One of the consequences of the worldwide increase in overweight and obesity is the increased prevalence of non-alcoholic fatty liver disease (NAFLD). At present, the global prevalence of NAFLD is estimated to be ~25%, ranging from 31–32% in the Middle East and South America to 24–27% in Europe and Asia, while the prevalence in Africa is ~14%. NAFLD encompasses a spectrum of liver lesions that includes simple steatosis, steatohepatitis, fibrosis and cirrhosis. Steatosis is the main feature in the majority of patients with NAFLD, and these patients generally do not have a substantial risk of liver-related adverse outcomes. However, the development of nonalcoholic steatohepatitis (NASH) — defined by the combination of liver steatosis, parenchymal damage (hepatocyte apoptosis and ballooning, and focal necrosis), lobular and/or portal inflammation and a variable degree of fibrosis — occurs in about 20–30% of patients with NAFLD, and can lead to cirrhosis and end-stage liver disease. The presence of hepatic fibrosis is the strongest predictor of disease-specific mortality in NASH, and the death rate ascribed to NASH-related cirrhosis is 12–25%. End-stage liver disease due to NASH is also an increasingly common indication for liver transplantation. Although progression of NAFLD to cirrhosis is more frequent among middle-aged (40–50 years old) and elderly people, NAFLD among obese children is associated with an increased risk of cirrhosis in adulthood. A further feature of NAFLD progression is its association with hepatocellular carcinoma (HCC). NAFLD-related cirrhosis is a rising cause of HCC in Western countries, accounting for 10–34% of the known aetiologies for this cancer. Nonetheless, growing evidence suggests that ~13–49% of all HCCs develop in patients with noncirrhotic NASH. Together, these data indicate that NAFLD and NASH substantially contribute to the prevalence of cirrhosis and HCC worldwide. Such a scenario is forecast to worsen in the near future as a result of the expected rise in the prevalence of NAFLD.

At present, lobular inflammation that characterizes NASH is considered the driving force in the disease progression to fibrosis, cirrhosis or HCC. Nonetheless, the presence of steatohepatitis is also associated with an increased risk of type 2 diabetes mellitus, cardiovascular diseases, chronic kidney diseases and osteoporosis, suggesting that liver inflammation might also represent a specific contributor to extrahepatic complications. The current view is that innate immune mechanisms represent a key element in supporting hepatic inflammation in NASH. Adaptive immunity: an emerging player in the progression of NAFLD

** Salvatore Sutti and Emanuele Albano* **

** Abstract ** In the past decade, nonalcoholic fatty liver disease (NAFLD) has become a leading cause of chronic liver disease and cirrhosis, as well as an important risk factor for hepatocellular carcinoma (HCC). NAFLD encompasses a spectrum of liver lesions, including simple steatosis, steatohepatitis and fibrosis. Although steatosis is often harmless, the lobular inflammation that characterizes nonalcoholic steatohepatitis (NASH) is considered a driving force in the progression of NAFLD. The current view is that innate immune mechanisms represent a key element in supporting hepatic inflammation in NASH. However, increasing evidence points to the role of adaptive immunity as an additional factor promoting liver inflammation. This Review discusses data regarding the role of B cells and T cells in sustaining the progression of NASH to fibrosis and HCC, along with the findings that antigens originating from oxidative stress act as a trigger for immune responses. We also highlight the mechanisms affecting liver immune tolerance in the setting of steatohepatitis that favour lymphocyte activation. Finally, we analyse emerging evidence concerning the possible application of immune modulating treatments in NASH therapy.

Chronic hepatic inflammation represents the driving force in the evolution of nonalcoholic steatohepatitis (NASH) to liver fibrosis and/or cirrhosis. In both humans and rodents, NASH is characterized by B cell and T cell infiltration of the liver as well as by the presence of circulating antibodies targeting antigens originating from oxidative stress. Interfering with lymphocyte recruitment and/or activation ameliorates experimental steatohepatitis and NASH-associated liver fibrosis. In rodent models of NASH, lymphocyte responses contribute to sustained hepatic macrophage activation and natural killer T cell recruitment. Alterations in regulatory T cell and hepatic dendritic cell homeostasis have a role in triggering immune responses during the progression of NASH.

Lymphocyte involvement in NASH

One of the histological features of NASH is diffuse lobular infiltration by lymphocytes. These cells are also an important component of periporal infiltrates associated with NASH ductular reactions. In ~60% of patients with NASH, B cells and T cells form focal aggregates, resembling ectopic lymphoid structures. Interestingly, the size and prevalence of these aggregates positively correlate with lobular inflammation and fibrosis scores. Hepatic infiltration by B cells and CD4+ and CD8+ T cells is also evident in different experimental models of NASH, in which it parallels with worsening parenchymal injury and lobular inflammation. These T cells express the memory or effector markers CD25, CD44 and CD69, along with enhanced production of the cytokine LIGHT (also known as TNFSF14), indicating their functional activation. Conversely, steatosis, parenchymal injury and lobular inflammation induced by long-term feeding with choline-deficient high-fat diet are greatly reduced in Rag1−/− mice, which lack mature B cells, T cells and NKT cells and are unable to mount adaptive immune responses. The prevention of hepatic steatosis in Rag1−/− mice seems to be unrelated to metabolic abnormalities, insulin resistance or changes in gut microbiota, but instead is related to LIGHT-mediated stimulation of fatty acid uptake by hepatocytes. Consistent with this finding, LIGHT deficiency improves insulin resistance, hepatic glucose tolerance and reduces liver inflammation in mice receiving NASH-inducing diets.

Liver lymphocyte infiltration and ectopic lymphoid structures are also evident in association with severe steatohepatitis and fibrosis following the administration of a high-fat diet to mice carrying a hepatocyte specific deletion of TCPTP (T cell protein tyrosine phosphatase) (AlbCre;Ptpn2fl/fl), which is responsible for the nuclear dephosphorylation of the transcription factors signal transducer and activator of transcription 1 (STAT1), STAT3 and STAT5. According to this study, liver lymphocyte recruitment in AlbCre;Ptpn2fl/fl mice with NASH depends on the specific stimulation of hepatocyte STAT1 activity, which promotes production of the lymphocyte chemokine CXC-chemokine ligand 9 (CXCL9). In this setting, reducing STAT1 but not STAT3 activation lowers CXCL9 expression, corrects hepatic recruitment of activated CD4+ and CD8+ T cells and ameliorates fibrosis. Interestingly, greater expression of CXCL9 as well as STAT1 and STAT3 target genes fibrinogen-like 1 (FGL1) and lipocalin-2 (LCN2) is observed in the livers of obese patients with NAFLD compared with those without steatosis, whereas expression of FGL1 and CXCL9 further increases in the livers of obese patients with NASH. CD4+ T cell recruitment in NASH also involves the hepatic production of vascular adhesion protein 1 (VAP1), an amino-oxidase constitutively expressed on human hepatic endothelium. Levels of circulating VAP1 are higher in patients with NASH than in patients with NAFLD or healthy control individuals, and are associated with increased severity of hepatic inflammation and fibrosis.

Role of CD4+ T helper cells

The recruitment of CD4+ T helper cells to the liver is observed in several experimental models of steatohepatitis as well as in patients with NASH. From a functional point of view, the polarization of CD4+ T cells as IFNγ-producing T helper 1 (T_h1) cells has been documented along with increased...
expression of the Th1 transcription factor T-bet\textsuperscript{29,34} (Table 1). In the same vein, IFNγ-deficient mice develop less steatohepatitis and fibrosis than wild-type littermates when fed with a methionine–choline deficient (MCD) diet\textsuperscript{1}. These findings are supported by clinical observations that both paediatric and adult patients with NASH are characterized by an increase in levels of liver and circulating IFNγ-producing CD4\textsuperscript{+} T cells\textsuperscript{36,37}. Moreover, in adult patients with NASH, plasma IFNγ levels positively correlate with the number and size of hepatic lymphocyte aggregates as well as with the severity of fibrosis\textsuperscript{38}.

In response to inflammatory stimuli, CD4\textsuperscript{+} T cells can also differentiate to type 17 T helper (Th17) cells, which are characterized by the expression of the nuclear receptor retinoic acid-related orphan receptor-γt and by the production of IL-17 and, to a lesser extent, IL-21, IL-22, \(\gamma\)δ T cells also account for the production of IL-17A in livers with steatohepatitis\textsuperscript{45}. Altogether, these data indicate that hepatic infiltration by Th17 cells and possibly CD4\textsuperscript{+} Th17 cells can substantially contribute to the mechanisms supporting lobular inflammation during NASH evolution (Table 1).

**Role of CD8\textsuperscript{+} cytotoxic T cells.** The evolution of NAFLD and NASH in both humans and mice is accompanied by an increase in the prevalence of activated cytotoxic CD8\textsuperscript{+} T cells in the liver\textsuperscript{39,30,31,32,33}. These cells are mainly recruited in response to signals mediated by IFNγ and they promote insulin resistance and liver glucose metabolism in mice receiving a high-fat diet\textsuperscript{46}. In the same way, \(\beta2m\textsuperscript{−/−}\) mice lacking CD8\textsuperscript{+} T cells and NKT cells are protected from both steatosis and NASH when fed with a choline-deficient high-fat diet, which is associated with reduced production of LIGHT by CD8\textsuperscript{+} T cells and NKT cells\textsuperscript{46}. The selective ablation of CD8\textsuperscript{+} T cells is also effective in ameliorating steatohepatitis in wild-type mice receiving a high-fat, high-carbohydrate (HF–HC) diet\textsuperscript{46}, suggesting an actual role in the pathogenesis of NASH (Table 1). Nonetheless, additional studies are required to

better characterize CD8+ T cell function in relation to disease progression.

Role of B cells. In addition to T cells, B cells are detectable within inflammatory infiltrates in liver biopsy samples from patients with NASH. In mouse models of NASH, we observed that B cells were activated in parallel with the onset of steatohepatitis and matured to plasmablasts and plasma cells. Mouse liver B cells mainly consist of bone-marrow-derived mature B220+IgM−CD23−CD43+ B1 cells resembling spleen follicular B cells. However, a small fraction of B220+IgM+CD23+CD43− B1 cells is also detectable. The functions of these two B cell subsets are not overlapping. On antigen stimulation, B1 cells mature in a T cell-independent manner to plasma cells producing IgM natural antibodies. Natural antibodies are pre-existing germline-encoded antibodies with a broad specificity to pathogens, but which are also able to crossreact with endogenous antigens, such as oxidized phospholipids and proteins adducted by the end products of lipid peroxidation. Conversely, the B2 subset requires T helper cells to proliferate and undergo antibody isotype class switching, which leads to plasma cells producing highly antigen-specific IgA, IgG or IgE.

In mice with NASH, the B cell response involves CD43+CD23− B2 cells and is accompanied by upregulation of the hepatic expression of B cell-activating factor (BAFF), one of the cytokines that drives B cell survival and maturation. Interestingly, circulating levels of BAFF are higher in patients with NASH than in those with simple steatosis, and levels correlate with the severity of steatohepatitis and fibrosis. Selective B2 cell depletion in mice overexpressing a soluble form of the BAFF–APRIL receptor transmembrane activator and cyclophilin ligand interactor (TACI) prevents plasma cell maturation. Furthermore, these mice have mild steatohepatitis and less fibrosis when receiving NASH-inducing diets. The contribution of B cells to the progression of NASH can be ascribed to the production of pro-inflammatory mediators as well as to their antigen-presenting capabilities (Table 1). In this respect, B cell activation in patients with NASH is associated with upregulation of major histocompatibility class II molecules in plasmablasts and precedes the recruitment of CD4+ and CD8+ T cells to the liver, whereas interfering with B2 cells reduces T_{reg} cell activation of liver CD4+ T cells and IFNγ production. These observations are consistent with previous studies indicating that B cells contribute to autoimmune hepatitis and liver fibrogenesis.

The pro-fibrogenic role of B cells is postulated to involve the production of pro-inflammatory mediators that stimulate hepatic stellate cells (HSCs) and liver macrophages. In turn, activated HSCs support liver B cell survival and maturation to plasma cells by secreting retinoic acid. So far, the clinical relevance of these findings has not been investigated in detail. However, serum levels of IgA are more frequently elevated among patients with NASH than in patients with simple steatosis, and are also an independent predictor of advanced liver fibrosis. Such upregulation of IgA directly relates to steatohepatitis given that IgA-producing plasma cells are detectable in the livers of AlbCrewPtn+/− mice with NASH fed a high-fat diet. Improved characterization of the origin and antigen specificity of NAFLD-related IgA might enable their use as possible serological markers for disease progression to cirrhosis.

Notably, the involvement of adaptive immunity in NASH (as outlined earlier) has many analogies with the data concerning the role of B cells and T cells in supporting insulin resistance and visceral adipose tissue (VAT) inflammation in obesity. In fact, obesity in both rodents and humans is associated with the expansion and activation of VAT CD4+ and CD8+ T cells, whereas T cell blockage or IFNγ neutralization reduce fat inflammation and insulin resistance. Similarly, B cells isolated from the VAT of obese mice show increased production of pro-inflammatory cytokines and promote T cell and macrophage activation, while a lack of B cells improves fat inflammation and insulin resistance. These data might explain why, in several experimental models of NASH, interference with adaptive immunity ameliorates liver lipid metabolism and steatosis by improving insulin resistance. Altogether, these data suggest the possibility that, in patients with metabolic syndrome, lymphocytes might support VAT and liver inflammation through similar mechanisms.

Oxidative stress and NASH immunity

A key issue for understanding the contribution of adaptive immunity in the evolution of NAFLD to NASH is the characterization of the antigenic stimuli that trigger lymphocyte responses. As mentioned earlier, oxidative stress and lipid peroxidation are common features of NAFLD and NASH. Oxidized phospholipids and reactive aldehydes generated during lipid peroxidation, such as malondialdehyde, not only act as DAMPs in activating hepatic inflammation but also form antigenic adducts with cellular macromolecules known as oxidative stress-derived epitopes (OSEs). OSEs are implicated in the stimulation of immune reactions responsible for plaque evolution in atherosclerosis and in the breaking of self-tolerance in several autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematosus. OSEs also include condensation products generated
by the interaction between malondialdehyde and acetaldehyde, known as malondialdehyde-acetaldehyde adducts (MAA)60.

The involvement of oxidative stress in driving NAFLD-associated immune responses came from observations that elevated titres of anti-OSE IgG were detectable in ~40% of adult patients with NAFLD or NASH in two unrelated cohorts62,63 and in 60% of children with NASH64. In particular, anti-OSE IgGs in adults with NAFLD or NASH target the cyclic MAA adduct methyl-1,4-dihydroxypropyridine-3,5-dicarboxaldehyde65. In patients investigated so far, high titres of anti-OSE IgGs are associated with the severity of lobular inflammation66, the prevalence of intrahepatic B cell and/or T cell aggregates67 and are an independent predictor of fibrosis68. The contribution of oxidative stress in stimulating adaptive immunity in NASH is further supported by animal data demonstrating that humoral and cellular responses against OSEs are linked with hepatic inflammation and parenchymal injury in a dietary rat model of NAFLD as well as in mice with NASH induced by the MCD diet69,70. In these settings, the increase in titres of anti-OSE IgG accompanies the maturation of liver B2 cells to plasma cells71,72, whereas reducing lipid peroxidation by supplementation with N-acetylcysteine or B2 cell depletion prevents antibody responses73,74. Conversely, mice preimmunized with malondialdehyde-adducted proteins, which also contain the MAA epitopes, before mice preimmunized with malondialdehyde–acetaldehyde, known as malondialdehyde-acetaldehyde adducts (MAA)60.

These opposite actions of anti-OSE IgG and IgM show many analogies to that observed in atherosclerosis69 and obesity-associated VAT inflammation70. Thus, B1 and B2 cell responses might exert antagonist activities in the pathogenesis of NAFLD, with IgG-producing B2 cells being involved in promoting pro-inflammatory mechanisms, and IgM from B1 cells having a protective action (TABLE 1). In this scenario, reduced levels of anti-OSE IgM in combination with stimulation of OSE-responsive B2 cells and T cells might exert a synergistic action in the development of NASH-associated immune responses.

**Innate and adaptive cell interplay**

A role for adaptive immunity in NASH is compatible with observations concerning the importance of innate responses in the pathogenesis of steatohepatitis. In fact, the network of cytokines generated by T<sub>\text{NHL}</sub>, T<sub>\text{NHL}</sub>17 and CD8<sup>+</sup> lymphocytes provide a potent stimulus for the activation of M1 hepatic macrophages (TABLE 1) which, in turn, support lymphocyte functions through the release of a variety of mediators including IL-12, IL-23, CXCL9, CXCL10 and CXCL11 (REF 21). Lymphocyte-stimulated secretion of IL-15 and IL-18 by macrophages might also promote NK cell activation, which has been shown to modulate mechanisms of steatohepatitis and fibrogenesis71.

Another component of innate immunity implicated in NAFLD and NASH is NKT cells, which are a T cell subset characterized by the coexpression of T cell receptor and NK cell surface receptors (NK1.1 in mice and CD161 or CD56 in humans)72. NKT cells recognize lipid antigens presented by CD1d-expressing antigen-presenting cells (APCs) and secrete a variety of cytokines (IL-4, IL-10, IFN\(\gamma\) and TNF) that can promote T<sub>H1</sub>, T<sub>H1</sub>7 and CD4<sup>+</sup>CD25<sup>+</sup> regulatory T (T<sub>\text{Rg}</sub>) cell activities73. Thus, NKT cells can both stimulate and suppress immune and/or inflammatory responses. NKT cell prevalence within the liver varies during the course of the disease as signals mediated by IL-12 and the T cell mucin domain-3/galectin-9 dyad reduce the numbers of NKT cells in steatosis and during the early phases of steatohepatitis75,76. Conversely, NKT cell expansion is evident in advanced NASH77,78 concomitant with enhanced secretion of LIGHT, IFN\(\gamma\), and IL-17A79,80. Interfering with NKT cells during advanced NASH effectively improves hepatic parenchymal injury, inflammation and fibrosis in different experimental models of the disease81,82. The large majority (95%) of liver NKT cells is represented by type I or invariant NKT (iNKT) cells75. Interestingly, the lack of iNKT cells in Jα18<sup>−</sup> mice or their inhibition in wild-type animals treated with the retinoic acid receptor-\(\gamma\) agonist tazarotene reduces CD8<sup>+</sup> T cell infiltration in the livers of these mice with NASH83, suggesting a strict interplay between cytotoxic T cells and iNKT cells in the mechanisms supporting steatohepatitis (FIG. 2). CXCL16 and IL-15 have been proposed to expand the pool of liver NKT cells in NASH76,77, acting as a chemoattractant and differentiation and/or survival factor, respectively78. We have observed that boosting anti-OSE immunity in mice with NASH stimulates an early expansion of the NKT pool by upregulating...
hepatic expression of IL-15\(^{29}\). On the other hand, mice deficient for IL-15 or IL-15 receptor-\(\alpha\) (IL-15R\(\alpha\)) are depleted of intrahepatic CD4\(^+\), CD8\(^+\) and NKT cells and, when receiving a high-fat diet, show milder steatosis and lobular inflammation than wild-type littermates\(^{29}\). Thus, IL-15 might act as a possible mediator in the signal network linking adaptive and innate immune cell responses during the evolution of steatohepatitis (Fig. 2).

**Fig. 2 | Role of oxidative stress in hepatic inflammation and parenchymal injury in nonalcoholic steatohepatitis.** Liver dendritic cells and other antigen-presenting cells (APCs) present oxidative stress-derived epitopes (OSE) to CD4\(^+\) T helper (TH) cells in the context of major histocompatibility complex class II (MHC II) molecules. This signal, together with enhanced expression of costimulatory molecules such as OX40, leads to the activation of CD4\(^+\) T cells and their TH1 cell or TH17 cell polarization. CD4\(^+\) TH1 cells also support both cytotoxic CD8\(^+\) T cell responses and B cell maturation of plasma cells secreting anti-OSE IgG. In turn, B cells can promote immune-inflammatory processes by antigen presentation to CD4\(^+\) T cells and by producing inflammatory cytokines. IFN\(\gamma\) and TH1 cell cytokines also stimulate liver macrophages to release M1 pro-inflammatory cytokines and chemokines (IL-12, CC-chemokine ligand 2 (CCL2) and CXC-chemokine ligand 9 (CXCL9)) that further contribute to recruiting monocytes and lymphocytes. Macrophages and dendritic cells also release B cell stimulating cytokines such as B cell-activating factor (BAFF), which are critical for B cell maturation to plasma cells. IL-15 produced by both hepatocytes and liver macrophages favours the survival of CD8\(^+\) T cells and, together with CXCL16, is implicated in promoting liver natural killer T (NKT) cell differentiation and survival. NKT cells and CD8\(^+\) T cells can further contribute to steatohepatitis through the secretion of LIGHT and IFN\(\gamma\). TCR, T cell receptor.
Mechanisms promoting adaptive immunity

Under physiological conditions the liver has an important immunosuppressive functions inducing tolerance to autoantigens and antigens from ingested food or commensal bacteria. These actions are mediated by a complex network of signals involving professional APCs, such as Kupffer cells and dendritic cells, as well as nonprofessional APCs including hepatocytes, hepatic sinusoidal endothelial cells and HSCs. These cells present antigens to T cells in a way that leads to T cell apoptosis, anergy or differentiation into CD4⁺CD25⁺FoxP3⁺ Treg cells. Additional immunosuppressive signals can also derive from NKT and NK cells and myeloid suppressor cells. In view of the specificity of the liver environment, the mechanisms responsible for subverting such tolerogenic milieu to trigger adaptive immunity in NASH remain underexplored.

Dendritic cells. Hepatic dendritic cells (HDCs) have an important role in orchestrating liver immune activity. HDCs account for <1% of total liver myeloid cells and are distinguished into plasmacytoid and myeloid (or classical) subsets, with the latter further subgrouped into type 1 and type 2 HDCs. During homeostasis, HDCs contribute to the tolerogenic environment of healthy livers. However, the onset of NASH is associated with expansion of myeloid HDCs and acquisition of the capacity to specifically stimulate CD4⁺ T cells. This response involves a subset of HDCs with high lipid content and is probably triggered by Toll-like receptor 4 stimulation induced by HMGB1 protein released by damaged or dying hepatocytes. However, mice lacking type 1 myeloid HDCs display increased susceptibility to steatohepatitis, suggesting that different HDC subsets might be involved in disease evolution. In fact, characterization of myeloid HDCs expanding in NASH reveals that a substantial fraction of these cells expresses the fractalkine receptor CX₃CR1 (CX₃C-chemokine receptor 1) along with monocyte markers, and produces high levels of TNFα, suggesting a role for monocyte-derived inflammatory dendritic cells in steatohepatitis. In addition, interfering with CX₃CR1 expression lowers the number of inflammatory HDCs and reduces both TNF production and hepatocyte death. Although HDC expansion and/or activation probably have key roles in stimulating the adaptive immune response in NASH, some aspects of this mechanism need further clarification. A study reported that an unspecific HDC depletion (by administration of diphtheria toxin in transgenic mice expressing the toxin receptor under the control of the dendritic cell marker CD11c (CD11c-DTR)) worsens NASH-associated hepatic inflammation and liver injury. These paradoxical results might be explained by the ablation of protective type 1 myeloid HDCs or of other cells expressing CD11c, such as NK cells. Indeed, depletion of NK1⁺DX5⁺Nkp46⁺ NK cells worsens hepatic inflammation and fibrosis in mice receiving the MCD diet.

A critical aspect of HDC action in NASH immunity involves antigen presentation to CD4⁺ T helper cells, which, in turn, supports cytotoxic CD8⁺ T cell and B cell responses. In these settings, T cell receptor-mediated signals are modulated by additional signals provided by costimulatory and coinhibitory molecules of the B7 and TNF families. Although the activity of costimulatory molecules has an important role in triggering T cell responses in VAT during obesity and in modulating anti-OSF immunity in atherosclerosis, their actual role in NASH is still poorly characterized.

In this respect, a study from 2018 has shed some light on the involvement of OX40 (CD134) in NASH. OX40 is a costimulatory molecule of the TNF family that is largely expressed on activated T cells in both mice and humans. Upon ligation by OX40 ligand (OX40L, CD252) which is present on APCs, OX40 promotes T cell responses. In mice receiving a high-fat diet, OX40 and OX40L are upregulated in the livers of mice with NASH, and OX40 deficiency selectively lowers hepatic CD4⁺ T cell recruitment and T₉₀:₁ and T₉₀:₁7 cell differentiation, ameliorating steatosis, and reducing the release of alanine aminotransferase and aspartate aminotransferase and the prevalence of M1 macrophages.

Interestingly, levels of soluble OX40 are also increased in the plasma of patients with NASH, positively correlating with the severity of steatohepatitis. These data, along with the observation that OX40 promotes insulin resistance and obesity-induced CD4⁺ T cell responses in VAT, suggest that OX40 and possibly other costimulatory molecules can critically influence adaptive immunity in NASH.

Regulatory T cells in the liver: T₉₀ cells in the liver have a key role in regulating liver immune tolerance by directly suppressing the proliferation and effector functions of CD4⁺ and CD8⁺ T cells through signals mediated by coinhibitory molecules such as cytotoxic T lymphocyte antigen 4 (CTLA-4) or by secreting IL-10 and transforming growth factor-β. T₉₀ cells are a subset of CD4⁺ T cells that express the transcription factor Forkhead box protein 3 (FOXP3) and originate either in the thymus or peripheral organs. Within the liver, immunosuppressive HDCs have an important role in directing naive CD4⁺ T cells to T₉₀ cell differentiation by expressing membrane-bound programmed cell death 1 ligand 1 (PD-L1) and by releasing IL-10 and kynurenine. T₉₀ cell analysis shows that levels of resting T₉₀ cells are lower both in the circulation and the liver of patients with NAFLD than in healthy control individuals. Such a reduction is more pronounced in patients with steatohepatitis than in patients with simple steatosis, paralleling T₉₀:₁ and T₉₀:₁7 T cell expansion. Conversely, levels of activated T₉₀ cells in the liver are unchanged in NAFLD despite an increase in the circulating levels of these cells. As a result, the liver T₉₀:₁:T₉₀:₁7 ratio is able to discriminate patients with NASH from those with steatohepatitis only, correlating with plasma levels of cytokeratin 18 (a marker of hepatocyte death). Interestingly, VAT inflammation in obesity is also associated with T₉₀ depletion and T₉₀:₁:T₉₀:₁7 cell imbalance.

At present, the mechanisms responsible for reducing the numbers of T₉₀ cells in NAFLD are poorly characterized. In fatty livers, T₉₀ cells are more susceptible to apoptosis in response to oxidative stress than in non-fatty livers. Additional mechanisms, including the
imperative of immunosuppressive functions of HDCs or interference with T\(_{reg}\) cell differentiation signals mediated by IL-33, might also be involved\(^{10}\). Imbalances in the secretion of adipokines by adipose tissue are additional factors that can affect T\(_{reg}\) cells, as increased leptin production in obesity has been shown to reduce T\(_{reg}\) cell differentiation whereas it stimulates dendritic cell activation and T\(_{h}1\) and T\(_{h}17\) polarization of CD4\(^+\) T cells\(^{41}\). The actual relevance of T\(_{reg}\) cells in the pathogenesis of steatohepatitis currently remains uncertain in view of the conflicting data obtained in experimental studies. Reducing numbers of T\(_{reg}\) cells in mice via combined deficiency of the costimulatory molecules CD80 and CD86 worsens adipose tissue inflammation and steatohepatitis induced by feeding with a high-fat diet\(^{102}\). By contrast, levels of T\(_{reg}\) cells in the liver are unchanged in different models of NASH despite extensive lymphocyte T\(_{h}1\) and T\(_{h}17\) cell activation\(^{33,44}\).

**Extrahepatic factors.** Along with the changes in HDCs and T\(_{reg}\) cells, studies in rodent models of NASH indicate that additional factors can affect hepatic immune tolerance. For instance, chronic liver inflammation induced by chronic CCI\(_4\) treatment or the MCD diet abolishes the capacity of Kupffer cells to promote liver T\(_{reg}\) cell expansion and tolerogenic responses, favouring instead the immunogenic stimulation of antigen-specific CD4\(^+\) T cells\(^{103}\). Thus, by acting at the same time as DAMPs and immunogenic antigens, OSEs generated within hepatocytes can both dampen hepatic immune tolerance and promote their own presentation to lymphocytes by APCs, triggering both B cell and T cell activation\(^{41,44}\) (Fig. 2).

Additional mechanisms contributing to the impairment of liver immune tolerance might involve alterations to the gut microbiota (dysbiosis), which is evident in some patients with NAFLD and NASH\(^{19,104}\). During homeostasis, Kupffer cells and hepatic sinusoidal endothelial cells are known to respond to low levels of endotoxins in the portal blood by releasing IL-10 (REF.\(^{80}\)). However, intestinal bacterial overgrowth and increased endotoxin reabsorption into the portal circulation can subvert the anti-inflammatory and immunosuppressive milieu by stimulating pro-inflammatory Kupffer cell activation, leading to a worsening of steatohepatitis\(^{105,106}\). Bacterial products can also directly promote hepatic CD8\(^+\) T cell accumulation and/or activation by inducing type I interferon production\(^{46}\). Further mechanisms by which dysbiosis might contribute to NASH-associated immune responses involve alterations in gut tolerance to autoantigens\(^{107}\) and the generation of short-chain fatty acids (such as acetate, propionate and butyrate) from carbohydrate fermentation\(^{19,83}\). Short-chain fatty acid production is increased in patients with NAFLD\(^{19,104}\), and increased faecal propionate and acetate levels are associated with reduced numbers of resting T\(_{reg}\) cells as well as with a higher T\(_{h}17\):resting T\(_{reg}\) cell ratio in the peripheral blood of patients with NAFLD\(^{104}\).

Altogether, the available evidence indicates that livers from patients with NAFLD might lose their tolerogenic environment in response to a variety of intrahepatic and extrahepatic stimuli (Fig. 3). In these circumstances, antigen presentation by both professional and non-professional APCs, together with the upregulation of costimulatory signals and an inflammatory cytokine milieu, are the background for effective B cell and T cell stimulation.

**Immunity and NAFLD-associated HCC**

NAFLD has emerged as an important risk factor for HCC, with an incidence of HCC of ~0.4% in patients with NAFLD\(^1\). HCCs commonly develop on a background of chronic liver inflammation and are often

---

**Fig. 3** Factors involved in stimulating the onset of adaptive immune responses during the evolution of nonalcoholic steatohepatitis. During the development of nonalcoholic steatohepatitis, the combined action of damage-associated molecular patterns (DAMPs) released by damaged hepatocytes, oxidative stress-derived epitopes (OSEs) and pro-inflammatory mediators affects the tolerogenic action of liver dendritic cells, Kupffer cells and sinusoidal endothelial cells. These changes contribute to a reduction in liver regulatory T (T\(_{reg}\)) cells and favours the expansion and activation of dendritic cells. Alterations in the gut-liver axis due to dysbiosis and obesity-related changes in the adipokine network are additional factors that affect liver immune tolerance. As a result, enhanced antigen presentation to lymphocytes associated with increased expression of costimulatory molecules leads to the development of both cellular and humoral immune responses. APC, antigen presenting cell; SCFA, short-chain fatty acid; T\(_{reg}\) cell, T helper cell.
associated with cirrhosis. In these settings, chronic necroinflammatory liver damage promotes compensatory hepatocyte growth allowing the emergence of mutated cell clones that are further supported in their growth by inflammatory mediators. Consistent with these mechanisms, steatohepatitis not only promotes carcinogen-induced HCCs but also leads to the spontaneous development of HCCs in mice receiving a choline-deficient diet. In a similar manner, in transgenic mice overexpressing the urokinase plasminogen activator, the URI or the MYC oncogene, induction of NASH (via a high-fat diet) leads to HCC. Unsurprisingly, adaptive immune responses involved in liver injury and inflammation also contribute to NAFLD-associated HCC. In fact, the lack of CD8+ T cells and NKT cells as well as interferon also contribute to NAFLD-associated HCC. In fact, the plasma cells that suppress antitumour cytotoxic CD8+ T cells are characterized by the accumulation of IgA-producing plasma cells, which are known to promote tumour cell growth when NASH is induced in mice receiving a choline-deficient diet. In a similar manner, spontaneous development of HCCs in mice receiving a choline-deficient diet has shown that oral OKT3 administration to patients with biopsy-proven NASH and type 2 diabetes mellitus ameliorates established NASH in mice.

However, the overall picture is still quite confused owing to conflicting results. For instance, despite the association of CD4+ T cells and T cells with NASH inflammatory mechanisms, one study has shown that the selective depletion of CD4+ T cells accelerates HCC growth when NASH is induced in mice with hepatocyte-specific overexpression of MYC. In these animals, CD4+ T cell loss has been ascribed to mitochondrial oxidative stress resulting from disrupted lipid metabolism. However, how these data relate to the expansion of CD4+ T cells observed in many different models of NASH is still incomplete, but a few studies have addressed the possibility of interfering with adaptive immunity as a novel approach for treating NASH. For instance, from the observation that the adhesion protein VAP1 promotes liver lymphocyte recruitment in NASH, VAP-1 neutralizing antibodies (BTT-1029) have been shown to reduce the severity of steatohepatitis and delay the onset of fibrosis in different experimental models of NASH.

These data not only suggest a complex role of adaptive immunity in the pathogenesis of NAFLD-associated HCC, but also highlight the unresolved issue of how adaptive immunity is modulated at different stages of NASH evolution and whether immune checkpoints might affect disease progression.

Targeting adaptive immunity in NASH

The current development of therapies for NAFLD and NASH has mainly focused on modulating metabolic disturbances, oxidative stress and innate immunity. Our knowledge regarding the involvement of B cells and T cells in inflammatory mechanisms of NASH is still incomplete, but a few studies have addressed the possibility of interfering with adaptive immunity as a novel approach for treating NASH. For instance, from the observation that the adhesion protein VAP1 promotes liver lymphocyte recruitment in NASH, VAP-1 neutralizing antibodies (BTT-1029) have been shown to reduce the severity of steatohepatitis and delay the onset of fibrosis in different experimental models of NASH. However, this effect might also involve inhibition of the amine oxidase activity of VAP1, which can promote cytotoxicity and oxidative stress by generating aldehydes and hydrogen peroxide. Studies have highlighted the role of B cells in NASH progression as well as the association between circulating levels of the B cell cytokine BAFF and the severity of steatohepatitis and fibrosis. Notably, treatment with the BAFF-neutralizing monoclonal antibody Sandy-2 prevents hepatic B2 cell responses and ameliorates established NASH in mice. The BAFF antagonist belimumab is already approved for the treatment of patients with systemic lupus erythematosus, and several other molecules with a similar action are under trial for the treatment of other B cell-driven autoimmune diseases. Thus, expanding our knowledge on the contribution of B cells to the pathogenesis of NASH might lead to the use of some of these agents as therapeutic approaches for those patients with NASH in whom adaptive immune mechanisms contribute to hepatic inflammation.

A different approach for targeting adaptive immunity in NASH relies on the possible applications of immunomodulatory treatments capable of stimulating Treg cells. For instance, the oral or nasal administration of antibodies targeting the T cell receptor-associated molecule CD3 has proved effective in ameliorating mouse autoimmune responses and atherosclerosis by inducing a specific subset of Treg cells that express latency-associated peptide (LAP) and T TI4. Accordingly, oral administration of the murine anti-CD3 monoclonal antibodies OKT3 plus β-glucosylceramide to obese leptin-deficient ob/ob mice induces LAP+ Treg cells and decreases adipose tissue inflammation along with liver steatosis and transaminase release. In humans, OKT3 antibodies effectively downmodulate Treg cell responses with a concomitant increase in the expression of Treg cell markers. Furthermore, a single-blind randomized placebo-controlled phase II clinical trial has shown that oral OKT3 administration to patients with biopsy-proven NASH and type 2 diabetes mellitus ameliorates alanine aminotransferase release, and...
improves blood glucose and insulin levels. Treg cell stimulation can also be achieved by the oral administration of hyperimmune cow colostrum (Imm124-E), which improves insulin resistance and liver injury in ob/ob mice. However, despite Imm124-E enhancing metabolic control in patients with NAFLD, it does not improve hepatic damage. Altogether, these preclinical and clinical data indicate that modulation of Treg cells has the potential to suppress inflammation in NASH. However, these studies are limited by the choice of the experimental models and the small number of patients investigated. Moreover, none of these studies has addressed the changes in immunological reactions associated with NASH.

The oral administration of antigens, a process known as oral tolerance, is emerging as an alternative way to downmodulate specific immune responses. Immune cells of the intestinal mucosa and gut-associated lymphoid tissues are known to be implicated in controlling immune reactions to food-derived antigens and gut microbiota, but this ability might also be exploited to induce immune tolerance to specific antigens. Oral tolerance has been used to prevent food allergies and coeliac disease through the stimulation of Treg cells and tolerogenic dendritic cells. At present, the only report addressing the effects of oral tolerance in NASH concerns the observation that dietary supplementation of ob/ob mice with proteins extracted from the liver of either ob/ob or wild-type mice improves insulin resistance and hepatic steatosis without affecting transaminase release and levels of circulating inflammatory cytokines. Additional studies in this field are urgently needed, as induction of oral tolerance through the administration of suitable molecules or by modulating the gut microbiota might represent an effective approach for achieving long-term control of the immune and inflammatory mechanisms underlying NAFLD evolution.

Conclusions
So far, the available data point to the involvement of adaptive immunity in the evolution of NAFLD. CD4⁺ T₄₁ and T₄₁7 cells are recruited within the liver at the onset of steatohepatitis; T₄₁ cytokines, and possibly T₄₁7 cytokines, generated by these lymphocytes provide a potent stimulus for hepatic macrophages, further driving chronic liver inflammation. In turn, macrophages contribute to lymphocyte recruitment and/or activation through the release of IL-12, IL-23 and lymphocyte chemokines. In addition, effector CD8⁺ T cells and B2 cells are also involved, although the relative role of these cells is still not fully defined. At present, oxidative stress represents the best characterized trigger of NASH-associated immune reactions. In this setting, the observation that anti-OSE IgGs are an independent risk factor for NASH progression to fibrosis suggests the possibility that elevated levels of circulating anti-OSE IgGs can identify a subset of patients with NASH in whom adaptive immunity might have a key role in promoting steatohepatitis.

Nonetheless, several unresolved issues remain in understanding the mechanisms by which adaptive immunity can contribute to NAFLD evolution (Box 1). For instance, evidence suggesting that B cells and CD4⁺ T cells infiltrating the liver in NASH originate from mesenteric lymph nodes and inflamed mesenteric adipose tissue raises the question of how gut–liver interactions influence NASH-associated adaptive immunity. In this setting, an additional question concerns the mechanism by which NAFLD affects the liver tolerogenic milieu to favour OSE presentation to APCs to B cells and T cells. Emerging evidence suggests the possibility that dysbiosis might have a role in this process. The characterization of these mechanisms would shed some light on the factors that influence the interindividual variability in the onset of adaptive immune reactions among patients with NAFLD or NASH. In a similar manner, more information is required to better characterize the interplay between B cells, T cells and other liver myeloid cells including macrophages, NK and NKT cells as well as the possible interactions with γδ T cells, innate lymphoid cells and mucosal-associated invariant T cells.

Another aspect of NAFLD-related immunity that deserves attention is the similarity of the antigens involved with those implicated in the pathogenesis of atherosclerosis. In this respect, experimental studies have shown that LDLr⁻/⁻ mice fed a HF–HC diet, an established rodent model of atherosclerosis, also develop NASH. Notably, removing OSE-modified LDLs ameliorates the diseases. Given that NAFLD is increasingly recognized as an independent risk factor for cardiovascular diseases, establishing whether anti-OSE antibodies might identify patients with NAFLD or NASH with specific risks for cardiovascular complications could be important.

In conclusion, clarifying the role of adaptive immunity in NAFLD and NASH will not only enhance our understanding of disease pathogenesis, but will also
enable identification of biomarkers that are able to discriminate patients with NAFLD at risk of developing NASH and/or patients with NASH at high risk of progression to cirrhosis or extrapathic complications. New insights into the role of immune mechanisms will also provide the rationale for novel treatments based on the modulation of liver tolerogenic responses and/or the application of a wide array of molecules already being studied in other conditions that are characterized by impaired immune regulation or autoimmunity.
