INTRODUCTION
Necrotizing soft tissue infections (NSTIs) encompass a rare but highly lethal spectrum of infections of the subcutaneous tissue and fascia. NSTIs are often associated with trauma or immunocompromised but can be seen in previously healthy people. Given the high mortality, reported at 25% in recent years1,2 and up to 76% with involvement of the perineum or trunk1, early recognition and consultation for debridement is essential to decrease mortality.

CASE REPORT
A previously healthy 54-year-old man presented to the emergency department (ED) with a chief complaint of altered consciousness. Over the preceding five days, the patient’s wife reported that he had worsening back and right-flank pain. He also had a productive cough and was seen by a physician three days prior and diagnosed with bronchitis and a lumbar strain. He was prescribed ciprofloxacin, baclofen, and hydrocodone 5mg/acetaminophen 500mg. Despite this, he worsened and developed fever to 39.2°C. On the day of presentation, he became confused and his wife brought him to the ED. Review of systems from the wife was otherwise negative.
Past medical history included hypertension and a brain angioma as a child. He had a 60 pack-year smoking history but denied intravenous (IV) or illicit drugs, recent trauma or illness. Physical exam showed temperature of 37.3°C, pulse 130 beats per minute, blood pressure 110/70 mm Hg and respiratory rate 16 breaths per minute. He appeared tired, diaphoretic, and older than stated age. His head and neck exam was noncontributory. Cardiac exam revealed tachycardia with normal S1 and S2. His lung exam was significant for diffuse rhonchi. The abdomen was soft and nontender to deep palpation. His skin, from his right flank to right paraspinous lumbar region, showed erythema and brawny edema with minimal elevation of the epidermis. This area was moderately tender and without crepitance. His mobility was limited by pain. Extremities were dry but skin was warm. There were no gross motor or sensory deficits. The patient was confused with speech limited mainly to in comprehensible sounds. He was easily aroused and complained of pain when he was turned to examine his back.
A metabolic panel revealed a blood urea nitrogen of 41 mg/dL (normal 8-22), creatinine 2.1 mg/dL (normal 0.5-1.3) and serum sodium 136 mEq/L. A complete blood count showed white blood cells (WBC) of 30.3 K/mm³ with a manual differential of 27.9 K/mm³ neutrophils. Serum lactate was 2.1 mmol/L (normal <2). The remainder of the laboratory results was unremarkable. An ECG showed sinus tachycardia without ST changes. No HIV test was done.
The patient's resuscitation included two liters IV normal saline without improvement in mental status or blood pressure. Given the area of skin elevation in his back and the clinical presentation of presumed sepsis, computed tomography (CT) scans of the head, chest, abdomen and pelvis were ordered. The CT of the head and chest were unremarkable; however, the CT scan of the abdomen and pelvis showed gas within and around the right paraspinous muscles with an adjacent large abscess measuring 28 (cranial to caudal) x 15 x 5 cm that extended from the gluteus muscle to the mid-thoracic level of the back concerning for necrotizing fasciitis (Figure). General surgery was immediately consulted and the
DISCUSSION

Necrotizing fasciitis (NF), a NSTI that has invaded fascial planes, is a rare but potentially fatal infection that requires early diagnosis and surgical intervention due to its rapid progression and high mortality. The incidence of NF in the United States is estimated at 500-1500 cases per year with mortality of 20-60%. The pathophysiology of NF involves release of bacterial toxins and enzymes resulting in rapidly progressing soft tissue necrosis. Pathogens further block the lymphatic and vascular systems, impairing the immune system and antibiotic delivery. Ultimately, if untreated, extensive inflammation and coagulation necrosis results in pathogen spread along fascial planes with eventual muscular and bony involvement. Mortality results from overwhelming sepsis and multiple organ failure.

There are many classification systems for distinguishing various types of NF, based on type of pathogen, location and/or extent of tissue involvement. While classification can be useful for refining antibiotic treatment or documentation purposes, there are no obvious distinguishing clinical features separating the various types, and initial treatment in the ED should be the same in all suspected cases of NF.

While many risk factors have been identified, including diabetes mellitus, chronic kidney disease, IV drug use and immune suppression, up to 50% of NF cases occur in otherwise healthy patients of all age ranges. Many cases have a precipitating factor, usually trauma. However, as in our patient, >20% present with unknown etiology. NF is primarily a clinical diagnosis with a wide spectrum of presentations, making early diagnosis difficult. The high rate of initial misdiagnosis in the ED, reported at 42.6%-86.4%, has been attributed to lack of systemic and/or cutaneous findings. While NF most often affects the extremities, it can affect any part of the body with the perirectal area. Wound cultures grew Streptococcus viridans, peptostreptococcus and porphyromonas species.

The patient returned to the OR the next day for more debridement and wound vac placement. Through his 17-day hospitalization, he had four additional debridements and wound vac changes, with continuous IV antibiotics. The patient recovered and was discharged home in stable condition. He was seen in general surgery clinic with no complications or need for additional surgical or medical interventions.

Table. Location of necrotizing soft tissue infections in recent prospective studies

| Study          | Extremity (%) | Perineal* (%) | Other location* (%) |
|----------------|--------------|---------------|---------------------|
| Ogilvie 2006   | 88 (57.9%)   | 58 (38.1%)    | 6 (4%)              |
| Frazee 2008    | 90 (73.7%)   | 23 (18.9%)    | 30 (24.6%)          |
| Anaya 2005     | 96 (57.8%)   | 37 (22.3%)    | 33 (19.9%)          |
| Wong 2003      | 71 (79.8%)   | n/a           | 18 (20.2%)          |
| Sudarsky 1987  | 33 (67%)     | 8 (24%)       | 3 (9%)              |

*Perineal includes buttock and upper leg in all studies. Other includes trunk only with exception of Frazee, which also includes shoulder, and Anaya, which includes head and neck.
Laboratory results associated with poor outcomes from NF are WBC counts >14,000 cells/mm3, serum sodium <135 mEq/L and a BUN >15-18 mg/dL.10 Given the lack of definitive clinical presentation, Wong et al.16,17 developed the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) that uses six predictive factors to distinguish NF from other soft tissue infections, which in one prospective study was shown to have a negative predictive value of 95% and a positive predictive value of 40%. Wong et al.18 thus argued that the LRINEC should be used to limit and target use of radiographic imaging rather than as an independent diagnostic tool for NF. However, utility of this instrument has not been validated in ED patients.

CT and magnetic resonance imaging (MRI) are most commonly used and studied. While MRI is more sensitive than CT for soft tissue infections, availability often limits its use. Findings on CT suspicious for NF include asymmetric deep fascial thickening, fat stranding and presence of fluid or gas.18 Plain films have a high specificity but low sensitivity in identifying subcutaneous gas. Imaging should be an adjunct to diagnosis and not delay operative treatment if suspicion for NF is high, since an open look by a surgeon is the criterion standard for diagnosis and allows for immediate treatment.5

Our patient initially presented to his primary medical doctor with low back pain and a productive cough that later progressed to fever and delirium. While these initial symptoms were vague, we suspected NF given the redness and exquisite tenderness of the back and right flank. Unusual features of this case include atypical location, lack of trauma and apparent previous healthy state of this patient. The emergency physician (EP) should consider NF even in these circumstances. In this, the diagnosis was made expeditiously with CT and early exploration.

Initial treatment in the ED for NF includes aggressive resuscitation, broad spectrum IV antibiotics, and immediate surgical consult.10 The criterion standard of treatment is repeated surgical debridement to ensure removal of all necrotic tissue along with deep incisional biopsy, wound cultures and antibiotics.2–4 Hyperbaric oxygen and IV immunoglobulin have also been used with mixed results and are seen as possible adjuvants, especially if risk of mortality is high.16,19

CONCLUSION

As in this patient, NF can occur in any location without precipitating factors and with vague symptoms, making early diagnosis difficult. Misdiagnosis can lead to delay in surgical debridement, which is the only identified modifiable factor that decreases mortality.16 Although NF is rare, the rapid progression and lethality warrants high clinical suspicion, early diagnosis by the EP and prompt treatment.
