Abstract

We explore realizations of minimal flavor violation (MFV) for leptons in the simplest seesaw models where the neutrino mass generation mechanism is driven by new fermion singlets (type I) or triplets (type III) and by a scalar triplet (type II). We also discuss similarities and differences of the MFV implementation among the three scenarios. To study the phenomenological implications, we consider a number of effective dimension-six operators that are purely leptonic or couple leptons to the standard-model gauge and Higgs bosons and evaluate constraints on the scale of MFV associated with these operators from the latest experimental information. Specifically, we employ the most recent measurements of neutrino mixing parameters as well as the currently available data on flavor-violating radiative and three-body decays of charged leptons, \( \mu \to e \) conversion in nuclei, the anomalous magnetic moments of charged leptons, and their electric dipole moments. The most stringent lower-limit on the MFV scale comes from the present experimental bound on \( \mu \to e\gamma \) and can reach 500 TeV or higher, depending on the details of the seesaw scheme. With our numerical results, we illustrate some striking differences among the seesaw types. Particularly, we show that in types I and III there are features which can bring about potentially remarkable effects which do not occur in type II. In addition, we comment on how a few of the new effective operators can induce flavor-changing dilepton decays of the Higgs boson.
I. INTRODUCTION

The standard model (SM) of particle physics has been immensely successful in describing a vast amount of experimental data at energies up to $\mathcal{O}(100)$ GeV \cite{1}. One of the major implications is that in the quark sector flavor-dependent new interactions beyond the SM can readily be ruled out if they give rise to substantial flavor-changing neutral currents (FCNC). This motivates the formulation of the principle of so-called minimal flavor violation (MFV), which postulates that the sources of all FCNC and $CP$ violation reside in SM renormalizable Yukawa couplings defined at tree level \cite{2,3}. The MFV framework offers a predictive and systematic way to explore new physics which does not conserve quark flavor and $CP$ symmetries.

The implementation of the MFV principle for quarks is straightforward, but for leptons there are ambiguities, as the SM by itself does not predict lepton-flavor violation. Since there is now compelling empirical evidence for neutrino masses and mixing \cite{1}, it is of interest to formulate MFV in the lepton sector by incorporating ingredients beyond the SM that can account for this observation \cite{4}. Yet, we lack knowledge regarding not only the origin of neutrino mass, but also the precise nature of massive neutrinos. They could be Dirac fermions, like the electron and quarks, as far as their spin properties are concerned. However, neutrinos being electrically neutral, there is also the possibility that they are Majorana particles. The mass-generation mechanisms and Yukawa couplings for the neutrinos in the two cases differ significantly. Since the MFV hypothesis is closely associated with Yukawa couplings, one expects that the resulting phenomenologies in the two scenarios are also different.

In the Majorana neutrino case, there have been studies in the literature on some aspects of MFV realizations in various seesaw scenarios \cite{4,5,6,7}, especially in the well-known simplest models of types I, II, and III \cite{8,9,10,11}. In this work, we take another look at these three seesaw schemes to investigate the contributions of new interactions organized according to the MFV principle. We adopt a model-independent approach, where such contributions consist of an infinite number of terms which are built up from leptonic Yukawa couplings and their products. It turns out that the infinite series can be resummed into only seventeen terms \cite{12}. This formulation allows one to have a much more compact understanding of the terms that pertain to a given process. We find that for the specific processes to be considered only a few of them are relevant. We apply this to extract lower limits on the scale of MFV in the three seesaw scenarios using the latest experimental data, including the existing bounds on flavor-violating leptonic processes and the most recent measurements of neutrino mixing parameters. Also, we will examine the similarities and differences among the three seesaw types in relation to their MFV phenomenologies. Especially, we demonstrate that in types I and III there are features which can bring about potentially remarkable effects which do not happen in type II.

The plan of this paper is as follows. In the next section, we describe the MFV framework for leptons in the case that neutrinos are Dirac fermions. In Section III we discuss the implementation of the MFV principle in scenarios involving Majorana neutrinos with masses generated via the seesaw mechanism of types I, II, and III. This is applied in Section IV, where we explore some of the phenomenology with effective dipole operators involving leptons and the photon. We evaluate constraints on the MFV scale associated with these operators from currently available data on flavor-violating radiative decays of charged leptons, $\mu \to e$ conversion in nuclei,
flavor-violating three-body decays of charged leptons, and their anomalous magnetic moments and electric dipole moments. With our numerical results, we illustrate some striking differences among the three seesaw types. In Section V we look at several other leptonic operators satisfying the MFV principle. A few of them can cause flavor-violating decay of the Higgs boson. We make our conclusions in Section VI.

II. LEPTONIC MFV WITH DIRAC NEUTRINOS

Let us begin by describing how to arrange interactions under the MFV framework for leptons assuming that neutrinos are of Dirac nature. Following the MFV hypothesis that renormalizable Yukawa couplings defined at tree level are the only sources of FCNC and CP violation, we need to start with such couplings for the neutrinos and charged leptons. We slightly extend the SM by including three right-handed neutrinos, $\nu_{k,R}$, which transform as $(1,1,0)$ under the SM gauge group $G_{\text{SM}} = SU(3)_C \times SU(2)_L \times U(1)_Y$. The Lagrangian responsible for the lepton masses can then be written as

$$L_m = -(Y_{\nu})_{kl} \bar{L}_{k,L} \nu_{l,R} \tilde{H} - (Y_e)_{kl} \bar{L}_{k,L} E_{l,R} H + \text{H.c.},$$  

(1)

where summation over $k,l = 1,2,3$ is implicit, $Y_{\nu,e}$ are Yukawa coupling matrices, $L_{k,L}$ represents left-handed lepton doublets, $\nu_{k,R}$ and $E_{k,R}$ denote right-handed neutrinos and charged leptons, $H$ is the Higgs boson doublet, and $\tilde{H} = i\tau_2 H^*$ involving the second Pauli matrix $\tau_2$. Under the SM gauge group, $L_{k,L}, E_{k,R},$ and $H$ transform as $(1,2,-1/2), (1,1,-1),$ and $(1,2,1/2)$, respectively.

The MFV hypothesis [3, 4] implies that $L_m$ is formally invariant under the global group $U(3)_L \times U(3)_\nu \times U(3)_E = G_{\ell} \times U(1)_L \times U(1)_\nu \times U(1)_E$ with $G_{\ell} = SU(3)_L \times SU(3)_\nu \times SU(3)_E$. This entails that $L_{k,L}, \nu_{k,R},$ and $E_{k,R}$ belong to the fundamental representations of the $SU(3)_L,\nu,E$, respectively,

$$L_L \to V_L L_L, \quad \nu_R \to V_{\nu} \nu_R, \quad E_R \to V_E E_R, \quad V_{L,\nu,E} \in SU(3)_{L,\nu,E},$$  

(2)

and under $G_{\ell}$ the Yukawa couplings transform in the spurion sense according to

$$Y_{\nu} \to V_L Y_{\nu} V_{\nu}^\dagger \sim (3,3,1), \quad Y_e \to V_L Y_e V_E^\dagger \sim (3,1,\bar{3}).$$  

(3)

Taking advantage of the requirement that the final effective Lagrangian be invariant under $G_{\ell}$, without loss of generality one can always work in the basis where $Y_e$ is diagonal,

$$Y_e = \frac{\sqrt{2}}{v} \text{diag}(m_e, m_\mu, m_\tau)$$  

(4)

with $v \simeq 246$ GeV being the Higgs’ vacuum expectation value (VEV), and $\nu_{k,L}, \nu_{k,R}, E_{k,L},$ and $E_{k,R}$ refer to the mass eigenstates. Consequently, one can express $L_{k,L}$ and $Y_{\nu}$ in terms of the Pontecorvo-Maki-Nakagawa-Sakata neutrino mixing matrix $U_{\text{PMNS}}$ as

$$L_{k,L} = \left( (U_{\text{PMNS}})^{kl} \nu_{l,L} \right), \quad Y_\nu = \frac{\sqrt{2}}{v} U_{\text{PMNS}} \hat{m}_\nu, \quad \hat{m}_\nu = \text{diag}(m_1, m_2, m_3),$$  

(5)
where \( m_{1,2,3} \) are the light neutrino eigenmasses and in the standard parametrization \[ U_{\text{PMNS}} = \begin{pmatrix} c_{12} c_{13} & s_{12} c_{13} & s_{13} e^{-i\delta} \\ -s_{12} c_{23} - c_{12} s_{13} e^{i\delta} & c_{12} c_{23} - s_{12} s_{13} e^{i\delta} & s_{13} e^{i\delta} \\ s_{12} s_{23} - c_{12} c_{13} e^{i\delta} & -c_{12} s_{23} - s_{12} c_{13} e^{i\delta} & c_{23} c_{13} \end{pmatrix}, \] (6) with \( \delta \) being the Dirac \( CP \)-violation phase, \( c_{kl} = \cos \theta_{kl} \), and \( s_{kl} = \sin \theta_{kl} \).

Based on the transformation properties of the fields and Yukawa spurions, one then uses an arbitrary number of Yukawa coupling matrices to put together \( G_\ell \)-invariant objects which can induce the desired FCNC and \( CP \)-violating interactions. Thus, for operators involving two lepton fields, the pertinent building blocks are

\[
\bar{L}_L \gamma_\alpha \Delta_\ell L_L, \quad \bar{\nu}_R \gamma_\alpha \Delta_\nu s \nu_R, \quad \bar{E}_R \gamma_\alpha \Delta_\nu s E_R, \quad \bar{\nu}_R (1, \sigma_{\alpha \beta}) \Delta_\nu L_L, \quad \bar{E}_R (1, \sigma_{\alpha \beta}) \Delta_\nu L_L . \] (7)

For these to be \( G_\ell \) invariant, the \( \Delta \)'s should transform according to

\[
\Delta_\ell \sim (1 \oplus 8, 1, 1), \quad \Delta_\nu s \sim (1, 1 \oplus 8, 1), \quad \Delta_\nu \sim (3, 3, 1), \quad \Delta_\nu s \sim (3, 1, 3). \] (8)

Since \( \bar{L}_L \gamma_\alpha \Delta_\ell L_L, \bar{\nu}_R \gamma_\alpha \Delta_\nu s \nu_R, \) and \( \bar{E}_R \gamma_\alpha \Delta_\nu s E_R \) must be Hermitian, \( \Delta_{\ell, \nu s \nu s, \nu e} \) must be Hermitian as well. To be acceptable terms in the Lagrangian, the above objects should be combined with appropriate numbers of other SM fields into singlets under the SM gauge group, with all the Lorentz indices contracted.

The MFV principle dictates that these \( \Delta \)'s are built up from the Yukawa coupling matrices \( Y_{\nu e} \) and \( Y_{\nu e}^\dagger \). Let us first discuss a nontrivial \( \Delta \) which transforms as \( (1 \oplus 8, 1, 1) \) under \( G_\ell \) and consists of terms in powers of

\[
\begin{align*}
A &= Y_{\nu} Y_{\nu}^\dagger = \frac{2}{v^2} U_{\text{PMNS}} m_{\nu}^2 U_{\text{PMNS}}^\dagger, \\
B &= Y_{\bar{\nu}} Y_{\bar{\nu}}^\dagger = \frac{2}{v^2} \text{diag}(m_{\nu e}^2, m_{\mu e}^2, m_{\tau e}^2),
\end{align*}
\] (9)
both of which also transform as \( (1 \oplus 8, 1, 1) \). Formally, \( \Delta \) is a sum of infinitely many terms, \( \Delta = \sum_{jkl...} \xi_{jkl...} A^{j} B^{k} A^{l} \cdots \) with coefficients \( \xi_{jkl...} \) expected to be at most of \( \mathcal{O}(1) \). Under the MFV framework, these coefficients must be real because otherwise they would introduce new sources of \( CP \)-violation beyond those in the Yukawa couplings. With the Cayley-Hamilton identity \( X^3 = X^2 \text{Tr} X + \frac{1}{2} X \left[ \text{Tr} X^2 - (\text{Tr} X)^2 \right] + \mathbb{I} \text{Det} X \) for an invertible \( 3 \times 3 \) matrix \( X \), one can resum the infinite series into a limited number of terms \[ 12 \]

\[
\Delta = \xi_1 \mathbb{I} + \xi_2 A + \xi_3 B + \xi_4 A^2 + \xi_5 B^2 + \xi_6 AB + \xi_7 BA + \xi_8 ABA + \xi_9 BA^2 + \xi_{10} BAB \\
+ \xi_{11} AB^2 + \xi_{12} ABA^2 + \xi_{13} A^2 B^2 + \xi_{14} B^2 A^2 + \xi_{15} B^2 AB + \xi_{16} AB^2 A^2 + \xi_{17} B^2 A^2 B , \] (10)
where \( \mathbb{I} \) stands for the \( 3 \times 3 \) unit matrix. Though one starts with all \( \xi_{jkl...} \) being real, the resummation process generally renders the coefficients \( \xi_e \) in Eq. (10) complex due to imaginary parts created among the traces of the matrix products \( A^j B^k A^l \cdots \) with \( j+k+l+\cdots \geq 6 \) after the application of the Cayley-Hamilton identity. The imaginary contributions turn out to be reducible to factors proportional to a Jarlskog invariant quantity, \( \text{Im} \text{Tr}(A^2 BAB^2) = (i/2) \text{Det}[A, B] \), which is much smaller than unity \[ 12 \].
With Eq. (10), one can devise the objects in Eq. (8). Thus, the first of the Hermitian combinations can be \( \Delta_\ell = \Delta + \Delta^\dagger \). To obtain nontrivial \( \Delta_{\nu,e} \), one can take \( \Delta_{\nu} = Y_{\nu}^\dagger \Delta \) and \( \Delta_{e} = Y_{e}^\dagger \Delta \). The construction of \( \Delta_{\nu,e} \) can be carried out in a similar way, except \( A \) and \( B \) are replaced by \( \tilde{A} = Y_{\nu}^\dagger Y_{\nu} \) and \( \tilde{B} = Y_{e}^\dagger Y_{e} \). Since \( \tilde{A} \) and \( \tilde{B} \) are diagonal, so are any powers of them. Therefore, \( \Delta_{\nu,e} \) do not produce any FCNC and \( CP \)-violation effects.

We end this section by mentioning that the above discussion can be easily applied to the quark sector with the renormalizable Yukawa Lagrangian given by

\[
L_m = - (Y_u)_{kl} \bar{Q}_{k,L} U_{l,R} \tilde{H} - (Y_d)_{kl} \bar{Q}_{k,L} D_{l,R} H + \text{H.c.},
\]

where \( Y_{u,d} \) are Yukawa coupling matrices, \( Q_{k,L} \) represents left-handed quark doublets, and \( U_{k,R} \) \( (D_{k,R}) \) denote right-handed up-type (down-type) quarks. These fields transform as \((3, 2, 1/6), (3, 1, 2/3), \) and \((3, 1, -1/3)\), respectively, under the SM gauge group \( G_{SM} \). In the basis where \( Y_d \) is diagonalized,

\[
Y_d = \frac{\sqrt{2}}{v} \text{diag}(m_d, m_s, m_b), \quad Y_u = \frac{\sqrt{2}}{v} V_{\text{CKM}}^\dagger \hat{m}_u, \quad \hat{m}_u = \text{diag}(m_u, m_c, m_t),
\]

where \( V_{\text{CKM}} \) is the Cabibbo-Kobayashi-Maskawa matrix which has the same standard parametrization as in Eq. (10). For MFV interactions, employing \( Y_{u,d} \) along with \( A = Y_u Y_u^\dagger \) and \( B = Y_d Y_d^\dagger \) as building blocks, one can construct objects such as \( \Delta_q, \Delta_u, \) and \( \Delta_d \), which are the quark counterparts of \( \Delta_\ell, \Delta_\nu \) and \( \Delta_e \), respectively \[13\].

**III. SEESAW MODELS WITH MFV**

If neutrinos are Majorana particles, the Yukawa couplings that take part in generating their masses differ from those in the Dirac neutrino case and depend on the model details. In this section we discuss how to realize the MFV hypothesis in the well-motivated seesaw models. The seesaw mechanism endows neutrinos with Majorana mass and provides a natural explanation for why they are much lighter than their charged partners. If just one kind of new particles are added to the minimal SM, there are three different scenarios \([8, 11]\): the famous seesaw models of type I, type II, and type III. A crucial step in the implementation of MFV in a given model is to identify the quantities \( A \) and \( B \) in terms of the relevant Yukawa couplings. This will be the emphasis of the section.

**A. MFV in type-I seesaw model**

In the type-I seesaw model the SM is slightly expanded with the inclusion of three gauge-singlet right-handed neutrinos, \( \nu_{k,R} \), which are allowed to possess Majorana masses \([8]\). The renormalizable Lagrangian for the lepton masses is

\[
L_m^I = - (Y_\nu)_{kl} \bar{L}_{k,L} \nu_{l,R} \tilde{H} - (Y_e)_{kl} \bar{E}_{k,L} E_{l,R} H - \frac{1}{2} (M_\nu)_{kl} \nu_{k,R}^\dagger \nu_{l,R} + \text{H.c.},
\]
where $M_\nu = \text{diag}(M_1, M_2, M_3)$ contains the right-handed neutrinos’ Majorana masses and the superscript $c$ refers to charge conjugation. Accordingly, the masses of the neutral fermions make up the $6 \times 6$ matrix

$$M = \begin{pmatrix} 0 & M_D \\ M_D^T & M_\nu \end{pmatrix} \quad (14)$$

in the $(U_{\text{PMNS}}(\nu_L)^c, \nu_R)^T$ basis, where $M_D = vY_\nu/\sqrt{2}$. If the nonzero elements of $M_\nu$ are much greater than those of $M_D$, the seesaw mechanism becomes operational [8], resulting in the light neutrinos’ mass matrix

$$m_\nu = -\frac{v^2}{2} Y_\nu^{-1} Y_\nu^T = U_{\text{PMNS}} \tilde{m}_\nu U_{\text{PMNS}}^T \quad (15)$$

where $U_{\text{PMNS}}$ contains the diagonal matrix $P = \text{diag}(e^{i\alpha_1/2}, e^{i\alpha_2/2}, 1)$ multiplied from the right, $\alpha_1, \alpha_2$ being the $CP$-violating Majorana phases. It follows that $Y_\nu$ in Eq. (5) is no longer valid, and one can instead pick $Y_\nu$ to be [14]

$$Y_\nu = \frac{i\sqrt{2}}{v} U_{\text{PMNS}} \tilde{m}_\nu^{1/2} O M_\nu^{1/2} \quad (16)$$

where $O$ is a matrix satisfying $OO^T = 1$. Since $O$ can be complex, it is a potentially important new source of $CP$ violation besides $U_{\text{PMNS}}$. From Eq. (16)

$$A = Y_\nu Y_\nu^T = \frac{2}{v^2} U_{\text{PMNS}} \tilde{m}_\nu^{1/2} O M_\nu^{1/2} O^\dagger \tilde{m}_\nu^{1/2} U_{\text{PMNS}}^T \quad (17)$$

whereas $B = Y_e Y_e^T$ in Eq. (9) is unchanged. These matrices are to be incorporated into the MFV objects $\Delta_{\ell,\nu,e}$. We note that, since $\tilde{A} = Y_\nu^\dagger Y_\nu = (2/v^2) M_\nu^{1/2} O^\dagger \tilde{m}_\nu O M_\nu^{1/2}$, here $\Delta_{\nu8}$ is no longer diagonal, but it pertains only to $\nu_R$ interactions.

Now, in the Dirac neutrino case, $A$ is given by Eq. (19) and therefore has tiny elements. In contrast, if $M_{1,2,3}$ in $M_\nu$ are sufficiently large, the eigenvalues of $A$ in Eq. (17) can be sizable. However, since as an infinite series $\Delta$ has to converge, $M_{1,2,3}$ cannot be arbitrarily large [12, 13]. Accordingly, in numerical work we require the biggest eigenvalue of $A$ to be unity, which implies that the elements of $B$ are comparatively much smaller.

### B. MFV in type-II seesaw model

The type-II seesaw model extends the SM with the addition of only one scalar SU(2)$_L$ triplet given by [9, 10]

$$T = \begin{pmatrix} T^+/\sqrt{2} & T^{++} \\ T^0 & -T^+/\sqrt{2} \end{pmatrix} \quad (18)$$

---

$^1$ The presence of $M_\nu$ breaks the global U(3)$_\nu$ completely if $M_{1,2,3}$ are unequal and partially into O(3)$_\nu$ if $M_{1,2,3}$ are equal [3].
which transforms as \((1, 3, 1)\) under the SM gauge group \(G_{\text{SM}}\). Accordingly, the Lagrangian describing the Yukawa couplings of leptons is

\[
\mathcal{L}_m^{\text{II}} = -(Y_e)_{kl} \tilde{L}_{k,L} E_{l,R} H - \frac{1}{2} (Y_T)_{kl} \tilde{L}_{k,L} \tilde{T} L_{l,L} + \text{H.c.},
\]  

(19)

with \(\tilde{T} = i\tau_2 T^\ast\). It respects lepton-number conservation if \(T\) is assigned a lepton number of \(-2\). After the VEV of the neutral component of \(T\) becomes nonzero, \(\langle T^0 \rangle = v_T/\sqrt{2}\), one obtains in \(\mathcal{L}_m^{\text{II}}\) the neutrino mass matrix

\[
m_\nu = \frac{1}{\sqrt{2}} v_T Y_{\nu} = U_{\text{PMNS}}^\dagger m_\nu U_{\text{PMNS}}^T\]

(20)
in the basis where the charged lepton's Yukawa coupling matrix, \(Y_{\nu}\), has been diagonalized. If the nonzero elements of \(Y_T\) are of \(\mathcal{O}(1)\), the tiny size of neutrino masses then comes from the suppression of \(v_T\) due to certain choices of the parameters in the scalar potential \(V\). One can express it as \([15]\)

\[
V = -m_H^2 H^\dagger H + M_T^2 \text{Tr}(T^\dagger T) + \frac{1}{2} \lambda_1 (H^\dagger H)^2 + \frac{1}{2} \lambda_2 [\text{Tr}(T^\dagger T)]^2 + \lambda_3 H^\dagger H \text{Tr}(T^\dagger T)
\]

\[
+ \lambda_4 \text{Det}(T^\dagger T) + \lambda_5 H^\dagger T^\dagger H + \frac{1}{\sqrt{2}} (\mu_T H^\dagger T^\dagger H + \mu^\dagger_T H T H),
\]

(21)

where \(m_H^2 > 0\) and \(M_T^2 > 0\). The \(\mu_T\) part explicitly breaks lepton-number symmetry and causes the first equality simplifies to \(\lambda_1 v^2 \simeq 2 m_H^2\) like in the SM, and with the additional conditions \(v \ll M_T/|\lambda_3|^{1/2}\) and \(v_T \ll |\mu_T|\) the second relation in Eq. (22) translates into

\[
v_T \simeq \frac{|\mu_T|^2}{2 M_T^2},
\]

(23)

which is small if \(|\mu_T|^2 \ll M_T^2\). This turns into the seesaw form \(v_T \sim v^2/M_T\) if \(|\mu_T| \sim M_T > v\), but the prerequisites just mentioned do not preclude a scenario with a relatively lighter triplet, in which \(M_T\) can be as low as the TeV level \([7]\), provided that \(|\mu_T| \ll v\).

Since the triplet couples to SM gauge bosons, a nonzero \(v_T\) will make the \(\rho_0\) parameter deviate from unity \([15]\),

\[
\rho_0 = \frac{m_W^2}{m_Z^2 \cos^2 \theta_W} = \frac{v^2 + 2 v_T^2}{v^2 + 4 v_T^2} \simeq 1 - \frac{2 v_T^2}{v^2}.
\]

(24)

Its empirical value \(\rho_0 = 1.00040 \pm 0.00024\) \([1]\) then implies, at the 2\(\sigma\) level, that \(v_T < 1.6\) GeV. This is much weaker than the requirement for the \(v_T\) range that can produce neutrino masses of \(\mathcal{O}(0.1\text{ eV})\) if the elements of \(Y_T\) are of \(\mathcal{O}(1)\).

To implement the MFV hypothesis in this seesaw scheme, one observes that the Lagrangian in Eq. (19) possesses formal invariance under the global group \(U(3)_L \times U(3)_E = G'_f \times U(1)_L \times U(1)_E\), with \(G'_f = SU(3)_L \times SU(3)_E\), if \(L_L\) and \(E_R\) belong to the fundamental representation of \(SU(3)_{L,E}\), respectively,

\[
L_L \rightarrow V_L L_L, \quad E_R \rightarrow V_E E_R, \quad V_{L,E} \in SU(3)_{L,E},
\]

(25)
and the Yukawa couplings are spurions transforming according to
\[ Y_e \rightarrow V_L Y_e V_L^T, \quad Y_T \rightarrow V_L Y_T V_L^T. \tag{26} \]

Here the building block \( \Delta \) still has the expression in Eq. (10), with \( B = Y_e Y_e^\dagger \) being the same as in Eq. (9), but unlike before
\[ A = Y_T Y_T^\dagger = \frac{2}{v_T^2} U_{\text{PMNS}} \hat{m}_\nu U_{\text{PMNS}}^\dagger, \tag{27} \]
where from Eq. (20)
\[ Y_T = \sqrt{2} v_T U_{\text{PMNS}} \hat{m}_\nu U_{\text{PMNS}}^T. \tag{28} \]

It is interesting to notice that \( A \) in Eq. (27) is the same as its Dirac-neutrino counterpart in Eq. (9), up to an overall factor. Due to this difference, whereas the elements of the latter are tiny, those in Eq. (27) can be of \( O(1) \) if \( v_T \) is similar in order of magnitude to the neutrino masses. This will in fact be realized in our numerical analysis, as we will again choose the largest eigenvalues of \( A \) to be unity, which amounts to imposing \( v_T = \sqrt{2} \max(m_1, m_2, m_3) \).

Compared to Eq. (17) in the type-I case, \( A \) in Eq. (27) is in general much simpler. In particular, it no longer depends on the Majorana phases in \( U_{\text{PMNS}} \) which have canceled out due to \( \hat{m}_\nu \) being diagonal and does not involve the \( O \) matrix which can supply potentially major extra effects including \( CP \)-violating ones [13].

C. MFV in type-III seesaw model

In the type-III seesaw model the new particles consist only of three fermionic SU(2) \(_L\) triplets [11]
\[ \Sigma_k = \begin{pmatrix} \Sigma_k^0 / \sqrt{2} & \Sigma_k^+ \\ \Sigma_k^- & -\Sigma_k^0 / \sqrt{2} \end{pmatrix}, \quad k = 1, 2, 3, \tag{29} \]
which transform as \((1, 3, 0)\) under the SM gauge group \( G_{\text{SM}} \). The Lagrangian responsible for the lepton masses is then
\[ \mathcal{L}_m^{\text{III}} = -(Y_e)_{kl} \bar{L}_{k,L} E_{l,R} H - \sqrt{2} (Y_\Sigma)_{kl} \bar{L}_{k,L} \Sigma_l \tilde{H} - \frac{1}{2} (M_\Sigma)_{kl} \text{Tr}(\Sigma_k^c \Sigma_l) + \text{H.c.} \tag{30} \]
where \( \Sigma_k^c \) is the charge conjugate of \( \Sigma_k \). For convenience, we define the right-handed fields \( \xi_{k,R} = \Sigma_k^- \) and \( \xi_{k,R} = \Sigma_k^0 \) and left-handed fields \( \xi_{k,L} = (\Sigma_k^c)^c \) and \( \xi_{k,L} = (\Sigma_k^c)^c \). In terms of matrices containing them and SM leptons, one can express the mass terms in \( \mathcal{L}_m^{\text{III}} \) after electroweak symmetry breaking as
\[ \mathcal{L}_m^{\text{III}} \supset -(E_L \xi_L) \begin{pmatrix} M_e & \sqrt{2} M_D \\ 0 & M_\Sigma \end{pmatrix} (E_R \xi_R) - \frac{1}{2} (\nu_L^c \nu_L) \begin{pmatrix} 0 & M_D \\ M_D^T & M_\Sigma \end{pmatrix} (\nu_R^c) + \text{H.c.}, \tag{31} \]
where $M_e = v Y_e / \sqrt{2}$ and $M_D = v Y_S / \sqrt{2}$ are $3 \times 3$ matrices and $\nu'_L = U_{\text{PMNS}} \nu_L$. For $M_S \gg M_D$ in their nonzero elements, a seesaw mechanism like that in type I becomes operational to generate the light neutrinos’ mass matrix

$$m_\nu = -\frac{v^2}{2} Y_S M^{-1}_S Y_\Sigma^T .$$

(32)

Hence it is tempting simply to write $Y_\Sigma$ in a similar way to $Y_\nu$ in type I,

$$Y_\Sigma = i \sqrt{2} v U_{\text{PMNS}} \hat{m}_\nu^{1/2} O M_S^{1/2} ,$$

(33)

and use $Y_e$ in Eq. (4) like before.

One, however, needs to justify this approximation because the light charged leptons, $E_k$, mix with the heavy ones, $E'_k$, as can be deduced from Eq. (31). They are related to the mass eigenstates $E'_k$ and $E'_k$ by

$$\begin{pmatrix} E_C \\ E'_C \end{pmatrix} = \begin{pmatrix} (U_{EE})_C & (U_{EE})_C \\ (U_{EE})_C & (U_{EE})_C \end{pmatrix} \begin{pmatrix} E'_C \\ E'_C \end{pmatrix} , \quad C = L, R .$$

(34)

This alters $U_{\text{PMNS}}$ in Eq. (33) to $(U_{EE})_L U_{\text{PMNS}}$ as well as $Y_e$ to $(U_{EE})_L Y_e (U_{EE})_R$. At leading order [16], $(U_{EE})_L = \mathbb{I}_M - M_D M^{-2}_S M^T_D$ and $(U_{EE})_R = \mathbb{I}$ for $M_D \ll M_S$. Thus, the deviations of $(U_{EE})_{L,R}$ from the unit matrix are negligible, and the approximation of $Y_\Sigma$ in Eq. (33) is justified. Accordingly, in type III with MFV we work with

$$A = Y_\Sigma Y_\Sigma^\dagger = \frac{2}{v^2} U_{\text{PMNS}} \hat{m}_\nu^{1/2} O M_S^{1/2} O^\dagger \hat{m}_\nu^{1/2} U_{\text{PMNS}}^\dagger$$

(35)

and, as in the previous scenarios, $B$ in Eq. (9). These are no different from those in type I, with $M_S = \text{diag}(M_1, M_2, M_3)$. Also, we fix the biggest eigenvalue of $A$ to one.

IV. LEPTONIC DIPOLE OPERATORS IN SEESAW MODELS WITH MFV

Having set up the basics of the MFV realizations in the minimal seesaw models of types I, II, and III, we now study some of the phenomenological implications and point out possible differences among them. It is clear from the last section that as far as MFV phenomenology is concerned type I and type III will be virtually alike because, with the new fermion masses being far above the TeV level, the building blocks for the quantity $\Delta$ are the same in both cases. However, within the MFV context we expect that marked differences can materialize between these two models and type II.

To explore the phenomenological consequences of MFV, one can adopt an effective theory approach [3, 4], assuming that the heavy degrees of freedom in the full theory have been integrated out. This is especially suitable for the seesaw scenarios under consideration, where the masses of the new particles are much greater than the energies of the processes which we examine in this paper. A number of higher-dimensional effective operators involving leptons have been listed in the leptonic MFV literature [4, 5]. Here we focus on dimension-six operators which generate
dipole interactions between SM leptons and gauge bosons. We deal with several other leptonic
operators in the next section.

The dipole operators of interest are

\[
O^{(e_1)}_{RL} = g' \bar{E}_R Y \sigma_{\kappa \omega}^\dagger \Delta_{\ell 1} \sigma_{\kappa \omega} H^\dagger L L B^{\kappa \omega}, \quad O^{(e_2)}_{RL} = g \bar{E}_R Y \sigma_{\kappa \omega}^\dagger \Delta_{\ell 2} \sigma_{\kappa \omega} \tau_\alpha L L W^{\kappa \omega},
\]

where \( W \) and \( B \) stand for the usual SU(2) \(_L\) \( \times U(1) \_Y \) gauge fields with coupling constants \( g \) and \( g' \), respectively, \( \tau_\alpha \) are Pauli matrices, summation over \( a = 1, 2, 3 \) is implicit, and \( \Delta_{\ell 1, \ell 2} \) have the same form as \( \Delta \) in Eq. (10), but with generally different \( \xi_r \). One can write the effective Lagrangian

\[
\mathcal{L}_{\text{eff}} = \frac{1}{\Lambda^2} [O^{(e_1)}_{RL} + O^{(e_2)}_{RL}] + \text{H.c.},
\]

where \( \Lambda \) is the scale of MFV and their own coefficients in this Lagrangian have been absorbed
by the \( \xi_r \) in their respective \( \Delta^\prime \)’s.

The terms in Eq. (37) with the photon have the general form

\[
\mathcal{L}_{E_k E_\ell \gamma} = \frac{\sqrt{\alpha \pi}}{\Lambda^2} \bar{E}_k \sigma_{\kappa \omega} \{ m_{E_k}(\Delta_\ell)^*_{kl} + m_{E_\ell}(\Delta_\ell)_{lk} \} - \left[ m_{E_k}(\Delta_\ell)_{kl} - m_{E_\ell}(\Delta_\ell)^*_{lk} \right] \gamma_5 \} E_l F^{\kappa \omega},
\]

where \( \alpha \simeq 1/137 \) is the fine-structure constant, \( F^{\kappa \omega} \) denotes the electromagnetic field-strength
tensor, \( (E_1, E_2, E_3) = (e, \mu, \tau) \), and hereafter \( \Delta_\ell = \Delta_{\ell 1} - \Delta_{\ell 2} \). These interactions contribute
to the flavor-changing decays \( E_\ell \rightarrow E_k \gamma, E_k E_j \rightarrow E_j^+ \) and nuclear \( \mu \rightarrow e \) conversion, as well as
to the anomalous magnetic moments \( (g - 2) \) and electric dipole moments (EDMs) of charged
leptons. We ignore the contributions from \( \mathcal{L}_{\text{eff}} \) to \( \mu \rightarrow e \) conversion and \( E_l \rightarrow E_k E_j^- E_j^+ \) that
are mediated by the Z boson due to the suppression by its mass. The flavor-changing transitions
and lepton EDMs have been searched for over the years, but with null results so far, leading to
increasingly severe bounds on their rates. For the electron and muon \( g - 2 \), the predictions and
measurements have reached high precision which continues to improve, implying that the inferred
room for new physics is small and progressively decreasing. Thus the experimental information
on these processes can offer very stringent restrictions on the scale \( \Lambda \) in Eq. (37). We address
this in the rest of the section.

A. Flavor-changing transitions and anomalous magnetic moments

We treat first observables that are not sensitive to \( C P \)-violating effects. In this case, we can
retain no more than three of the 17 terms of \( \Delta \) in Eq. (10), as the others are suppressed by
comparison. Since we pick the largest eigenvalue of the \( A \) matrix to be one in order to enhance
the impact of new physics, the elements of \( A \) are much greater than those of the \( B \) matrix, whose
biggest eigenvalue is \( 2m_\tau^2/v^2 \simeq 1.0 \times 10^{-4} \). As a consequence, the matrix elements of terms in
Eq. (10) with at least one power of \( B \) are in general significantly smaller due to this suppression
factor than terms without any \( B \). Thus we can make the approximation \( \Delta = \xi_1 \mathbb{I} + \xi_2 A + \xi_4 A^2 \)
in dealing with such observables.
Among the flavor-changing decays $E_l \to E_k \gamma$, one can expect the most severe constraint from $\mu \to e\gamma$ which has the strictest measured limit \[^1\]. With its amplitude derived from Eq. (38), one determines its branching ratio to be
\[ B(\mu \to e\gamma) = \frac{\alpha \tau_\mu m_\mu^5}{\Lambda^4} |(\Delta \ell)_{21}|^2, \tag{39} \]
where $\tau_\mu$ is the muon lifetime, the electron mass has been neglected, and
\[ (\Delta \ell)_{jk} = \xi_2 A_{jk} + \xi_4 (A^2)_{jk}. \tag{40} \]
From Eq. (39), one can easily obtain the corresponding formulas for $\tau \to e\gamma$ and $\tau \to \mu\gamma$ by appropriately changing the flavor indices. These tau decays can place complementary restraints on the dipole couplings.

Searches for $\mu \to e$ conversion in nuclei can offer constraints on new physics competitive to those from $\mu \to e\gamma$ measurements \[^17\]. Assuming that the flavor-changing transition is again due to the dipole operators alone, one can write the conversion rate in nucleus $N$ as \[^18\]
\[ B(\mu N \to eN) = \frac{\alpha \pi m_\mu^5 |(\Delta \ell)_{21} D_N|^2}{\Lambda^4 \omega^N_{\text{capt}}}, \tag{41} \]
where $D_N$ is the dimensionless overlap integral for $N$ and $\omega^N_{\text{capt}}$, the rate of $\mu$ capture in $N$. Based on the existing experimental limits on $\mu \to e$ transition in various nuclei \[^1\] and the corresponding $D_N$ and $\omega^N_{\text{capt}}$ values \[^18\], one expects that the data on $\mu \text{Ti} \to e\text{Ti}$ and $\mu \text{Au} \to e\text{Au}$ may supply important restrictions. To calculate their rates, we will employ $D_{\text{Ti}} = 0.087$, $D_{\text{Au}} = 0.189$, $\omega^{\text{Ti}}_{\text{capt}} = 2.59 \times 10^6$/s, and $\omega^{\text{Au}}_{\text{capt}} = 13.07 \times 10^6$/s \[^18\].

Another kind of flavor-changing process which receives contributions from the interactions in Eq. (38) is the three-body decay $E_l \to E_k E_j \bar{E}_j$. If there are no other contributions, one can express its rate as
\[ \Gamma_{E_l \to E_k E_j \bar{E}_j} = \frac{\alpha^2 m_\mu^5 |(\Delta \ell)_{ik}|^2}{4\pi \Lambda^4} \mathcal{I}_{E_l \to E_k E_j \bar{E}_j}, \tag{42} \]
where the $m_{E_k}$ terms in Eq. (38) have been neglected and the factor $\mathcal{I}_{E_l \to E_k E_j \bar{E}_j}$, from the phase-space integration, can be calculated using formulas available in the literature \[^5\]. The factors relevant to the processes we will examine are $\mathcal{I}_{\mu \to e\bar{e}e} = 9.885$, $\mathcal{I}_{\tau \to \mu\mu\bar{\mu}} = 3.264$, $\mathcal{I}_{\tau \to e\bar{e}e} = 16.97$, $\mathcal{I}_{\tau \to e\bar{e}e} = 17.41$, and $\mathcal{I}_{\tau \to e\bar{e}e} = 3.01$.

For numerical analysis, we need in addition the values of the various neutrino parameters, especially their masses and the elements of the mixing matrix $U_{\text{PMNS}}$. For these, we adopt the numbers quoted in Table I from a recent fit to global neutrino data \[^19\]. Most of them depend on whether neutrino masses fall into a normal hierarchy (NH) or an inverted one (IH). Since empirical information on the absolute scale of $m_{1,2,3}$ is still far from precise \[^1\], for definiteness we set $m_1 = 0$ ($m_3 = 0$) in the NH (IH) case. As for the Majorana phases $\alpha_{1,2}$, there are still no data available on their values.

To proceed, we also need to specify the $A$ matrix, which is model dependent, as seen in the preceding section. For the type-I or -III seesaw scenario, $A$ in Eq. (17) \[^{17}\] [or (35)] can have many
different realizations, depending on $M_\nu$ and $O$. We consider first the least complicated possibility that the right-handed neutrinos $\nu_{k,R}$ are degenerate, with $M_\nu = M \mathbb{1}$, and $O$ is a real orthogonal matrix, in which case

$$A = \frac{2M}{v^2} U_{\text{PMNS}} \hat{m}_\nu U_{\text{PMNS}}^\dagger$$  \hspace{1cm} (43)$$

with eigenvalues $\hat{A}_{1,2,3} = 2M m_{1,2,3}/v^2$. Explicitly, including this in Eq. (10) yields

$$\begin{align*}
(\Delta \ell)_{21} & = -c_{12} c_{13} \left( s_{12} c_{23} + e^{i\delta} c_{12} s_{23} s_{13} \right) \left( \xi_2 \hat{A}_1 + \xi_4 \hat{A}_3 \right) \\
& + s_{12} c_{13} \left( c_{12} c_{23} - e^{i\delta} s_{12} s_{23} s_{13} \right) \left( \xi_2 \hat{A}_2 + \xi_4 \hat{A}_3 \right) \\
& + e^{i\delta} s_{23} c_{13} s_{13} \left( \xi_2 \hat{A}_3 + \xi_4 \hat{A}_2 \right),
\end{align*}  \hspace{1cm} (44)$$

$$\begin{align*}
(\Delta \ell)_{31} & = c_{12} c_{13} \left( s_{12} s_{23} - e^{i\delta} c_{12} c_{23} s_{13} \right) \left( \xi_2 \hat{A}_1 + \xi_4 \hat{A}_3 \right) \\
& - s_{12} c_{13} \left( c_{12} s_{23} + e^{i\delta} s_{12} c_{23} s_{13} \right) \left( \xi_2 \hat{A}_2 + \xi_4 \hat{A}_3 \right) \\
& + e^{i\delta} c_{23} c_{13} s_{13} \left( \xi_2 \hat{A}_3 + \xi_4 \hat{A}_2 \right),
\end{align*}  \hspace{1cm} (45)$$

$$\begin{align*}
(\Delta \ell)_{32} & = - \left( s_{12} c_{23} + e^{-i\delta} c_{12} s_{23} s_{13} \right) \left( s_{12} s_{23} - e^{i\delta} c_{12} c_{23} s_{13} \right) \left( \xi_2 \hat{A}_1 + \xi_4 \hat{A}_3 \right) \\
& - \left( c_{12} c_{23} - e^{-i\delta} s_{12} s_{23} s_{13} \right) \left( c_{12} s_{23} + e^{i\delta} s_{12} c_{23} s_{13} \right) \left( \xi_2 \hat{A}_2 + \xi_4 \hat{A}_3 \right) \\
& + c_{23} s_{23} c_{13} s_{13} \left( \xi_2 \hat{A}_3 + \xi_4 \hat{A}_2 \right).
\end{align*}  \hspace{1cm} (46)$$

Later on we will also provide examples for a case in which $O$ is complex.

With $(\Delta \ell)_{kl}$ specified, we can determine lower limits on the MFV scale $\Lambda$ from the experimental information on the observables described above. The particular data we use are listed in the first two columns of Table I. Since in our model-independent approach $\xi_{2,4}$ are free constants, for simplicity we assume that only one of them is nonzero at a time. For $\xi_4 = 0$, we scan the ranges of the neutrino mass and mixing parameters quoted in Table I in order to maximize

| Parameter     | NH       | IH       |
|---------------|----------|----------|
| $\sin^2 \theta_{12}$ | 0.308 ± 0.017 | 0.308 ± 0.017 |
| $\sin^2 \theta_{23}$ | 0.437$^{+0.033}_{-0.023}$ | 0.455$^{+0.139}_{-0.031}$ |
| $\sin^2 \theta_{13}$ | 0.0234$^{+0.0020}_{-0.0019}$ | 0.0240$^{+0.0019}_{-0.0022}$ |
| $\delta / \pi$ | 1.39$^{+0.38}_{-0.27}$ | 1.31$^{+0.29}_{-0.33}$ |
| $\delta m^2 = m_2^2 - m_1^2$ | (7.54$^{+0.20}_{-0.22}$) × 10$^{-5}$ eV$^2$ | (7.54$^{+0.26}_{-0.22}$) × 10$^{-5}$ eV$^2$ |
| $\Delta m^2 = |m_3^2 - (m_1^2 + m_2^2)/2|$ | (2.43 ± 0.06) × 10$^{-3}$ eV$^2$ | (2.38 ± 0.06) × 10$^{-3}$ eV$^2$ |

TABLE I: Results of a recent analysis of global three-neutrino oscillation data [19], in terms of best-fit values and allowed 1σ ranges of the mass-mixing parameters. The neutrino mass hierarchy may be normal ($m_1 < m_2 < m_3$) or inverted ($m_3 < m_1 < m_2$).
TABLE II: Lower limits on $\Lambda = \Lambda/|\xi_2^\ell|^{1/2}$ associated with dipole operators $O_{RL}^{(\ell_1,\ell_2)}$ inferred from experimental upper-bounds on the branching ratios of flavor-violating leptonic transitions, as explained in the text. In this and the remaining tables, the unbracketed (bracketed) results correspond to the normal (inverted) hierarchy of light neutrino masses with $m_{1(3)} = 0$.

$\Lambda$ makes $\max(\hat{A}_1, \hat{A}_2, \hat{A}_3) = 1$. This allows us to extract the maximal lower-limits on $\hat{A} = \Lambda/|\xi_2^\ell|^{1/2}$ from the measured bounds on $B(\mu \to e\gamma)$, $B(\tau \to e\gamma)$, and $B(\tau \to \mu\gamma)$ listed in Table III which are the strictest ones to date in their respective groups of processes with the same flavor changes. Subsequently, we apply the acquired values of $(\Delta_\ell)_{21,32,31}$ to obtain limits from the other experimental bounds in this table. We collect the $\hat{A}$ numbers in the third column which correspond to the NH (IH) of neutrino masses. For comparison, employing the central values in Table I would give us results which are smaller by up to 30%. It is worth mentioning that in all this computation the right-handed neutrino mass is $\mathcal{M} \simeq (6.0-6.3) \times 10^{14}$ GeV.

For the type-II scheme, $\Lambda$ is given only in Eq. (27), which has eigenvalues $\hat{A}_{1,2,3} = 2m_{1,2,3}/v_T^2$ and leads to

\begin{equation}
(\Delta_\ell)_{21} = -c_{12}c_{13}\left(s_{12}c_{23} + e^{i\delta}c_{12}s_{23}s_{13}\right)\left(\xi_2^\ell \hat{A}_1 + \xi_4^\ell \hat{A}_2\right) + s_{12}c_{13}\left(c_{12}c_{23} - e^{i\delta}s_{12}s_{23}s_{13}\right)\left(\xi_2^\ell \hat{A}_2 + \xi_4^\ell \hat{A}_3\right) + e^{i\delta}s_{23}c_{13}s_{13}\left(\xi_2^\ell \hat{A}_3 + \xi_4^\ell \hat{A}_3\right)
\end{equation}

and its $(\Delta_\ell)_{31,32}$ counterparts, which are analogous to those in Eqs. (45) and (46), respectively. Utilising these matrix elements, we take steps similar to those elaborated in the previous paragraph, while adjusting $v_T$ such that $\max(\hat{A}_1, \hat{A}_2, \hat{A}_3) = 1$, in order to extract from data the lower limits on $\hat{A}$ for $\xi_4^\ell = 0$. We collect the results in the fourth column of Table III which correspond to $v_T \sim 0.07$ eV. With $\xi_2^\ell = 0$ instead, we obtain comparable numbers for $\Lambda_{\min}/|\xi_4^\ell|^{1/2}$, specifically 285 (320) TeV from the $B(\mu \to e\gamma)$ data. Now, since $2\hat{A}_k\mathcal{M}^2v_T^2 = \hat{A}_k^2v^4$, one realizes
that the numbers in the fourth column of Table II are also the limits on \( \Lambda/|\xi_4^{1/2} | \) in the type-I case of the last paragraph with \( \xi_2 = 0 \).

It is clear from Table II that to date the most stringent constraint on the dipole operators in Eq. (37) comes from the measured bound on \( \mu \rightarrow e \gamma \) among processes that change lepton flavor. It is instructive to entertain the consequence of this for the calculated branching ratios of the other transitions if other operators are absent or have only minor impact. Thus, employing the \( \hat{\Lambda}_{\text{min}} \) numbers belonging to \( \mathcal{B}(\mu \rightarrow e \gamma) \) in Table II and the corresponding neutrino parameter values, we compute the results listed in Table III. The ratios of any two of them and the relative size of any one of them with respect to \( \mathcal{B}(\mu \rightarrow e \gamma) \) are, therefore, predictions of the particular scenario considered. They can be checked experimentally if two or more of these processes are detected in the future, as the presence of other operators with nonnegligible effects would likely lead to a different set of predictions. Since the numbers in Table III are at least two orders of magnitude below their current experimental bounds, it is of interest to make comparison with the projected sensitivities of future experiments on lepton flavor violation.

There are planned searches for \( \mu \rightarrow e \gamma \) with projected sensitivity reaching a few times \( 10^{-14} \) within the next five years [21]. If they come up empty, the predictions in Table III will decrease somewhat, probably by up to an order of magnitude. Nevertheless, the prediction for \( \mu \rightarrow 3e \) in Table III will likely still be testable with new experiments looking for it which will start running in a couple of years and may be able to probe a branching ratio as low as \( 10^{-16} \) after several years [22, 23]. Complementary checks may be available from upcoming searches for flavor-violating tau decays which can improve their current empirical limits by two orders of magnitude [22]. Potentially severe restrictions will be supplied by future measurements on \( \mu \rightarrow e \) conversion in nuclei which will begin in a few years and are expected to achieve sensitivity at the level of \( 10^{-17} \) or better eventually [22, 23].

| Observable | Types I & III | Type II |
|------------|--------------|---------|
| \( \mathcal{B}(\mu Ti \rightarrow e Ti) \) | \( 2.4 (2.4) \times 10^{-15} \) | \( 2.4 (2.4) \times 10^{-15} \) |
| \( \mathcal{B}(\mu Au \rightarrow e Au) \) | \( 2.2 (2.2) \times 10^{-15} \) | \( 2.2 (2.2) \times 10^{-15} \) |
| \( \mathcal{B}(\mu^- \rightarrow e^- e^- e^+) \) | \( 3.3 (3.3) \times 10^{-15} \) | \( 3.3 (3.3) \times 10^{-15} \) |
| \( \mathcal{B}(\tau \rightarrow \mu \gamma) \) | \( 7.9 (14) \times 10^{-13} \) | \( 1.7 (1.4) \times 10^{-12} \) |
| \( \mathcal{B}(\tau^- \rightarrow \mu^- \mu^- \mu^+) \) | \( 1.5 (2.7) \times 10^{-15} \) | \( 3.3 (2.6) \times 10^{-15} \) |
| \( \mathcal{B}(\tau^- \rightarrow \mu^- e^- e^+) \) | \( 7.8 (14) \times 10^{-15} \) | \( 1.7 (1.3) \times 10^{-14} \) |
| \( \mathcal{B}(\tau \rightarrow e \gamma) \) | \( 2.5 (5.7) \times 10^{-14} \) | \( 8.6 (4.6) \times 10^{-14} \) |
| \( \mathcal{B}(\tau^- \rightarrow e^- e^- e^+) \) | \( 2.5 (5.7) \times 10^{-16} \) | \( 8.7 (4.7) \times 10^{-16} \) |
| \( \mathcal{B}(\tau^- \rightarrow e^- \mu^- \mu^+) \) | \( 4.3 (9.9) \times 10^{-17} \) | \( 15 (8.0) \times 10^{-17} \) |

TABLE III: Predictions calculated from the contributions of the dipole operators alone, with the \( \hat{\Lambda}_{\text{min}} \) numbers from the experimental bound on \( \mathcal{B}(\mu \rightarrow e \gamma) \) in Table II and the neutrino parameter values used to determine them.
As another significant observation from Table II, it indicates that no remarkable differences in the bounds on $\Lambda$ appear among the three types of seesaw models if in type I or III the right-handed neutrinos are degenerate and the $O$ matrix is real, with $A$ in Eq. (43). If $O$ is complex and/or the right-handed neutrinos are nondegenerate, $A$ is less simple which may give rise to more pronounced deviations from the type-II results. To illustrate this, we next explore the possibility that $O$ is complex.

With $\nu_{k,R}$ still degenerate, $M_\nu = M_\uparrow$, but $O$ complex, $A$ is more complicated,

$$A = \frac{2}{v^2} M U_{\text{PMNS}} \hat{m}_\nu^{1/2} O O^\dagger \hat{m}_\nu^{1/2} U_{\text{PMNS}}^\dagger .$$

(48)

One can always write $OO^\dagger = e^{2iR}$ with a real antisymmetric matrix

$$R = \begin{pmatrix} 0 & r_1 & r_2 \\ -r_1 & 0 & r_3 \\ -r_2 & -r_3 & 0 \end{pmatrix} .$$

(49)

Since $OO^\dagger$ is not diagonal, $A$ generally has dependence on the Majorana phases in $U_{\text{PMNS}}$ if they are not zero. To concentrate first on demonstrating how $O$ can bring about significant new effects, we switch off the Majorana phases, $\alpha_{1,2} = 0$. Subsequently, for illustration, we pick $r_1 = r_2 = r_3 = \rho$ and again scan the parameter ranges in Table I in order to get the highest $\Lambda/|\xi_{2,4}|^{1/2}$ from the experimental bound on $B(\mu \rightarrow e\gamma)$, with the condition that the largest eigenvalue of $A$ in Eq. (48) is unity. We exhibit the resulting dependence on $\rho$ in Figure 1. It reveals that, in this example, the contribution of $O$ can boost $\Lambda_{\text{min}}$ by up to 80% with respect to its value when $O$ is real, which implies that the predicted branching ratio is enhanced by an order of magnitude.

![Figure 1](image-url)

FIG. 1: Variation of the lower limit on $\hat{\Lambda} = \Lambda/|\xi_2^\ell|^{1/2}$, subject to $B(\mu \rightarrow e\gamma)$ data, versus complex-$O$ parameter $\rho = r_1 = r_2 = r_3$ in the absence of the Majorana phases, $\alpha_{1,2} = 0$, for $\xi_2^\ell = 0$ and degenerate $\nu_{k,R}$ (solid curves), as explained in the text. The dashed curves depict the corresponding variation of the lower limit on $\Lambda/|\xi_4^\ell|^{1/2}$ for $\xi_2^\ell = 0$. 

15
Turning our attention now to the impact of the Majorana phases, we make the same choice of $r_{1,2,3} = \rho$ as in the preceding paragraph, select $\alpha_1 = 0$ and $\rho = -1$, and let $\hat{\Lambda}_{\text{min}}$ vary as a function of $\alpha_2$, in similar steps to those in the last example. We display the variation in Figure 2, which shows that although the Majorana phases in this instance can increase the lower limits on $\Lambda$ only moderately, they can induce sizable reduction of it. Hence the associated decay rate is affected in roughly the same way. All these examples demonstrate that the $O$ matrix and Majorana phases in types I and III can produce striking effects which do not occur in type II.

Before finishing this subsection, we examine limitations from the anomalous magnetic moments, $a_\ell$, of charged leptons. The Lagrangian for $a_\ell$ is $\mathcal{L}_{a_\ell} = \sqrt{\alpha} \bar{a}_\ell \ell \sigma^{\kappa\omega} F_{\kappa\omega}/(2m_\ell)$, which gets contributions from the flavor-diagonal couplings in Eq. (38). Accordingly

$$a_{E_k} = \frac{4 m_{E_k}^2}{\Lambda^2} \left[ \xi_{1\ell}^k \delta_{kk} + \xi_{2\ell}^k A_{kk} + \xi_{4\ell}^k (A^2)_{kk} \right],$$

(50)

where we have ignored the tiny $\text{Im}\xi_{1,2,4}^{\ell}$. Since $a_\ell$ is much suppressed by the electron mass, and since the measurement of $a_\tau$ is not yet precise [1], the strongest restrictions from anomalous magnetic moments can be expected from $a_\mu$. Currently its experimental and SM values differ by $a_\mu^{\text{exp}} - a_\mu^{\text{SM}} = (249 \pm 87) \times 10^{-11}$ [24], which suggests that we can require the new contributions to satisfy $|a_\mu| < 3.4 \times 10^{-9}$. Assuming again that the right-handed neutrinos are degenerate and the $O$ matrix is real, if only one of $\xi_{1,2,4}^{\ell}$ is nonzero at a time, from this $a_\mu$ bound we infer $\Lambda/|\xi_{1,2,4}^{\ell}|^{1/2} > 3.6, 2.7, 2.5$ TeV. Upon comparing these numbers with those in Table II we conclude that the muon $g - 2$ cannot at present compete with the flavor-violating leptonic transitions in restraining $\Lambda$.

![FIG. 2: Variation of the lower limit on $\hat{\Lambda} = \Lambda/|\xi_2^\ell|^{1/2}$, subject to $B(\mu \to e\gamma)$ data, versus $\alpha_2$ for $\alpha_1 = 0$, degenerate $\nu_{k,R}$, and complex-$O$ parameter $\rho = r_1 = r_2 = r_3 = -1$ (solid curves), as explained in the text. The dashed curves depict the corresponding variation of the lower limit on $\Lambda/|\xi_4^\ell|^{1/2}$ for $\xi_2^\ell = 0$.](image-url)
B. Lepton EDMs

The interactions in Eq. (38) also contribute to a charged lepton’s electric dipole moment, denoted by \(d_\ell\), which is a sensitive probe for the presence of new sources of CP violation, as the SM prediction is very small [23]. The Lagrangian for \(d_\ell\) is \(\mathcal{L}_{d_\ell} = -(i\bar{d}_\ell/2)\tilde{\ell}\sigma^{\mu\nu}\gamma\_5\ell F_{\mu\nu}\), and so

\[
d_{E_\ell} = \frac{\sqrt{2} e v}{\Lambda^2} \text{Im}(Y_e\Delta_\ell)_{kk}. \tag{51}
\]

Unlike the observables treated in the previous subsection, the pertinent terms in \(\Delta_\ell\) are those with higher orders in \(A\) and \(B\). Thus for the electron [13]

\[
d_e = \frac{\sqrt{2} e v}{\Lambda^2} \left[ \xi_{12}^\ell \text{Im}((Y_e\Lambda\Lambda^2)_{11}) + \xi_{16}^\ell \text{Im}((Y_e\Lambda\Lambda^2)_{11}) \right], \tag{52}
\]

where we have again neglected \(\text{Im}\xi_{16}^\ell\). Hereafter we drop \(\xi_{16}^\ell\) term which is suppressed by a factor of \(B\) relative to the \(\xi_{12}^\ell\) term.

The latest analysis on \(d_e\) under the MFV framework has been performed in Ref. [13] for the Dirac neutrino case as well as the type-I (and hence also type-III) seesaw model. If neutrinos are Dirac particles, \(d_e\) has the form

\[
d_{e}^{D} = \frac{32 e m_e}{\Lambda^2 v^s} (m_\mu^2 - m_\tau^2) (m_1^2 - m_2^2) (m_2^2 - m_3^2) (m_3^2 - m_1^2) \xi_{12}^\ell J_\ell, \tag{53}
\]

where \(J_\ell = \text{Im}(U_{e2}U_{\ell3}U^*_{e3}U^*_{\ell2})\) is a Jarlskog invariant for \(U_{\text{PMNS}}\). This turns out to be independent of the \(m_{1,2,3}\) individually because the neutrino squared-mass differences defined in Table II imply that \((m_1^2 - m_2^2)(m_2^2 - m_3^2)(m_3^2 - m_1^2) = \delta m^2 (\Delta m^2)^2 - \frac{1}{2} (\delta m^2)^3\). On the other hand, in types I and III with degenerate \(\nu_{k,R}\) and a real \(O\) matrix, in which case \(A\) is given by Eq. (43),

\[
d_{e}^{\text{III}} = \frac{32 e m_e M^3}{\Lambda^2 v^s} (m_\mu^2 - m_\tau^2) (m_1^2 - m_2^2) (m_2^2 - m_3^2) (m_3^2 - m_1^2) \xi_{12}^\ell J_\ell, \tag{54}
\]

Since \(m_k \ll M\), one can see that \(d_{e}^{D}\) is considerably suppressed relative to \(d_{e}^{\text{III}}\). In contrast, for type II one derives

\[
d_{e}^{\text{II}} = \frac{32 e m_e}{\Lambda^2 v^2 v_T^6} (m_\mu^2 - m_\tau^2) (m_1^2 - m_2^2) (m_2^2 - m_3^2) (m_3^2 - m_1^2) \xi_{12}^\ell J_\ell = \left(\frac{v}{v_T}\right)^6 d_{e}^{D}, \tag{55}
\]

which is far above \(d_{e}^{D}\) due to \(v_T \ll v\). From these formulas, one can readily find those for \(d_{\mu,\tau}\) by cyclically changing the mass subscripts.

Numerically, \(d_{e}^{D} = 1.3 \times 10^{-99} e\, \text{cm GeV}^2/\Lambda^2\) [13], which is too minuscule to yield any useful restraint on \(\hat{\Lambda}\) from the newest data \(|d_e|_{\text{exp}} < 8.7 \times 10^{-29} e\, \text{cm}\) from the ACME experiment [26]. In the Majorana neutrino case, the type-I (or -III) prediction in Eq. (51) has been evaluated in Ref. [13] to yield the limit \(\hat{\Lambda} > 0.36 (0.12)\) TeV corresponding to \(M = 6.16 (6.22) \times 10^{14}\) GeV for the NH (IH) of neutrino masses.

In type II, from Eq. (55) we arrive at

\[
\frac{d_{e}^{\text{II}}}{e\, \text{cm}} = 2.7 (2.6) \times 10^{-31} \left(\frac{\text{eV}}{v_T}\right)^6 \left(\frac{\text{GeV}}{\Lambda}\right)^2, \tag{56}
\]
for the NH (IH) case. Then $|d_e|_{\text{exp}} < 8.7 \times 10^{-29} \, e\, c\, m$ translates into

$$\hat{\Lambda} > 0.055 \,(0.054) \, \text{GeV} \left(\frac{\text{eV}}{v_T} \right)^3. \quad (57)$$

With $v_T \simeq 0.069 \, \text{eV}$ from the requirement that the largest eigenvalue of $A$ in Eq. (27) be unity, it follows that

$$\hat{\Lambda} > 0.17 \, \text{TeV}, \quad (58)$$

which is roughly comparable to its counterparts in type I (or III) quoted above.

In the preceding discussion, $d_e$ is caused by the $CP$-violating Dirac phase $\delta$ in $U_{\text{PMNS}}$, and the Majorana phases $\alpha_{1,2}$ therein do not take part. However, if $O$ is complex, the phases in it may give rise to an extra contribution to $d_e$ and the Majorana phases can modify it further. As investigated in detail in Ref. [13], these new $CP$-violating contributions to $d_e$ can be more important than those of $\delta$. Such effects do not occur in type II, as $d_e^{\text{II}}$ does not have dependence on $O$ or $\alpha_{1,2}$.

V. ADDITIONAL LEPTONIC OPERATORS

Besides the dipole operators, there are other dimension-six operators that can arise in the three simplest seesaw scenarios under the MFV framework [3]. Focusing on operators that are purely leptonic or couple leptons to SM gauge and Higgs bosons, we have

$$\mathcal{L}_{\text{eff}}' = \frac{1}{\Lambda^2} \sum_{m=1}^{3} O_{4L}^{(m)} + \frac{1}{\Lambda^2} \left[ O_{RL}^{(e3)} + \text{H.c.} \right] + \frac{1}{\Lambda^2} \sum_{n=1}^{2} O_{LL}^{(n)}, \quad (59)$$

where

$$O_{4L}^{(1)} = \bar{L}_l \gamma^\mu \Delta_{4l}^{(1)} L_L \bar{E}_R \gamma_\mu \mu^2, \quad O_{4L}^{(2)} = \bar{L}_l \gamma^\mu \Delta_{4l}^{(2)} \mu^2, \quad O_{4L}^{(3)} = \bar{L}_l \gamma^\mu \Delta_{4l}^{(3)} \mu^2,$$

$$O_{LL}^{(1)} = \bar{L}_l \gamma^\mu \Delta_{4l}^{(1)} L_L H^\dagger i D_\mu H, \quad O_{LL}^{(2)} = \bar{L}_l \gamma^\mu \Delta_{4l}^{(2)} H^\dagger i D_\mu H,$$

with the $\Delta$’s having the approximate expression $\Delta = \xi_1 I + \xi_2 A + \xi_3 A^2$ like before, but with generally different coefficients $\xi_{1,2,3}$ of their own, and $D_\mu$ being the usual covariant derivative involving SM gauge bosons.

The first three of these operators contribute directly to $E_k^- \rightarrow E_l^- E_i^- E_i^+$ and $E_k^- \rightarrow E_l^- E_j^- E_j^+$ with $l \neq j$, whereas the last three contribute mainly via diagrams mediated by the $Z$ boson. Here we assume that the dipole operators $O_{RL}^{(1,2)}$ treated in the last subsection are absent. To see what constraints can be derived from the experimental information on these decays, for simplicity we select $\Delta_{4l}^{(1,2)} = I$. We then find their branching ratios to be [3], respectively,

$$B(E_k \rightarrow E_i E_i \bar{E}_i) = \frac{\tau_{E_k} m_{E_k}^5}{1536 \, \pi^3 \Lambda^4} \left[ |(A_+)_{ik}|^2 + 2 |(A_-)_{ik}|^2 \right],$$

$$B(E_k \rightarrow E_l E_j \bar{E}_j) = \frac{\tau_{E_k} m_{E_k}^5}{1536 \, \pi^3 \Lambda^4} \left[ |(A_+)_{ik}|^2 + |(A_-)_{ik}|^2 \right], \quad (61)$$
where the final masses have been neglected relative to the initial one, \( \tau_{E_k} \) is the lifetime of \( E_k \), and the matrices \( A_\pm \) are combinations of the \( \Delta \)'s,

\[
A_+ = \left[ \Delta^{(1)}_{LL} + \Delta^{(2)}_{LL} \right] \sin^2 \theta_W + \Delta^{(3)}_{4l} ,
\]

\[
A_- = \left[ \Delta^{(1)}_{LL} + \Delta^{(2)}_{LL} \right] \left( \sin^2 \theta_W - \frac{1}{2} \right) + \Delta^{(1)}_{4l} + \Delta^{(2)}_{4l} ,
\]

(62)

with \( \sin^2 \theta_W = 0.23 \) and the contributions from \( O^{(e3)}_{RL} \) having been neglected due to suppression by \( m_E^2/m_Z^2 \).

To illustrate the lower limits on \( \Lambda \) obtainable from the data on these decays, already quoted in Table II, for definiteness we further assume that either only \( O^{(1,2,3)}_{4L} \) with \( \Delta^{(1)}_{4l} = \Delta^{(2)}_{4l} = \Delta^{(3)}_{4l} \) or \( O^{(1,2)}_{LL} \) with \( \Delta^{(1)}_{LL} = \Delta^{(2)}_{LL} \) are contributing at a time, with \( \xi_4 = 0 \) in the \( \Delta \)'s, and that in type I (or III) the \( A \) matrix is given by Eq. (43). Using the maximal \( A_{kl} \) determined earlier, we infer the lower bounds on \( \hat{\Lambda} \) presented in Table IV.

Obviously, for these operators the measured limit on \( B(\mu^- \to e^-e^-e^+) \) provides the strictest constraint among the flavor-violating processes. To see the implication of this for the predictions on the tau three-body modes, we calculate their branching ratios with the \( \hat{\Lambda}_{\text{min}} \) numbers belonging to \( \mu^- \to e^-e^-e^+ \) in Table IV and the neutrino parameter values employed to extract them. We display the results in Table V which are larger than their counterparts in Table III by roughly two orders of magnitude. This considerable variation in predictions will help make it easier to identify the underlying physics if one or more of the flavor-violating transitions we study are observed in the future.

The first two of the operators in Eq. (59) also contribute to \( \tau^- \to E_i^- E_i^- E_j^+ \) with \( i \neq j \). Its branching ratio is

\[
B(E_k \to E_i E_i E_j^+) = \frac{\tau_{E_k} m_{E_k}^5}{768 \pi^3 \Lambda^4} \left| D_{E_k \to E_i E_i E_j^+} \right|^2 ,
\]

(63)

where

\[
D_{E_k \to E_i E_i E_j^+} = \frac{[\Delta^{(1)}_{LL}]_{ik} [\Delta^{(1)}_{LL}]_{lj}}{[\Delta^{(1)}_{LL}]_{ij}} + \frac{[\Delta^{(2)}_{LL}]_{ik} [\Delta^{(2)}_{LL}]_{lj}}{[\Delta^{(2)}_{LL}]_{ij}} + \frac{[\Delta^{(3)}_{LL}]_{ik} [\Delta^{(3)}_{LL}]_{lj}}{[\Delta^{(3)}_{LL}]_{ij}} .
\]

(64)

| Process | \( \hat{\Lambda}_{\text{min}}/\text{TeV} \) |
|---------|------------------|
| \( \mu^- \to e^-e^-e^+ \) | \( \begin{array}{c|c|c|c|c} \hline \text{Types I \& III} & \text{Type II} \\ \hline \hline O_{4L}^{(1,2,3)} & O_{LL}^{(1,2)} & O_{4L}^{(1,2,3)} & O_{LL}^{(1,2)} \\ \hline 118 (107) & 64 (58) & 102 (109) & 56 (59) \\ \hline 11 (1) & 5.8 (6.2) & 11 (11) & 6.1 (6.2) \\ \hline 9.6 (10) & 5.4 (5.7) & 10 (10) & 5.7 (5.7) \\ \hline 6.2 (5.3) & 3.4 (2.9) & 5.5 (5.3) & 3.0 (2.9) \\ \hline 5.4 (4.6) & 3.0 (2.6) & 4.7 (4.6) & 2.7 (2.6) \\ \hline \end{array} \) |

TABLE IV: Lower limits on \( \hat{\Lambda} = \Lambda/|\xi_2|^{1/2} \) associated with operators \( O_{4L}^{(1,2,3)} \) and \( O_{LL}^{(1,2)} \) inferred from data on flavor-violating decays of charged leptons, as explained in the text. Only \( O_{4L}^{(1,2,3)} \) or \( O_{LL}^{(1,2)} \) are assumed to be present at a time.
TABLE V: Predictions calculated from the contributions of either $O^{(1,2,3)}_{4L}$ or $O^{(1,2)}_{LL}$ alone, with the $\hat{\Lambda}_{\text{min}}$ numbers from the experimental bound on $\mathcal{B}(\mu^- \to e^- e^+)$ in Table IV and the neutrino parameter values used to determine them.

For simplicity, we choose $[\Delta^{(1)}_{ii}]_{ik} [\Delta^{(1)}_{ii}]_{lj} = [\Delta^{(2)}_{ii}]_{ik} [\Delta^{(2)}_{ii}]_{lj} = \xi_2 A_{ik} A_{lj}$. Subsequently, we scan the parameter ranges in Table I to maximize $A_{ik} A_{lj}$, while setting the largest eigenvalue of $A$ to unity. With the results, we extract from the experimental bounds $\mathcal{B}(\tau^- \to e^- e^+ \mu^+) < 1.5 \times 10^{-8}$ and $\mathcal{B}(\tau^- \to \mu^- \mu^+ e^+) < 1.7 \times 10^{-8}$ \cite{1}, respectively, the limits $\hat{\Lambda}_{\text{min}} > 2.9 (2.7)$ and $6.0 (5.8)$ TeV in type I or III for the normal (inverted) hierarchy of neutrino masses. The corresponding results for type II are $\hat{\Lambda}_{\text{min}} = 2.7 (2.7)$ and $5.5 (5.8)$ TeV, respectively. If the above choice for these operators is to satisfy the measured limit on $\mathcal{B}(\mu^- \to e^- e^+)$ as well, we arrive at $\hat{\Lambda}_{\text{min}}$ in the (27-146) TeV range instead and the branching ratios of $\tau^- \to e^- e^+ \mu^+, \mu^- \mu^+ e^+$ below $10^{-10}$, like those in Table IV.

We note that the renormalizable couplings of the scalar triplet to leptons as described by Eq. (19) induce at tree level $T$-mediated diagrams that correspond to extra operators such as $(Y_T)_{km}(Y_T)^*_{ln} \bar{L}_{k,L} \gamma^\mu L_{l,L} \bar{L}_{m,L} \gamma^\mu L_{n,L}/M_T^2$ \cite{4,7}, which we do not analyze explicitly in this work. They also contribute to the three-body charged-lepton decays, and so for $(Y_T)_{kl} = \mathcal{O}(1)$ the lower bounds on $M_T$ are comparable in order of magnitude to those on $\hat{\Lambda}_{\text{min}}$ in Table IV, although $M_T$ in general is not the same as $\Lambda$. Thus our requirement in type II that the biggest eigenvalue of $A = Y_T^* Y_T$ be unity translates into the limitation $M_T > \mathcal{O}(100 \text{ TeV})$ according to the table. With such a mass, the triplet scalars would be undetectable at the LHC. If we relax the condition on $A$, the minimum of $M_T$ can be lowered, but at the same time $\hat{\Lambda}_{\text{min}}$ also becomes weakened. Specifically, for $M_T$ at the TeV level, which may be within LHC reach, $Y_T$ needs to be two orders of magnitude smaller.

Finally, we address the potential impact of $O^{(e3)}_{RL}$ and $O^{(1,2)}_{LL}$ on the decay of the recently discovered Higgs boson. Their presence can bring about modifications to the standard decay modes of the Higgs and/or cause it to undergo exotic decays \cite{27}. As data from the LHC will continue to accumulate with increasing precision, they may uncover clues of new physics in the couplings of the Higgs.

The latest LHC measurements have begun to reveal the Higgs couplings to leptons. The ATLAS and CMS Collaborations have observed $h \to \tau^+ \tau^-$ and measured its signal strength to be $\sigma/\sigma_{\text{SM}} = 1.42^{+0.44}_{-0.38}$ and $0.91 \pm 0.27$, respectively \cite{28,29}. In contrast, the only experimental information available on $h \to \mu^- \mu^+$ to date are the bounds $\mathcal{B}(h \to \mu^- \mu^+) < 1.5 \times 10^{-3}$ and $1.6 \times 10^{-3}$ from ATLAS and CMS, respectively \cite{30,31}. On the other hand, CMS \cite{32} has...
Intriguingly reported the detection of a slight excess of $h \rightarrow \mu^+\tau^-$ events with a significance of 2.5$\sigma$. If the finding is interpreted as a statistical fluctuation, it translates into the limit $\mathcal{B}(h \rightarrow \mu\tau) = \mathcal{B}(h \rightarrow \mu^-\tau^+) + \mathcal{B}(h \rightarrow \mu^+\tau^-) < 1.57\%$ at 95% CL $[32]$. In view of these data, we demand nonstandard contributions to respect

$$0.7 < \frac{\Gamma_{h \rightarrow \tau\mu}}{\Gamma_{h \rightarrow \tau\mu}^{\text{SM}}} < 1.8, \quad \frac{\Gamma_{h \rightarrow \mu\mu}}{\Gamma_{h \rightarrow \mu\mu}^{\text{SM}}} < 6.7, \quad \frac{\Gamma_{h \rightarrow \mu\tau}}{\Gamma_{h \rightarrow \mu\tau}^{\text{SM}}} < 1.5\%,$$

where $\Gamma_{h \rightarrow \tau\mu}^{\text{SM}} = 257$ keV, $\Gamma_{h \rightarrow \mu\mu}^{\text{SM}} = 894$ eV, and $\Gamma_{h \rightarrow \mu\tau}^{\text{SM}} = 4.08$ MeV $[33]$ are the SM widths for a Higgs mass $m_h = 125.1$ GeV, which reflects the average of the newest measurements $[28, 34]$.

One can write the amplitude for $h \rightarrow E_k^- E_l^+$ as

$$\mathcal{M}_{h \rightarrow E_k^- E_l^+} = \bar{u}_{E_k} (y_{kl}^L P_L + y_{kl}^R P_R) v_{E_l},$$

where $u$ and $v$ are the leptons’ spinors and in the SM at tree level $y_{kl}^{LR} = \delta_{kl} m_{E_k}/v$. Its decay rate is then

$$\Gamma_{h \rightarrow E_k^- E_l^+} = \frac{m_h}{16\pi} \left(|y_{kl}^L|^2 + |y_{kl}^R|^2\right),$$

where in the kinematic factor the lepton masses have been neglected compared to $m_h$. Including the contributions of $O_{RL}^{(e3)}$ and $O_{LL}^{(1,2)}$, we have

$$y_{kl}^L = \frac{\delta_{kl} m_{E_k}}{v} - \frac{m_{E_k} m_h^2}{2\Lambda^2 v} (\Delta_{RL})_{kl} - \frac{(m_{E_k} + m_{E_l})v}{2\Lambda^2} [\Delta_{LL}^{(1)} + \Delta_{LL}^{(2)}]_{kl},$$

$$y_{kl}^R = \frac{\delta_{kl} m_{E_l}}{v} - \frac{m_{E_l} m_h^2}{2\Lambda^2 v} (\Delta_{RL})_{kl}^*.$$

Assuming that either only $O_{RL}^{(e3)}$ or $O_{LL}^{(1,2)}$ with $\Delta_{LL}^{(1)} = \Delta_{LL}^{(2)}$ are contributing at a time and maximizing the relevant elements of $A$, which is in Eq. $[43]$ for type I and Eq. $[27]$ for type II, we get the numbers collected in Table VI for $\xi_1 = \xi_4 = 0$, which fulfill the conditions in Eq. $[65]$. These results are much weaker than those in Table IV but do not necessarily conflict with them. The reason is that $O_{4L}^{(1,2,3)}$ do not directly affect the dilepton Higgs decays, but contribute to the three-body lepton decays and hence can cancel the contributions of $O_{LL}^{(1,2)}$ to the latter if both

| Process | $\hat{\Lambda}_{\text{min}}$/TeV |
|---------|-----------------|
| $h \rightarrow \mu^-\mu^+, \tau^-\tau^+$ | Types I & III | Type II |
| $O_{RL}^{(e3)}$ | $0.17 (0.17)$ | $0.46 (0.45)$ | $0.17 (0.17)$ | $0.44 (0.45)$ |
| $O_{LL}^{(1,2)}$ | $0.17 (0.17)$ | $0.44 (0.45)$ |
| $h \rightarrow \mu^+\tau^+$ | $0.08 (0.09)$ | $0.24 (0.25)$ | $0.09 (0.09)$ | $0.25 (0.25)$ |

**TABLE VI:** Lower limits on $\hat{\Lambda} = \Lambda/|\xi_2|^{1/2}$ associated with operators $O_{RL}^{(e3)}$ and $O_{LL}^{(1,2)}$ inferred from measurements on dilepton Higgs decays, as explained in the text. Only $O_{RL}^{(e3)}$ or $O_{LL}^{(1,2)}$ are assumed to be contributing at a time.

21
of them are present simultaneously, which implies the need for some degree of fine-tuning. Now, in calculating the numbers in Table VI we treated the flavor-diagonal modes independently of the \( \mu^\pm \tau^\pm \) channels. If the requirements from \( h \to \mu^- \mu^+, \tau^- \tau^+ \) data, which led to the higher \( \hat{\Lambda}_{\text{min}} \) values in the table, are to be satisfied also by the contributions to \( h \to \mu^\pm \tau^\pm \), we find that \( \Gamma_{h \to \mu \tau}/\Gamma_{h}^{\text{SM}} \) cannot be more than about 0.15%.

VI. CONCLUSIONS

The application of the MFV hypothesis to the lepton sector provides a framework for systematically analyzing the predictions of different models in which lepton-flavor nonconservation and CP violation arise from the leptonic Yukawa couplings. We have explored this in the simplest seesaw scenarios where neutrino mass generation is mediated by new fermion singlets (type I) or triplets (type III) and by a scalar triplet (type II). Taking a model-independent effective-theory approach, we consider the phenomenological implications by analyzing the contributions of new interactions that are organized according to the MFV hypothesis and consist of only a limited number of terms which have been resummed from an infinite number of them.

More specifically, we evaluate constraints on the MFV scale \( \Lambda \) associated with leptonic dipole operators from the latest experimental information on flavor-violating \( E_k \to E_l \gamma \) decays, nuclear \( \mu \to e \) conversion, flavor-violating three-body decays of charged leptons, muon \( g-2 \), and the electron’s EDM. We find that the existing data, especially the bound on \( \mathcal{B}(\mu \to e \gamma) \), can restrict the lower limit on \( \Lambda \) to over 500 TeV or more, depending on the details of the seesaw scheme. In types I and III, this corresponds to the new fermions responsible for the seesaw mechanism being superheavy, with masses roughly of order \( 10^{15} \) GeV. On the other hand, it is interesting to point out that in type II, although the VEV of the scalar triplet needs to be \( v_T \sim 0.07 \) eV in our approach, its mass does not have to be \( 10^{15} \) GeV and can be as low as a few hundred TeV. If \( M_T \) is to be within LHC reach, in the TeV range, \( v_T \) has to be of \( \mathcal{O}(10 \, \text{eV}) \) instead. Another major difference between type I (or III) and type II is that in the former the Yukawa couplings of the new fermions contain features which can have substantially enhancing effects, including CP-violating ones, and which do not exist in type II.

Beyond the dipole operators, we look at additional dimension-six operators that involve only leptons or couple them to the SM gauge and Higgs bosons. Since these operators contribute to the flavor-changing three-body decays as well, the associated MFV scale must satisfy their experimental bounds. Based on the resulting strongest constraints, we estimate predictions on some of these processes which are markedly distinguishable from the corresponding predictions from the dipole operators.

It is interesting that some of the extra operators can also contribute to the flavor-conserving and flavor-violating leptonic decays of the Higgs boson and are therefore subject to constraints from future Higgs measurements at the LHC which will continue to improve in precision. Upcoming searches for other processes that violate lepton flavor will offer complementary tests on the different seesaw scenarios we have studied. The examples we have presented serve to illustrate the great importance of making such experimental efforts.
