1 Editorial

Biomaterials are required to possess various properties, such as high strength, corrosion resistance and tribological resistance. A hybrid surface modification, which combines fine particle peening (FPP) with gas nitriding at low temperature, improved both the fatigue properties and electrochemical characteristics of austenitic stainless steels due to the formation of a nitrided layer containing expanded austenite, called the “S-phase”. Therefore, this original paper† was recommended by the JSMS Committee on Biomedical Materials and selected for the special issue “Visiting old, innovating new”, because the hybrid surface treatment proposed in this paper would be an effective method for biomaterials utilized under severe conditions. The original Japanese paper† was translated into a review paper in English with slight modification and addition of a few recent references.

2 Introduction

Austenitic stainless steels exhibit lower fatigue strength and tribological resistance than carbon steels; therefore, nitriding is usually performed for austenitic stainless steels utilized as mechanical components. Gas nitriding has been widely used in various fields of engineering due to its high productivity, while a passive film at the surface of austenitic stainless steels, which prevents nitrogen diffusion, should be removed when gas nitriding is performed. Generally, acid cleaning and gas reduction processes are performed prior to gas nitriding for removal of the passive film; however, these chemical processes cause some problems, namely, damage to the furnace, and adverse environmental effects due to the need for disposal of waste acid‡.

Therefore, an efficient pre-treatment process was introduced prior to gas nitriding. For example, Hamaishi et al.‖ reported that nitrogen diffusion into austenitic stainless steels was facilitated during gas nitriding due to the formation of iron oxides induced by atmospheric preheating. The present authors‖ have reported the introduction of fine particle peening (FPP) as a pre-processing step to facilitate the diffusion of nitrogen into the material‖, which results in the formation of a nitrided layer on austenitic stainless steels.

However, nitriding, which is generally performed at 500-570 °C, was found to reduce the corrosion resistance of these steels, because the concentration of chromium in the substrate is reduced due to the formation of chromium nitrides during nitriding.§. Ichii et al.¶ developed low temperature nitriding at 400 °C to suppress the reduction of corrosion resistance and formed an expanded form of austenite, called the S-phase, with high corrosion resistance∥. Furthermore, compressive residual stress was generated¶ due to the formation of the S-phase; therefore, low temperature nitriding could improve the fatigue properties of austenitic stainless steels∥. However, the long nitriding duration required due to the reduction in the nitrogen diffusion rate caused by the low nitriding temperature is problematic.

In this study, in order to form a nitrided core and facilitate nitrogen diffusion into austenitic stainless steels, we performed FPP treatment prior to gas nitriding. The aims of this study are to characterize the nitrided layer generated by gas nitriding at various temperatures after FPP treatment, and to examine the effect of the FPP treatment on the fatigue properties and electrochemical characteristics of surface-modified austenitic stainless steel (JIS-SUS316).

3 Experimental Procedures

3.1 Materials and Specimen

The material used in this study was JIS-SUS316 austenitic stainless steel with the chemical composition shown in Table 1. Cylindrical specimens (Ø15 mm with a thickness of 4 mm) were prepared for the purpose of characterizing the microstructure and examining the electrochemical characteristics of the surface-modified steels. SUS316 steel bars of 16 mm diameter were also machined into the shape and dimensions shown in Fig. 1. The stress concentration factor of the specimen for the rotating bending fatigue test was 3.35. In this study, notched specimens were used to prevent subsurface-induced fatigue failure‖. After machining, the cylindrical specimens were polished with

Visiting old, innovating new

The shot particles used in this study were 63 μm in diameter and made from a high-speed tool steel with the chemical composition shown in Table 2.

The gas nitriding process was then performed at 400, 475 and 550 °C for 20, 3.5 and 2 hours, respectively, in a nitrogen and ammonia environment to form a nitrided layer 20 μm in thickness. Figure 2 shows a flowchart illustrating the specimen preparation; four types of specimens were prepared with different surface-modified layers. In the series name, “F” represents FPP, “N” represents nitriding and the number represents the nitriding temperature.

3.2 Testing

The depth distribution of the micro-Vickers hardness was measured for the cylindrical specimens. The surface microstructures of the surface-modified specimens were characterized using optical microscopy, scanning electron microscopy (SEM), glow discharge optical emission spectroscopy (GD-OES) and X-ray photoelectron spectroscopy (XPS). The crystal structures of the cylindrical specimens were identified using X-ray diffraction (XRD) with Cu Kα radiation.

Electrochemical polarization tests were performed using a three-electrode electrochemical cell connected to a computer-driven potentiostat. The test specimen was the working electrode, platinum was used as the counter electrode, and the saturated calomel electrode (SCE) was used as the reference electrode. As the electrolyte solution, 3 wt% NaCl solution was deaerated with nitrogen gas for 20 min prior to use to decrease the oxygen concentration and maintained at 25 °C. In the anodic potentiodynamic polarization test, the potential was increased at a sweep rate of 40 mV/min after holding at the self-potential for 30 s.

Residual stress was also measured at the transverse section of the smallest diameter of the fatigue test specimen using XRD using Cr Kα radiation. A Position-Sensitive Proportional Counter (PSPC) system based on the sin²ψ method was used under the conditions: collimator diameter 2 mm, measuring time 60 s and measurement error less than 100 MPa. Since residual stress measurement was difficult for the notched specimens, we measured the residual stress of a smooth specimen with the same surface modification.

High-cycle fatigue tests were performed at room temperature in air using an Ono-type rotating bending fatigue testing machine at 1200 rpm to suppress the rise of temperature. In this study, the fatigue limit was defined as the maximum stress amplitude applied to the specimen without fatigue failure. In order to investigate the fracture mechanism, fracture surfaces were observed with an SEM.

4 Results and Discussion

4.1 Effect of Nitriding Temperature in Hybrid Surface Treatment on Nitrided Layer Formed on SUS316

First, the AISI 316 austenitic stainless steels treated with the hybrid surface modification were characterized. Figure 3 shows the typical features of the microstructures observed by an optical microscope for the FN series after etching with a 10% oxalic acid solution. In Fig. 3(a), a local stratification pattern was observed near the surface of an F series specimen. This stratification pattern is generated by the concentration of severe plastic deformation. It was reported that the stratification-patterned layer contained a fine-grained structure. Figs. 3(b)–(d) reveal the presence of a unique black structure near the surface of the FN series.

Figure 4 shows the micro-Vickers hardness distribution of the cylindrical specimens at various cross-sectional depths. In
this figure, the dotted line represents the average hardness value of the P series. In the case of the nitriding-only specimens (N400, N475 and N550 series), the hardness values were almost the same as that of the P specimen, although nitriding was performed. This result indicates that nitrogen diffusion was suppressed during the gas nitriding due to the passive film on austenitic stainless steel. On the other hand, in the case of the FN series specimens (FN400, FN475 and FN550 series), which were treated with both FPP and gas nitriding, the hardness values near the surface were much higher than those of the F series specimens. These results mean that FPP introduced as a pre-processing step facilitated the diffusion of nitrogen into the austenitic stainless steels during the subsequent gas nitriding. Figure 4 also reveals that the thickness of the hardened layer was approximately 20 μm; therefore, the unique black structure of Fig. 3  Longitudinal optical micrographs of the F and FN series etched with 10% oxalic acid solution. (Peening pressure: 0.6 MPa, Peening time: 10 s)

Fig. 5  X-ray diffraction patterns (Cu radiation). (Peening pressure: 0.6 MPa, Peening time: 10 s)

Fig. 7  Anodic polarization curves. (Peening time: 10 s)

true

20 μm thickness observed in Figs. 3(b)-(d) corresponded to the nitrided layer. Furthermore, the hardness values of the FN series tended to increase with the nitriding temperature.

To clarify the reason for the variation in surface hardness depending on the nitriding temperature, crystal structures of the FN series were analyzed using XRD. The XRD analysis (Fig. 5) revealed the diffraction peaks of Fe4N in the FN475 and FN550 series. In contrast, the peaks of Fe2N were not detected in the FN400 series, but the peaks of the S-phase were observed.

Characterization of the nitrided layer induced by the hybrid surface modification depended on the gas nitriding temperature, with the S-phase being formed with low temperature nitriding.

4-2 Effect of Hybrid Surface Treatment on Corrosion Characteristics of SUS316

Figure 6 shows the anodic polarization curves for the FN400, FN475, FN550 and P series. A rapid increase in current density was observed in the FN550 series at -0.1 V, which was higher than that of the P series. This is because the Cr concentration was reduced in the FN550 series due to the formation of chromium nitrides (CrN and Cr2N) observed in the XPS spectrum24). In contrast, no rapid increase in current...
density was observed in the FN400 and FN475 series at approximately 0.3 V, which corresponded to the pitting potential of the P series. This is because the S-phase was formed on the surfaces of the FN400 and FN475 series samples, as shown in Fig. 5.

Thus, the electrochemical characteristics of austenitic stainless steels were dependent on the nitriding temperature, and low temperature nitriding improved the electrochemical characteristics.

4.3 Mechanism of Nitrided Layer Formation by Hybrid Surface Treatment

In general, a passive film prevents nitrogen from diffusing into austenitic stainless steel. FPP could form fine-grained structures, which increased the nitrogen diffusion rate, but did not change the chemical composition of the passive film on the materials. In this section, the mechanism of the generation of a nitrided layer on austenitic stainless steel pre-treated with FPP was elucidated based on the microstructural changes induced by FPP.

The passive film on the FPP-treated specimen was evaluated by electrochemical corrosion tests. Figure 7 shows the anodic polarization curves for the F and P series. In both series, a passivation region was observed because of the passive film formed on the austenitic stainless steel. However, the current density in the F series was dependent on the pressure of the FPP, and an unstable passive region was observed in the FPP-treated specimens. This could possibly be attributed to a transferred layer of steel shot particles.

To test this hypothesis, depth profiles of tungsten, which is a component of the steel shot particles used in this study, were measured using GD-OES. Figure 8 presents the depth profiles of tungsten in the F and P series, respectively. The signal intensity on the vertical axis is proportional to the elemental concentration and the sputtering time on the horizontal axis corresponds to the depth from the surface. The signal intensity of the P series remained constant, whereas a W-rich region was observed in the F series, and the signal intensity tended to increase with the peening pressure. This result means that a transferred layer from the steel shot particles was formed on the F series, which influenced the electrochemical properties of the austenitic stainless steel as shown in Fig. 7.

Based on these results, nitrided cores may be formed in the transferred shot particle layer during the subsequent nitriding process. To verify this assumption, an F series specimen was polished to remove transferred shot particles and subsequently treated by gas nitriding. As a result, a nitrided layer was not observed on this F series specimen, which suggests that the existence of a transferred shot particle layer is important for the generation of a nitrided layer on the surface of austenitic stainless steel.

The nitrogen diffusion mechanism is illustrated schematically in Fig. 9. Figure 9(a) represents the formation of the transferred shot particle layer and fine-grained structure by FPP, and Figures 9(b)-(d) represent the formation of nitrided cores and nitrogen diffusion during the subsequent gas nitriding. Shot particles transferred onto the FPP-treated surface were nitrided (Fig. 9(b)), forming the nitrided cores. Then, nitrogen diffusion occurred in the nitrided shot particles, and nitrogen diffused rapidly throughout the
fine-grained structure\(^{(6,7,22)}\) (Fig. 9(c)), resulting in the formation of a nitrided layer (Fig. 9(d)). The crystal structure of the nitrided layer depended on the nitriding temperature, with the S-phase being formed by low-temperature nitriding.

**4-4 Effect of Hybrid Surface Treatment on Fatigue Properties of SUS316**

Figure 10 shows the results of high-cycle fatigue tests. In this figure, the vertical axis represents the nominal stress amplitude applied to the specimen surface. The fatigue limits of the N series were similar to those of the F and P series. On the other hand, the fatigue limits of the FN series were higher than those of the F and P series. The results show that the fatigue limits of the FN series did not depend on the nitriding temperature. As shown by SEM observation of the fracture surfaces (Fig. 11), the F and FN series failed in the surface fracture mode. Therefore, the improvement in the fatigue properties achieved by the hybrid surface modification is attributed to the formation of the nitrided layer.

Figure 12 shows the compressive residual stress measured at the surface under two conditions: \(2\theta = 148.5^\circ\) and \(156.4^\circ\) at the \(\alpha\)-Fe (211) plane. High compressive residual stress was generated in the F series. The FN series exhibited almost the same compressive residual stress values as the F series. This result suggests that the differences between the F and FN series in terms of the fatigue limit can be attributed to the differences in surface hardness.

In order to clarify the mechanism by which compressive residual stress is generated by the hybrid surface modification, FPP-treated specimens (F series) were heated under the same conditions as in the nitriding process, but in a vacuum environment (FH series). The value of compressive residual stress measured in the F-H series was lower than that of the F series. This result means that compressive residual stress generated by FPP was released due to the high temperature\(^{(6,7)}\). Furthermore, the FN series showed higher compressive residual stress compared with the FH series; therefore, compressive residual stress was released and generated during the subsequent gas nitriding step, simultaneously.

Thus, it was demonstrated that FPP treatment prior to gas nitriding is highly effective in improving the electrochemical characteristics and fatigue properties of austenitic stainless steel. This is because a nitrided layer with high hardness and compressive residual stress is formed by the hybrid surface modification.

**5 Conclusion**

In order to facilitate the diffusion of nitrogen into austenitic stainless steel (JIS-SUS316), fine particle peening (FPP) was performed prior to gas nitriding. The effects of the FPP treatment on the gas nitriding behavior and consequent electrochemical and fatigue properties of the austenitic stainless steel were evaluated. Rotating bending fatigue tests were conducted at room temperature on surface-modified austenitic stainless steel. Fatigue fracture mechanisms were also elucidated on the basis of the results of fracture surface observation and microstructural characterization. The
following conclusions were reached:

1. FPP treatment prior to nitriding enables the generation of a nitrided layer with high hardness on austenitic stainless steel. Expanded austenite, called the S-phase, is formed on surfaces treated by low-temperature nitriding.

2. Hybrid surface modification at low temperature improves the electrochemical characteristics of austenitic stainless steel due to the formation of the S-phase.

3. Nitrogen diffusion occurs in a transferred shot particle layer and is facilitated by the fine-grained structure induced by the FPP treatment.

4. The hybrid surface modification improves the fatigue properties of austenitic stainless steel, and the fatigue limit does not depend on the nitriding temperature.

The authors would like to thank Dr. Kengo Fukazawa for measuring the residual stress.
