Ganglion cysts are common lesions that are most often found around the joints of the hands and feet. Ganglia around the distal femur usually occur within the synovial membrane or tendon sheath, but rarely within muscles. Several cases of intramuscular ganglions in the hand and wrist have been reported, but a ganglion cyst in the quadriceps muscle has rarely been addressed in studies. In this report, we present a 17-year-old patient with a painful movable mass in the intramuscular area of the quadriceps femoris that was diagnosed by ultrasound and treated by excision and biopsy.

Keywords: Intramuscular ganglion cyst, Quadriceps muscle

Ganglion cysts are benign soft-tissue masses that usually originate from the joint capsule or tendon sheath and contain gel-like fluid. The pathogenesis of ganglia is obscure. A ganglion cyst's connection with the joint capsule is formed due to secondary degeneration of the capsule. Brooks¹ suggested that a ganglion cyst may arise from extraarticular synovial remnants in the adjacent joints at the time of joint formation. In the orthopedic practice, soft tissue ganglia are commonly encountered in the dorsal wrist and lateral aspect of the hand, whereas intramuscular ganglia have rarely been reported².

In this report, we present a case of intramuscular ganglion cyst in the quadriceps femoris that was treated with excision and biopsy with a review of the literature.

Case Report

A 17-year-old male patient visited our institution with a complaint of a painful movable mass on the lateral distal aspect of the right femur that was not caused by trauma. The mass had been slowly growing for 6 months and started to cause increasing pain from one month ago. The patient had no history of other systemic disease. In the physical examination, a firm and movable mass with a size of a quail egg was palpated in the lateral distal aspect of the right femur. The size of the mass did

not change during joint motion. Neither muscle weakness and numbness nor abnormal sensation was observed in the lower leg. In the absence of abnormal findings on radiography, ultrasound was performed, in which a cystic tumor approximately 4.1×2.5 cm in size was identified in the quadriceps femoris (Fig. 1). A magnetic resonance imaging (MRI) was considered unnecessary because it had a relatively distinct border and was well-encapsulated. Exploration and excision of the mass were performed under the assumption of a vascular lesion or a lipoma within the vastus lateralis of the quadriceps femoris. Noninvasive methods such as aspiration and steroid injection could be an option, but surgical excision was our treatment of choice in order to reduce the possibility of recurrence. Intraoperatively, spindle-shaped swelling was observed and a firm mass was palpated in the vastus lateralis of the quadriceps femoris. The mass could be dissected with ease from the surrounding tissue and had a stalk as other ganglion cysts. When the muscle sheath was removed, the mass was found to originate from the muscle, not from the muscle sheath. In the naked eye, the intramuscular cystic mass was 3.4×2.2×1.4 cm in size, weighed 4.7 g, and had some muscle tissue on its smooth surface (Fig. 2). When dissected upon excision, clear jelly-like fluid was noted in the sac. The biopsy results showed that the cystic wall was composed of fibrous tissue, lacked a synovial lining, and had muscular tissue on the surface, which led us to the diagnosis of an intramuscular ganglion cyst (Fig. 3). Rehabilitation was started after two weeks of splint immobilization. There has been neither recurrence nor complications for the 1 year and 6 months of follow-up period.

**Discussion**

Ganglion cysts are the most common soft tissue lesions of the hand that are composed of a fluid-filled sac connected to a synovial sheath, a tendon sheath, or a tendon. The male to female prevalence ratio of ganglion cysts is 1:3. They can occur at any age especially in people in their teens and 30s. The pathogenesis of ganglion cysts has not yet been determined. Some studies associate them with mucoid degeneration of soft tissues, outpouchings of tissues through defects in the joint capsule or tendon sheath, or a trauma. The most common area of occurrence is the radial side of the extensor digitii communis tendon on the dorsum, followed by the area between the flexor carpi radialis and the abductor pollicis longus tendons on the volar side of the wrist. Ganglions cysts arise from joints in most cases and rarely from the tendon sheath, cartilage, cruciate ligaments, nerves, and muscles. They have no communication with adjacent joint capsules in 30% of the cases.

Intraarticular ganglion cysts in the knee have been rarely reported. Although most of the ganglia around the knee joint are located in the tendon sheath or joint capsule, they can form in the meniscus, anterior cruciate ligament, posterior cruciate ligament, and common peroneal nerve. Intraosseous ganglion cysts that are characteristically located in the epiphysis of long bones are mostly solitary and involve the distal end of the tibia. Currently, there are only 2 reported cases of ganglion cysts in the quadriceps femoris that were diagnosed using plain radiography, ultrasound, and computed tomography. In our patient, the diagnosis was relatively easily made using ultrasound only.
The majority of ganglion cysts are palpable tender lumps without any accompanying symptoms. However, when a ganglion cyst exerts pressure on the nerves or blood vessels, pain, numbness, and muscle weakness may occur or tenderness and discomfort during joint motion may present from the initial stage.

Plain radiography is not reliable for the diagnosis of ganglion cysts. Although ultrasound is a valuable diagnostic tool, it is limited in its ability to evaluate the relationship between a cyst and adjacent soft tissues. MRI is essential for the differential diagnosis from other masses such as vascular lesions and lipomas. In our patient, MRI was considered unnecessary because the mass was seen well-encapsulated with a distinct border on ultrasound.

Ganglion cysts can regress spontaneously and recur occasionally. It is important to identify during surgery whether a lesion is a mass, has a connection with a joint, or is associated with intraarticular disease and to perform thorough excision in order to reduce the likelihood of recurrence. Ganglia rarely recur with proper curative measures, but inappropriate treatment methods can result in a recurrence rate of 50%.

The cure rate of ganglion cysts has no association with gender, age, and size and location. Nelson et al. reported that the cure rate was 94% after excision under general anesthesia or axillary nerve anesthesia, 84% after excision under local anesthesia with a tourniquet in place, and 65% after rupture by direct pressure or aspiration with or without a steroid injection, and draining using threads to surgical excision with or without arthroscopy.

Intramuscular ganglion cysts are rare with only a few cases involving the hand present in the literature. Ganglion cysts in the distal femur have been rarely reported. In this case report, we described a case of an intramuscular ganglion cyst in the vastus lateralis of the quadriceps femoris that was successfully treated with excision without complications.
