ is unimodular, using that $(C^+, o; C)$ was unimodular, because any local modification rule that depends only on the rooted isometry class of the neighborhood of each vertex for a unimodular graph preserves unimodularity. One can view $\mathcal{T}$ as a cover of $C^{++}$; let $p$ be some fixed cover map. Then $p(\omega) = C \cup O$ and $p(\mathfrak{f}) = C^+$. There is a natural measure preserving bijection between simple random walk paths on $\mathcal{T}$ and on $C^{++}$, defined by $p$. Since the random walk criterion of unimodularity holds for $(C^{++}, o; C, O)$, it also holds for $(\mathcal{T}, o; \omega, \mathfrak{f})$.

The second claim follows from Theorem 3.2 in [2].

For the ergodicity of $\omega$, note that if there was a non-trivial translation-invariant property that it satisfied, then, conditioned on this property, the rooted tree $(T_0, o)$ that can be reconstructed from $\omega$ would still be a unimodular random graph, a non-trivial component in the ergodic decomposition of $(C^+, o)$. However, $(C^+, o)$ is obviously ergodic. □

4 Expansion properties of a component in the noised $\omega$-percolation

For any $\epsilon > 0$ and $\delta > 0$, let $\eta^\epsilon$ and $\eta_\delta$ be independent Bernoulli bond percolation configurations on $E(\mathcal{T})$ of parameters $\epsilon$ and $\delta$ respectively. Define $\omega^\epsilon_\delta = (\omega \cup \eta^\epsilon) \setminus \eta_\delta$. We will show that, if $\delta$ and $\epsilon$ are small enough, then the component of $o$ in $\omega^\epsilon_\delta$ is infinite and has no anchored expansion with positive probability.

First we will examine the subgraph $T_0$ as in the construction of the percolation; recall that $T_0$ was sampled from $C^+$, so by a slight abuse of notation we will identify the two and use references from the construction of $C^+$. Let $A$ be the event that $o$ is a leaf of type 0 in $T_0$. We mention that a leaf of type 0 necessarily has to be in $L_0 \subset \mathcal{C}$. Conditioned on $A$, for every $n \in \mathbb{N}^+$ we will define a finite subgraph $H_n = H$ in $\omega^\epsilon_\delta \cap \mathfrak{f}$. Let $w(o) = w$ be the 3$n$-grandparent of $o$. Let any 2$n$-grandchild $v$ of $w$ be called $n$-good if $\xi_v = 1$. If $v$ is $n$-good, then every $n$-grandchild of $v$ has type at least $n$, and thus the ternary subtree $T_v$ of $C^+$ rooted in $v$ has depth at least $2n$: the first $n$ levels are in $\mathcal{C}$, and the remaining levels are in $F_0 \setminus C_{n,0}$. Let us denote by $A'_n$ the event that $A$ holds and at least one $n$-good $v$ exists. Note that

$$P(A'_n \mid A) \geq 1 - (1 - 4^{-n})^{3^{2n}} > 1 - \exp(-(9/4)^n),$$

and therefore, if $A'$ denotes the event that $\{A'_n \text{ occurs for all but finitely many } n\}$, then $P(A' \mid A) = 1$.

Condition on $A'$, and let $v = v(o)$ be an $n$-good vertex.

Let $t_v$ be the $\omega^\epsilon_\delta$-component of $v$ in $T_v$ up until generation $n$. Conditioned on $A'$, this is the first $n$ generations of a branching process, whose mean offspring is $3(1 - \delta)$. We will need a small large deviations lemma for such branching processes. It follows, for instance, from [4], but we include here a direct proof for the sake of completeness.

Lemma 4. Consider a branching process $(Z_n)_{n=1}^\infty$ with offspring distribution $X$ that has expectation $\mu > 1$ and variance $\sigma < \infty$. Fix any $\kappa \in (1, \mu)$. Then, there exists $\lambda = \lambda(\mu, \sigma, \kappa) > 0$ such that

$$P(Z_n < \kappa^n \mid Z_m > 0 \text{ for all } m \geq 0) < \exp(-\lambda n),$$

for all $n$ large enough. If $X \sim \text{Binom}(3, 1 - \delta)$, then $\lambda$ can be made arbitrarily large by taking $\delta$ small enough.
Let us remark that one can not generally get a bound that is better than exponential in $n$. For instance, in the case of $X \sim \text{Binom}(3, 1 - \delta)$, the first $\alpha n$ generations for any $\alpha \in (0, 1)$ could always be just one child, which happens with an exponentially small probability and reduces the size of $Z_n$ by an exponential factor.

**Proof.** We start by recalling a much weaker bound, using just the second moment method (see, e.g., [23, Exercise 12.12]). The first moment is $\mathbb{E}Z_n = \mu^n$. Regarding the variance,

$$\text{Var}(Z_n) = \mathbb{E}(\text{Var}(Z_n \mid Z_{n-1})) + \text{Var}(\mathbb{E}(Z_n \mid Z_{n-1})) = \sigma^2 \mu^{n-1} + \mu^2 \text{Var}(Z_{n-1}).$$

Writing $\gamma_n := \text{Var}(Z_n)/\mu^{2n}$, we get the recursion $\gamma_n = \sigma^2/\mu^{n+1} + \gamma_{n-1}$, and thus $\lim_{n \to \infty} \gamma_n = \sigma^2/(\mu^2 - \mu)$. Therefore, $\text{Var}(Z_n) \sim \sigma^2 \mu^{2n}/(\mu^2 - \mu) \sim (\mathbb{E}Z_n)^2$. By the Paley-Zygmund inequality, there exists $b = b(\mu, \sigma) > 0$ such that, for all $n \geq 0$,

$$\Pr(Z_n \geq b\mu^n) \geq b. \quad (2)$$

When $X \sim \text{Binom}(3, 1 - \delta)$ with $\delta$ small, then $\sigma$ is small, hence, using Chebyshev’s inequality instead of Paley-Zygmund, we can make $b$ arbitrarily close to 1.

Consider now the depth-first exploration of the tree, as in [23, Figure 12.4]: when a vertex in the depth-first order is examined, its entire offspring is revealed. Under the conditioning that the tree is infinite, every generation $i \geq 0$ has a last time when it is visited by this exploration; denote by $v_i$ the vertex at which this happens, and by $X_i$ the offspring of $v_i$. Let $E_i$ denote the event that the first time the exploration visits $v_i$ will actually be the last time when it visits this generation, and furthermore, the exploration leaves at least one child of $v_i$ unexplored. This happens exactly when $X_i \geq 2$ and the first child of $v_i$ that gets examined by the exploration has an infinite offspring. If we denote the sigma-algebra generated by $\{E_i : i = 0, 1, \ldots, j\}$ by $\mathcal{E}_j$, then

$$\Pr(E_{j+1} \mid \mathcal{E}_j) \geq q := \Pr(X \geq 2) \Pr(Z_m > 0 \ \forall m \geq 0) > 0.$$ 

When $X \sim \text{Binom}(3, 1 - \delta)$, this $q$ converges to 1 as $\delta \to 0$. Therefore, for any $\alpha \in (0, 1)$, the probability that out of $\{E_i, i = 0, 1, \ldots, \alpha n\}$ less than $\alpha nq/2$ events will occur is smaller than

$$\Pr(\text{Binom}(\alpha n, q) < \alpha nq/2) \leq \exp(-cn), \quad (3)$$

with some $c = c(\alpha, q) > 0$, which goes to infinity as $q \to 1$. Let $I$ be the set of indices $i \in \{0, 1, \ldots, \alpha n\}$ for which $E_i$ occurs, and condition on the event $\{|I| \geq \alpha nq/2\}$.

For each $i \in I$, denote the progeny of the unexplored second child by $\{Z^{(i)}_j : j \geq 0\}$. The main idea is that

$$Z_n \geq \sum_{i \in I} Z^{(i)}_{n-1-i}, \quad (4)$$

where the summands are independent. By (2), we have $\Pr(Z^{(i)}_{n-1-i} < \kappa^n) < 1 - b$ if $\kappa^n \leq b\mu^{n-1-i}$, which does hold for all $i \leq \alpha n$ whenever $\alpha > 0$ is small enough so that $\kappa < \mu^{1-\alpha}$, and when $n$ is large enough. Combining (2), (3), and (4),

$$\Pr(Z_n < \kappa^n) \leq \exp(-cn) + (1 - b)^{\alpha nq/2} < \exp(-\lambda n),$$

for some $\lambda > 0$ and all $n$ large enough. For $X \sim \text{Binom}(3, 1 - \delta)$ as $\delta \to 0$, we have $c \to \infty$, $b \to 1$, and $q \to 1$, while $\alpha$ is fixed by $\kappa$ and $\mu$, hence we can take $\lambda \to \infty$. \qed
Getting back to the analysis of our process, Lemma 4 implies that, for $\delta > 0$ small enough,

$$\mathbb{P}(|t_v| < 2^n \mid A') \leq 2^{-n}. \quad (5)$$

If there is a path from $v$ to a leaf in $T_v$ then define $t_v^+ := t_v$, otherwise define $t_v^+$ as the $\omega_5^c$ component of $v$ in $T_v$. Since $t_v \subset t_v^+$, (5) remains valid with $t_v$ replaced by $t_v^+$. Let $P_v$ be the path between $o$ and $v$. We have

$$\mathbb{P}(P_v \subset \omega_5^c \mid o) \geq (1 - \delta)^{5n}, \quad (6)$$

for almost every $\omega \in A'$. Putting these together, we obtain that, conditioned on $A'$, for $\delta$ small enough, with probability at least $(1 - \delta)^{5n} - 2^{-n} > 4^{-n}$, we have that $P_v \subset \omega_5^c$ and $|t_v^+| > 2^n$. Call this event $B_n$. Conditioned on $B_n$, define $H := P_v \cup t_v^+ \subset \omega_5^c$. We have just seen $\mathbb{P}(B_n \mid A') > 4^{-n}$ and that, conditioned on $B_n$,

$$|H| \geq 5n + 2^n. \quad (7)$$

Next we find an upper bound on the size of the boundary $\partial H$ of $H$ inside $\omega_5^c$. For any fixed $u$ of $T_v \cap L_0$, the probability that $T_u \cap \omega_5^c$ has a path from $u$ to distance $n$ in $T_v \setminus E(C)$ is trivially bounded by $\epsilon^n 3^n$. If this event does not happen for any $u$, then the boundary of $t_v^+$ in $\omega_5^c$ consists only of the single edge of $P_v$ incident to $v$. By a union bound we conclude

$$\mathbb{P}(|\partial H| > 2|P| + 7 \mid B_n) \leq \mathbb{P}(|\partial t_v^+| > 1 \mid B_n) \leq \epsilon^n 3^n |T_v \cap L_0| \leq \epsilon^n 9^n. \quad (8)$$

To summarize, for $\delta, \epsilon$ small enough we have just obtained the following:

**Proposition 5.** Conditioned on $A'$, for all but finitely many $n \in \mathbb{N}^+$, with probability at least $c_n := \mathbb{P}(B_n \mid A') - \epsilon^n 9^n \geq 8^{-n}$ there exists an $H \subset \omega_5^c \cap \mathcal{R}$ such that $o \in H$, and

$$|\partial H| \leq 10n + 7 \quad \text{and} \quad |H| \geq 5n + 2^n. \quad (9)$$

Say that $o$ is $n$-nice (or just nice), if the conclusion in Proposition 5 holds. Recall the construction of $\mathcal{T}_1$ and $\mathcal{T}_2$: if we pick any vertex $x$ of $R_o$, then $(F_x, x)$ is rooted isomorphic to $(F_o, o)$. Hence conditioning on $A'$ means that an analogous event holds for $x$ as well, namely, $x$ is a leaf (of type 0) in $F_x$ and there is an $n$-good vertex for it. Hence we can define $x$ to be $n$-nice just the way we defined it for $o$. Moreover, for all $x \in V(R_o)$ the events of $x$ being nice are conditionally independent of each other, because they are determined by $\eta'$ and $\eta_0$ on disjoint edge sets (the $F_x$).

Now consider $\Pi := R_o \cap \omega_5^c$. Let $E$ be the event that $o$ is in an infinite component of $\Pi$, and let $\Pi_r$ be the ball of radius $r$ around $o$ in this component. By Lemma 4, we have that $\mathbb{P}(|\Pi_r| > 2^r \mid E)$ tends to 1, exponentially fast in $r$. Then

$$\mathbb{P}(\text{there is no } n\text{-nice point in } \Pi_r \mid E \cap A') \leq \mathbb{P}(|\Pi_r| < 2^r \mid E \cap A') + (1 - c_n)^2,$$

with $c_n \geq 8^{-n}$ from the proposition. Choosing $r = r_n = n^2$, say, this quantity tends to 0, superexponentially fast in $n$. We can conclude that on $E \cap A'$, almost surely for all but finitely many $n \in \mathbb{N}^+$ there is an $n$-nice vertex $x_n$ at distance at most $n^2$ from $o$ in $\Pi$. Then consider the $H = H_n(x_n)$ from Proposition 5 that corresponds to this $x_n$ in $F_{x_n}$. Let $Q_n$ be the path in $\Pi$ between $o$ and $x_n$, and define $K_n = Q_n \cup H_n$. Then, using the proposition, we have

$$|\partial K_n| \leq 12n + n^2 \quad \text{and} \quad |K_n| \geq 5n + 2^n. \quad (10)$$

This shows that $K_n$ is an anchored Følner sequence in $\omega_5^c$, i.e., satisfies $|\partial K_n|/|K_n| \to 0$, finishing our proof.
