(Dated: October 27, 2018)

We present new Au/La$_{2-x}$Sr$_x$CuO$_4$ (LSCO) point-contact conductance measures as a function of voltage and temperature in samples with $0.08 \leq x \leq 0.2$. Andreev reflection features disappear at about the bulk $T_c$, giving no evidence of gap for $T > T_c$. The fit of the normalized conductance at any $T < T_c$ supports a $(s+d)$-wave symmetry of the gap, whose dominant low-$T$ s component follows the $T_c(x)$ curve in contrast with recent angle-resolved photoemission spectroscopy and quasi-particle tunneling data. These results prove the separation between pseudogap and phase-coherence superconducting gap in LSCO at $x \lesssim 0.2$.

PACS numbers: 74.50.+r, 74.25.Dw, 74.72.Dn

In a recent paper, G. Deutscher claimed the existence of two distinct energy scales - that is, two distinct gaps - in high-$T_c$ superconductors (HTS) [1]. According to his discussion, one of these gaps should appear at $T^* > T_c$ in optimally-doped and underdoped samples and could be due to an incoherent pairing between charge carriers (whose physical origin is still under discussion) which leads to a pair pre-formation. This gap, $\Delta^*$, would coincide with the pseudogap observed by angle-resolved photoemission spectroscopy (ARPES) and tunneling experiments. The second gap, $\Delta_c$, would appear at $T_c$ and would be associated to the achievement of the phase coherence by the pre-formed pairs and, consequently, to the onset of superconductivity. This phase-coherence gap can be observed only by experimental tools sensitive to the phase coherence of the pairs, i.e. Josephson effect and/or Andreev reflection experiments. At the present moment low-temperature tunneling [2] and very recent ARPES experiments [3] in La$_{2-x}$Sr$_x$CuO$_4$ (LSCO) have shown at $x < 0.2$ the presence of a large gap which increases at the lowering of the doping level. Very few experiments have instead been performed to investigate the Andreev gap [2, 3] and, to our knowledge, none at all to study in detail its dependence on the temperature and on the doping in the region from overdoped to underdoped.

In this letter, we present and discuss the results of point-contact experiments on La$_{2-x}$Sr$_x$CuO$_4$ samples. Despite the polycrystalline nature of the samples, a very careful point-contact technique allowed obtaining reproducible Andreev reflection curves and studying for the first time their behaviour in a broad temperature and doping range. In order to extract information about the dependence of the Andreev gap on $x$ and $T$, we fitted the experimental curves with the generalized BTK model by Y. Tanaka and S. Kashiwaya [4] for various possible symmetries of the order parameter. We found that the dependence of the Andreev gap on temperature and Sr content experimentally proves the existence of two distinct energy scales, a large pseudogap and a smaller superconducting gap, in LSCO.

The high-quality La$_{2-x}$Sr$_x$CuO$_4$ polycrystalline samples used in our measurements were prepared by conventional solid-state reaction at 1000°C by using stoichiometric amounts of the high-purity precursor oxides La$_2$O$_3$, CuO, and SrO$_2$. After the first reaction step the bulk materials were finely ground, pressed into small rectangular bars and sintered to obtain higher density samples. The sintering temperature was selected between 1100 and 1150°C for different Sr amount. When the dopant concentration was greater than $x=0.1$, quenching was required from higher temperatures (1170°C) to ensure chemical homogeneity. All samples were structurally characterized by XRD powder diffraction [7], and their actual stoichiometry was determined by means of EDS microprobe analysis, which evidenced the absence of impurities and confirmed their nominal Sr concentrations: $x = 0.08, 0.10, 0.12, 0.13, 0.15$ and 0.20. The typical linear dimension of the grains, as observed by means of AFM or SEM measurements, was 5÷10 µm. AC susceptibility and resistivity measurements were used to determine the critical temperatures, which were in good agreement with the standard curve of $T_c$ as a function of $x$ for LSCO [8]. The width of the resistive transition was of the order of 3÷5 K for all the Sr contents.

We performed on these samples point-contact experiments with Au tips, whose ending-part diameter was always less than $\sim 2$ µm [9], obtained by electro-chemical etching (with a HNO$_3$+HCl solution) of a 0.2 mm diam-
Figure 1 shows the low-temperature experimental normalized conductance data (vertically shifted for clarity) for the six doping values previously mentioned. We systematically normalized only the data sets for which dI/dV at |V| > 20 mV was reasonably constant and did not show sensible variations at the change of temperature. All the results that we show in the present letter are obtained from this kind of data.

The normal-state resistances of the junctions for all dopings are indicated near the curves in Fig. 1. With these contact resistances, and with the estimation of k_F (from E_F ~ 100 meV) and of the mean free path (from k_F l ≈ 13 at the transition temperature as reported in Ref. [11]) one obtains that the contact radius a ranges from 146 Å (when R ~ 90 Ω) to about 800 Å (when R ~ 3 Ω), while l ranges from 40 to 70 Å from underdoped to overdoped. Then, if single contacts are established between the tip and the material under study, they are not in the Sharvin limit. On the other hand, the I−V characteristics give no evidence of heating phenomena. In fact, the variation of conductance with bias is within that expected in the ballistic regime [11] and much smaller than that expected if the junction was heated up to a bias-dependent temperature above the bath one. Thus, we can exclude to be in the Maxwell (thermal) regime, which is enough to ensure that the conditions for energy-resolved spectroscopy are fulfilled, as widely shown in literature [12]. The logical consequence, also supported by the polycrystalline nature of our samples and by the softness of the Au tip, is that the low contact resistances can be explained by the presence of several parallel ballistic contacts between sample and tip [13].

Thus, the features we observed in the experimental data of Fig. 1 are with no doubt due to Andreev reflection at the S-N interface. Nevertheless, some differences are present with respect to the ideal curves predicted for a very low potential barrier by the well-known BTK model [14]. The maximum value is less than that expected and the shape is not always compatible with a pure s-wave symmetry of the order parameter. Moreover, some more or less pronounced oscillations of dI/dV are present at |V| ≥ 10 mV. These oscillations have been already observed in HTS and can be due to the presence of localized electron states in the interface potential barrier [15].

Figure 2 shows the temperature dependence of the normalized conductance in samples with x = 0.08 (a) and x = 0.2 (b). As in all the other samples, the Andreev features disappear at the bulk T_c (or at a slightly lower temperature) and a change in the shape of the curves is evident at the increase of T (see, for example, the curve at T = 12.3 K in Fig. 2b). As we will show later, this last feature can be explained by a change in the relative weight of the isotropic and anisotropic gap components.

To evaluate the gap and to study its dependence on the doping content, we fitted the normalized conductance curves by using the generalized BTK model introduced some years ago by S. Kashiwaya and Y. Tanaka [16]. In order to properly fit our data in the whole temperature range, we introduced in the original model of Ref. [16] the effect of the temperature and of the broadening parameter Γ which takes into account the finite lifetime of the quasiparticles. Various symmetries of the order parameter were used (s, s+id, s+d and anisotropic s). The pure d_{x^2−y^2} symmetry was not considered because it was unable to properly fit the low-voltage part of all our low-temperature data for any value of the fit parameters.

In the case of mixed pair symmetry and at constant
Let us now go back to the discussion of the low-temperature conductance curves shown in Fig. 1. The results of their fits are consistent with those obtained in LSCO by Deutscher et al. [1]. Table I shows the temperature of the junction and the values of $\Delta_s$, $\Delta_d$, $\Gamma$ and $Z$ for the curves of Fig. 1 together with the Andreev critical temperature $T_c^\Lambda$ and $2\Delta_s/k_B T_c^\Lambda$ for every doping value.

In Fig. 4 the doping dependencies of the low-temperature $\Delta_s$ and $\Delta_d$ (solid circles and solid squares, respectively) determined from the data of Fig. 1 are compared to those of the ARPES leading-edge shift (LE) recently determined in LSCO [3] (open circles) and of the gap determined by tunneling measurements (open squares) [4]. Both the ARPES LE and the tunneling gap values increase monotonically at the decrease of the doping and reach very large values ($15 \div 20$ meV for the ARPES LE in strongly underdoped samples). On the contrary, the dominant isotropic gap component determined from Andreev reflection data increases at the decrease of the doping in the overdoped region up to a maximum approximately located at the optimum doping, and then strongly reduces in the underdoped region, following the critical temperature behaviour (thick solid line). Let us stress that this conclusion does not depend on the model used to fit the experimental data, and holds true even if the Andreev gap is simply identified with the energy at which the conductance at negative (positive) bias has the maximum (minimum) slope. Also notice that the value of $\Delta_s$ for $x = 0.2$ almost coincides with that measured by tunneling, and this further supports our results, even for low contact resistances.

The main findings that follow from the results shown above can be so summarized: i) all the Andreev reflection features disappear at about the bulk $T_c$ of the samples (see Fig. 4, open triangles). The Andreev spectroscopy thus gives no evidence of gap at $T > T_c$ in LSCO, even in the underdoped region; ii) the fit of the Andreev curves

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|c|c|c|}
\hline
Doping & $T$ (K) & $\Delta_s$ (meV) & $\Delta_d$ (meV) & $\Gamma$ (meV) & $Z$ & $T_c^\Lambda$ (K) & $2\Delta_s/k_B T_c^\Lambda$ \\
\hline
0.08 & 4.22 & 3.4 & 2.5 & 0.19 & 0.20 & 9.6 & 8.2 \\
0.10 & 4.22 & 4.8 & 3.1 & 0.27 & 0.23 & 25.3 & 4.4 \\
0.12 & 4.22 & 5.6 & 0 & 0.92 & 0.18 & 26.0 & 5.0 \\
0.13 & 4.22 & 6.8 & 0 & 1.50 & 0.17 & 29.1 & 5.4 \\
0.15 & 4.65 & 6.8 & 0 & 0.44 & 0.08 & 35.3 & 4.5 \\
0.20 & 5.61 & 6.0 & 3.5 & 1.00 & 0.13 & 27.9 & 5.0 \\
\hline
\end{tabular}
\caption{Best-fit parameters and temperatures for the curves of Fig. 1.}
\end{table}
for all \( x \) values indicate that, at low-temperature, the \( s \)-wave component of the gap is dominant and independent of the symmetry used for the fit. Pure \( d \)-wave symmetry is unable to fit the data; iii) in contrast with the ARPES leading-edge shift in LSCO, the low-temperature dominant Andreev \( \Delta_s \) decreases at the decrease of \( x \) in the underdoped region and globally follows the \( T_c \) vs \( x \) behaviour.

These results give a complete experimental evidence for the existence of two energy scales in LSCO. The smallest one represents the phase-coherence (superconducting) gap, while the greatest is related to the gap-like features (pseudogap) observed by ARPES and quasiparticle tunneling experiments. As shown in Fig. 4, these two energy scales seem to merge slightly above the optimum doping. The present results are also a direct prove that the pseudogap is a property of the non-superconducting state of LSCO. The question arises of what could be its origin. Despite the large number of theoretical models proposed, the answer is still not clear.

Very recently, a two-gap model appeared in literature [17] which explains the pseudogap features in underdoped cuprate superconductors in the framework of incoherent pre-formed pairs around the M points of the Brillouin zone. According to this model, a bifurcation at \( x_h > x_{\text{opt}} \) is expected between the mean-field \( T_c \) curve (which has a maximum at \( x = x_{\text{opt}} \) ) and the temperature of pair pre-formation \( T^* \) (assumed to be linearly increasing at the lowering of \( x \)). Another recent model [18], on the contrary, analyzes the transition to the superconducting state in the presence of a preformed normal-state pseudogap resulting from interactions in the particle-hole channel, and predicts for the superconducting gap and the ARPES leading-edge shift the same doping dependence as \( T_c \) and \( T^* \) respectively, in very good agreement with our experimental results. In conclusion, both these approaches seem able to explain the experimental findings shown in Fig. 4.

Although further theoretical investigation is necessary to enlighten the real nature of the pseudogap state, we believe to have experimentally proved in a broad doping range \( (0.08 \leq x \leq 0.2) \) the existence of two energy scales in LSCO, related to the separation between a large incoherent pseudogap and a smaller phase-coherent superconducting gap which follows the \( T_c \) vs. \( x \) behaviour.

The interpretation of these results could play an essential role in the way to the comprehension of the microscopic mechanism leading to high-\( T_c \) superconductivity in LSCO.
