Abstract
Neglecting spin effects, one introduces here a subtle approximation for the scattering angle, which allows the obtaining of a logarithmic leading Regge pole, consistent with the Froissart-Martin bound. A simple parameterization is also introduced for the proton-proton total cross section. Fitting procedures are implemented only for the highest energy experimental data available. The intercept for a linear approach is obtained, indicating the presence of a soft pomeron. The Tsallis entropy in the impact parameter space is calculated using the Regge pole formalism. This entropy depends on a free parameter, whose value implies the existence of a central or non-central maximum value for the entropy. The hollowness effect is discussed in terms of this parameter.

Keywords: Tsallis entropy, Regge pole, total cross section, pomeron, impact parameter

1. Introduction

The complex angular momentum theory or Regge theory, for short, is one of the attempts to understand the strong interaction of elementary particles initiated at the end of 1950’s [1–3]. The straight connection between the spectrum of particles and their scattering pattern at high energy is one of the achievements of Regge theory. In the so-called Chew-Frautschi plot [4, 5], one has an example of Regge trajectories subject to experimental verification.

The Regge poles, also called reggeons, can be divided into pomerons and odderon. The pomerons have a $C = +1$ parity and the odderon a $C = -1$ parity. Then, the pomerons have the same coupling with particles and antiparticles. The odderon distinguishes particles from antiparticles. In the scattering amplitude at very large energy ($\sqrt{s}$) and small transferred momentum ($\sqrt{t}$), the pomeron is the leading contribution and odderon, its counterpart, is the non-leading (or secondary) contribution [6]. A possible odderon exchange at small $t$ could explain the dip region in the proton-proton ($pp$) and proton-antiproton ($\bar{p}p$) scattering. In the total cross section ($\sigma_{\text{tot}}(s)$) case, the general belief is that a triple pole exchange may explain the Froissart-Martin bound saturation, $\sigma_{\text{tot}}(s) \sim (\ln s)^2$. On the other hand, the odderon contributes with a less rapid rise ($\ln s$) for the total cross section as $s \to \infty$. Therefore, for example, for the ISR energies, the mixing contributions of pomerons and odderons are important to take into account the experimental data subtleties. On the other hand, at LHC scale, only the pomeron contribution is dominant [7]. Despite this theoretical understanding, several unfruitful attempts have been performed to associate a specific trajectory to the pomeron. Recently, possible experimental evidence for the odderon [8] has been subject to some debate [9–11].

The leading Regge pole, unfortunately, does not obey the Froissart-Martin bound, a remarkable theoretical result of the 1960s. Of course, one can argue this violation occurs far from the present-day energies, in the so-called Planck scale [6]. One can also claim this violation may be avoided through the eikonalization of the Regge pole [12].

In the present work, the validity of the Froissart-Martin bound in the Regge theory is restored introducing an approximation, near the forward region, resulting in logarithmic leading Regge poles. One introduces an approximation in the scattering angle representation, reducing its amplitude but allowing its logarithmic representation. Based on this result, one proposes a simple parameterization for the $pp$ total cross section. Carrying out a fitting procedure for the total cross section, considering only experimental data above 1 TeV up to the cosmic-ray data, one obtains an intercept favoring the soft pomeron. The $pp$ experimental data are also used in the fitting procedures, as shall be explained in the text.

The geometrical arrangement of quarks and gluons, the so-called partons, brings the question of how they contribute
to the hadron internal entropy and how this entropy can be utilized to explain the stability/instability of the hadrons. The formal relation between the Tsallis entropy and the real part of the profile function, in the impact parameter formalism, can help to understand how this scenario may lead to the appearance of instabilities regions inside the proton, above some critical temperature [13]. Using the results achieved here, one presents the Tsallis entropy for the logarithmic leading Regge pole in the impact parameter space. This entropy depends on a free parameter, which choice may result in a central or non-central value for the maximum of the entropy. If this parameter is independent of the impact parameter $b$, then the entropy is mostly central ($b = 0$ fm). On the other hand, if this parameter is $b$-dependent, then the entropy reaches its maximum at $b = 0$ fm. The $b$-dependence or $b$-independence lead to different values for the maximum of the entropy. Then, the correct choice of this parameter may help to understand the emergence of a gray area [14, 15], also known as the hollowness effect [16–23]. If the entropy is maximum at $b = 0$ fm, then the hollowness effect is absent for $pp$ and $p\bar{p}$ elastic scattering. Then the maximum of the inelastic overlap function, for example, occurs at $b = 0$ fm. Yet, if the maximum of the entropy occurs in $b = 0$ fm, then this result may favor the existence of the hollowness effect since the maximum of the inelastic overlap function also arises in $b = 0$ fm.

The paper is organized as follows. In section 2, using an approximation for the scattering angle, one introduces a logarithmic leading Regge pole obeying the Froissart-Martin bound. One also presents a fitting procedure for the $pp$ total cross section above 1.0 TeV, including high energy non-accelerators data, obtaining the pomeron intercept. In a second fitting procedure, the experimental data for the $p\bar{p}$ total cross section above 1.0 TeV were also used simultaneously with the data for $pp$, resulting in a slightly different soft pomeron value. In section 3, a possible relation between the Regge pole and the Tsallis entropy is presented. The hollowness effect is also discussed based on a free parameter. Section 4 presents the critical remarks.

2. The Regge pole and the Froissart-Martin bound

The Regge theory is an interesting way to furnish a physical interpretation of the mathematical poles that arise in the complex angular momentum plane. The scattering amplitude, in this formalism, can be written as an analytic function of the angular momentum $J$. Then, its behavior in the $s$-channel is due to the exchange of one-particle (or due to a composite particle), represented in the $t$-channel as the Regge pole. Hereafter, $s$ is the squared energy, and $t$ the squared transferred momentum, both in the center-of-mass system.

2.1. Basic picture

As well-known, the Regge poles appear from the theoretical approach used and, for $s \gg |t|$ ($t$ physical is negative), only the leading pole becomes important for the scattering amplitude [24]. Indeed, one assumes that partial wave expansion of the scattering amplitude is dominated by a finite number of isolated moving poles in the complex angular momentum plane. Mathematically, for the simple pole and a scattering angle given by

$$\cos \theta = 1 + \frac{2t}{s},$$

one writes the following asymptotic function for the scattering amplitude

$$A(s, t) \rightarrow (\eta + e^{-i\alpha(t)})\beta(t)(s/s_0)^{\alpha(t)}, \quad s \rightarrow \infty,$$

where $\eta = \pm 1$ is the signature related with the crossing symmetry $s \leftrightarrow u$ (or $s \leftrightarrow -s$ for high energies), $\sqrt{s_0}$ is some critical energy, and $\beta(t)$ is the residue function of the pole depending only on $t$. The asymptotic behavior of (2) comes from the fact that, for $s \gg |t|$, one has the asymptotic property

$$P_l(s/s_0) \rightarrow (s/s_0)^l,$$

i.e. the Legendre polynomial $P_l(s/s_0)$ is dominated by its leading term $(s/s_0)^l$. The main role in the leading Regge pole determination is performed by $\alpha(t)$, also known as the Regge trajectory. It can be obtained using the plot of mass$^2 \times J$ (or spin). For example, for several mesons, it can be extracted from the experimental data collected over the years [25]. A reaction with positive $t$ implies the existence of physical particles of angular momentum $J$, and mass $\alpha(t = m_t^2) = J_t$. The $\alpha(t)$ has a simple mathematical form for positive $t$

$$\alpha(t) = \alpha(0) + \alpha',$$

where $\alpha'$ is the slope. The linearity of $\alpha(t)$, established a long time ago, is not true everywhere [26], and seems to be more evident for light baryons and mesons. Nonetheless, one maintains here the linearity of $\alpha(t)$ by its simplicity. Then, $\alpha(0)$ and $\alpha'$ can be easily obtained from fitting procedures of the experimental data. Using (2), one can write the differential cross section of the process as

$$\frac{d\sigma}{dt} \approx (s/s_0)^{2\alpha(t)},$$

and the resulting total cross section is given by

$$\sigma_{tot}(s) \approx (s/s_0)^{\alpha(t)-1}.$$
Pomeranchuk theorem stated that a scattering process should vanish (asymptotically) if the charge exchange had occurred [28], in full agreement with the experimental data available. The Pomeranchuk theorem initial version states, roughly speaking, that $\sigma_{tot}^{pp} - \sigma_{tot}^{\bar{p}p} \to 0$, as the energy tends to infinity [28]. Other versions, contrarily, had shown that $\sigma_{tot}^{pp}/\sigma_{tot}^{\bar{p}p} \to 1$ as $s \to \infty$ [29, 30]. In any one of these versions, one assumes (not yet proven) that total cross section is finite for $s \to \infty$. This theoretical statement implies the existence of an exchange particle that does not differ from antiparticle at high energies with vacuum quantum numbers is a hard task in particle physics.

The odderon is defined as the $C$-odd (or $C = -1$) contribution for the scattering amplitude. At very large $s$ and small $t$, it is a non-leading contribution. It may either do not vanish relative to the pomeron or vanish as a small power of $s$ or power of $\ln s$ [6]. Yet, considering energies $\sqrt{s} \lesssim 1.0$ TeV, the mixing of the leading and non-leading trajectories may explain the different patterns observed in the $pp$ and $p\bar{p}$ scattering, for example, tends to the same value as $s \to \infty$. Table 1 shows the expected pomeron quantum numbers [32]. Without any doubt, the detection of particles with vacuum quantum numbers is a hard task in particle physics.

Nowadays, there are several candidates to be the pomeron, $\alpha(0) = \alpha_{\bar{p}}(0)$. The so-called soft pomeron, constructed from multi peripheral hadronic exchanges, is the simplest one and possess an intercept $\alpha_0^b = 1.06$ [39, 40] or $\alpha_0^b = 1.08$ [31]. Despite its mathematical simplicity, its dynamical origin is not well-understood [41]. The hard pomeron possesses origin in the Hera and ZEUS experiments on deep inelastic scattering at DESY. The rise at $x < 0.01$, where $x$ is the Bjorken scale, suggests a higher intercept $\alpha_0^b = 1.44$ [42]. However, the soft pomeron is a pole, and the hard pomeron is a cut in the $\alpha_{1\rho}(t)$ plane, i.e. an exchange of, at least, two pomerons. There are, also, the perturbative-QCD pomerons: the Low-Nussinov pomeron [43, 44] and the BFKL pomeron [45, 46].

### 2.2. Alternative approach

There is a mathematical disagreement between (6) and (7) for $1 < \alpha_{\bar{p}}(0)$. The validity of the Regge theory relative to the Froissart-Martin bound can be restored imposing a constraint on the scattering angle as well as a mathematical approximation on the cosine series. Firstly, one restricts the scattering angle (1) to the range $0 \leq \cos \theta \leq 1$ as well as $|t| \ll s$. This restriction covers both the forward and the near-forward scattering cases. In this range, it is possible to write the following approximation for the cosine of the scattering angle

$$\cos(\theta) = 1 + \frac{2t}{s} \approx \ln \left(1 + \sqrt{e} \left(1 + \frac{2t}{s}\right) \right).$$

(8)

The above result can be achieved by using the usual cosine series written as

$$\cos(x) = 1 - \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{(2n)} x^{2n}.$$  

(9)

The factorial number is the problematic term for our purposes. To circumvent it, one uses Stirling’s approximation

$$(2n)! \approx (2n)^{2n} e^{-2n} \sqrt{2\pi},$$

(10)

moreover, ones notices the following inequalities are valid for $n \in \mathbb{N}$

$$(2n)^{2n + \frac{1}{2}} \geq n^{n + \frac{1}{2}} \geq n^n \geq n.$$  

(11)

Of course, the result (11), when replaced in the convenient series, possibly implies a slower convergence than the original cosine series. Now, to reduce the series on the r. h. s. of (9) into the logarithmic series, one notices that using (11) one can always find a real number $a$, satisfying

$$\frac{e^{2n}}{\sqrt{2\pi} (2n)^{2n + \frac{1}{2}}} \leq \frac{a^{2n}}{n}.$$  

(12)
The above inequality holds for $a = e$, for example. Using the results (10) and (12), one can exchange the series on r.h.s. of (9) by the approximation
\[ \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n} x^{2n} \approx \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n} [(ax)^2]^n \]
\[ = \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n} [(y)^n], \quad (13) \]
with the condition $y \geq 0$. Using the last result, one finally obtains
\[ 1 - \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n} [(y)^n] = \ln \left( \frac{e}{1 + y} \right) \quad (14) \]
To ensure the first-order approximation, one uses
\[ y = e - \left[ 1 + \sqrt{e} \left( 1 + \frac{2t}{s} \right) \right] \quad (15) \]
where the factor $\sqrt{e}$ comes from the fact that $y \geq 0$. Observe that, for $t = 0$, one has $\cos \theta = 1$, and the approximation performed furnishes $\cos \theta \approx 0.97$.

Using the asymptotic properties of the Legendre polynomial, one writes taking into account the approximation (8),
\[ P_l(s) \rightarrow \ln \left( \frac{s}{\sqrt{s}} \right)^l, \quad (16) \]
and one adopts $\sqrt{s} \approx 25.0 \text{ GeV}$ and $\sqrt{s} < \sqrt{s}$ as the energy where the total cross section data achieves its minimum value [13, 47]. Indeed, the above result can be used to write the asymptotic scattering amplitude (neglecting the signature and the residue function)
\[ A(s, t) \rightarrow \ln \left( \frac{s}{\sqrt{s}} \right)^{\alpha(t)}, \quad (17) \]
and, therefore, the optical theorem culminate in the simple relation for the total cross section (without subtractions)
\[ \sigma_{tot}(s) \rightarrow \ln \left( \frac{s}{\sqrt{s}} \right)^{\alpha_{tot}(0)}, \quad (18) \]

In the specified range for $\cos(\theta)$, it respects the Froissart-Martin bound if $\alpha_{tot}(0) \leq 2$, providing a physical relation between the pomeron intercept, $\alpha_{tot}(0)$, and the saturation of that bound. The particle allowing the maximum growth for $\sigma_{tot}$, obeying the Froissart-Martin bound as $s \rightarrow \infty$, is a pomeron with an intercept $\alpha_{tot}(0) = 2$.

2.3. Fitting results

As well-known, in the usual formulation of the Regge pole, the soft pomeron occurs for an intercept $1.04 \sim 1.08$. Considering a total cross section written as (6), this value represents the over-saturation of the Froissart-Martin bound. However, in the approach presented here, the Froissart-Martin bound saturates only for $\alpha_{tot}(0) \rightarrow 2$.

As an exercise, one extracts here $\alpha_{tot}(0) = \alpha_{p}$ by a fitting procedure using the experimental data for $\sigma_{tot}^{pp}$ and $\sigma_{tot}^{pp}$ above $\sqrt{s} = 1.0 \text{ TeV}$ up to the cosmic-ray data. The experimental data were collected from Particle Data Group [25]. Moreover, $\sigma_{tot}^{pp}$ at $\sqrt{s} = 2.76 \text{ TeV}$ is from [48]. In this energy regime, one uses a parameterization based on the Regge approach performed above, writing
\[ \sigma_{tot}(s) = \beta \ln (s/s_0)^{\alpha_{p}}, \quad (19) \]
where $\beta$ and $\alpha_{p}$ are free fitting parameters. This parameterization (19) may represents a double, $\ln(s/s_0)$, or a triple, $\ln(s/s_0)^2$, pole exchange, depending on the value of the pomeron intercept. For $\alpha_{p} \rightarrow 1$, the double exchange is favored and for $\alpha_{p} \rightarrow 2$, the triple pole dominates. Then, a triple pole exchange favors the saturation of the Froissart-Martin bound.

The fitting procedure is described as follows. Firstly, only the experimental data for $\sigma_{tot}^{pp}$ above $1.0 \text{ TeV}$ are used in the fitting procedure (set 1). Secondly, the experimental data for $pp$, above $\sqrt{s} = 1.0 \text{ TeV}$, are added to the $pp$ experimental data and this joint data-set is fitted (set 2). The main goal of set 2 is to compensate for the absence of $pp$ experimental data in the range $1.0 \text{ TeV} < \sqrt{s} < 2.0 \text{ TeV}$, trying to improve the statistical results. One notes there is no data selection in any ensemble.

Figures 1(a) and (b) shows the fitting results for the set 1 and set 2, respectively. Table 2 displays the values of the fitting parameters. One can analyze these results considering the Froissart-Martin bound and the soft pomeron points of view. The Froissart-Martin point of view, these values for the intercept ensure its non-saturation. The Froissart-Martin exponents obtained are $0.93 \pm 0.25$ (set 1) and $1.05 \pm 0.05$ (set 2), very below its expected saturation value. These intercepts represent a soft pomeron, indicating a process dominated by the exchange of a double pole—two gluon exchange. Furthermore, these intercepts are far from the Froissart-Martin bound saturation and below the usual hard pomeron prediction $\alpha_{p} = 1.4$ for diffractive processes [49].

Although simple, the parameterization (19) furnishes a reasonable statistical description of the data, as can be observed from the $\chi^2/ndf$ results shown in table 2.

From these slopes, one can determine the mass of the particle by assuming a specific spin. Using the slope $\alpha = 0.25 \text{ GeV}^{-2}$ from [50] for soft pomeron, one writes the linear Regge trajectory as ($|t| = m^2$)
\[ \alpha(m^2) = 0.93 + 0.25m^2, \quad (20) \]
and
\[ \alpha(m^2) = 1.05 + 0.25m^2, \quad (21) \]
and, for example, a particle with spin $J = \alpha(m^2) = 2$ result in a particle with $m = 2.07 \text{ GeV}$ and $m = 1.95 \text{ GeV}$, respectively. These results point out the existence of a soft pomeron with mass $\sim 2.0 \text{ GeV}$.

The relation between the internal entropy of the colliding hadron and the pomeron intercept may help to understand how the pomeron exchange contributes to the rise of the entropy. Recently, a simple scheme to calculate the hadron entropy has been proposed, assuming the Tsallis entropy as proportional to the real part of the profile function [13].
3. Tsallis entropy and the Regge pole

The increasing correlation between the hadron internal constituents prevents the use of the Boltzmann entropy. On the other hand, this strong correlation allows the use of the Tsallis entropy [13]. This entropy takes into account the strong interaction among quarks and gluons inside the hadron, using the information on the possible phase transition occurring in

Figure 1. The panel (a) shows the set 1 and the panel (b) the set 2. In both panels, the curve represents the fitting procedure using the parameterization (19). Experimental data are from [25] and $\sigma^{pp}_{\text{tot}}$ at $\sqrt{s} = 2.76$ TeV is from [48].
the total cross section experimental data at $\sqrt{s}$. The entropic index $w$ is replaced by the ratio $s/s_c$, allowing its physical interpretation in terms of the collision energy. The Tsallis entropy can be written in the impact parameter representation as [13]

$$S_T(s, b) \approx \frac{1}{s/s_c - 1} \left[1 - \text{Re} \Gamma(s, b)\right]^2,$$

where $\text{Re} \Gamma(s, b)$ is the real part of the profile function, which can be connected with the Regge asymptotic amplitude (17) in the impact parameter space through a Fourier-Bessel transform. It is important to stress that in $b$-space the squared energy $s$ is fixed for each experiment.

The ratio $s/s_c$ can be written in a more general formulation as $(s/s_c)_{\alpha_1}$, where $\alpha_1$ can depend on the particle species and the collision type, for example. Currently, the information about the entropic index $w(s) = (s/s_c)_{\alpha_1}$ is limited to negative charged pions in proton-proton collisions, stating $\alpha_1 = 0.007$ [51]. On the other hand, there are studies in particle production processes indicating the rise of $w(s)$ with the collision energy [51–54]. Therefore, at present-day energies, $\alpha_1$ shows a weak $s$-dependence.

The Regge theory is based on the asymptotic behavior of the Legendre polynomial for $s \to \infty$, which means $s_c \ll s$. In this situation, it is possible to find $\alpha_2$ satisfying the following approximation

$$\frac{1}{(s/s_c)_{\alpha_2}} - 1 \approx \frac{1}{\alpha_1 \ln(s/s_c)_{\alpha_2}},$$

for $s \gg s_c$. Therefore, the Tsallis entropy is written as

$$S_T(s, b) \approx \frac{1}{\alpha_1 \ln(s/s_c)_{\alpha_2}} \left[1 - \text{Re} \Gamma(s, b)\right]^2.$$  \hspace{1cm} (24)

The above result implies the entropy is positive for $s_c \ll s$, as obtained in [13]. From the above discussion, one adopts without loss of generality $\alpha_1 = 1$, since for $\alpha_1 > 0$ there is no changes in the entropy behavior [13]. Furthermore, the approximation (24) may connect the Regge poles in the $t$-space with the behavior of the Tsallis entropy in $b$-space, as seen later. The $\text{Re} \Gamma(s, b)$ can be obtained assuming the asymptotic amplitude (17), resulting in the Tsallis entropy generated by the leading Regge pole

$$S_T(s, b) \approx \frac{1}{\ln(s/s_c)_{\alpha_2}} \left[1 - e^{-\frac{(s/s_c)_{\alpha_2}}{2\alpha_2 \ln(\ln s/s_c)}}\right]^2.$$  \hspace{1cm} (25)

This result, despite constraints and approximations, is positive for $s_c < s$ and, except for the presence of $\alpha_2$, can be determined only by the leading Regge pole behavior. The role of $\alpha_2$ is analyzed in two situations. Firstly, assuming a $b$-independence, and later, a linear $b$-dependence.

The $b$-independence of $\alpha_2$ is displayed in the figure 2, which show the Tsallis entropy for the leading Regge pole using (25). Figure 2(a) is obtained by taking $\alpha_2 = 0.1$. Figure 2(b) shows the Tsallis entropy for $\alpha_2 = \alpha_0 = 1.05$. It is interesting to note that, for every $\alpha_2$, it is produced a non-physical entropy state outside the hadron. This result indicates the need for a cutoff for the Tsallis entropy in the Regge pole representation at the hadron edge, where one expects $S_T = 0$. Thus, one considers the effective size of the hadron at $b_0$ where $S_T(s, b_0) = 0$. Note that as the energy rises as well rises the largest value of the entropy.

Now, one adopts a linear $b$-dependence for $\alpha_2$. For the sake of simplicity, one uses for $\alpha_2$ a linear $b$-dependence applying the mnemonic rule $|t| \to b^2$ into (4). Then is possible to connect this approach to the experimental results in $t$-space. Thus, one writes the following ansatz for $\alpha_2$

$$\alpha_2 = \alpha(b) = \alpha_0 + \frac{\alpha'}{b^2}.$$  \hspace{1cm} (26)

Figure 3 shows the result for the entropy, considering (26) and using the intercept obtained here and the slope taken from the literature. There is also a cutoff for the Tsallis entropy in this case. The main difference observed between these two Tsallis entropies is based on the adoption of $b$-dependence or $b$-independence for $\alpha_2$. First of all, assuming $\alpha_2$ as $b$-independent, then the entropy grows mainly near the hadron core, achieving its maximum at $b = 0$ fm. In this scenario, the main contribution for the entropy is given by the hadron internal constituents, located near the hadron core.

On the other hand, considering the $b$-dependent situation, one has $S_T \approx 0$ for $b \to 0$, as shown in the figure 3. The main contribution for the entropy comes from the constituents located in the region $b \approx 0.5$ fm up to the hadron edge.

These two results, based on the $\alpha_2$ behavior, introduces a novel perspective in the existence or not of the so-called gray area [14, 15], also known as hollowness effect [16–23]. As well-known, the absence of a maximum for the inelastic overlap function at $b = 0$, for example, is the main consequence of such effect. In the picture introduced here, the existence of the hollowness effect is a consequence of the behavior of $\alpha_2$. It is important to stress that hollowness effect may exist for high $|t|$ values ($b \to 0$ fm), and taking into account the constraint $|t| \ll s$. Therefore, this effect, if it exists, should occur only for $s$ above the TeV scale being negligible for $|t| \approx s$. In this situation, the approximation (8) still holds, ensuring the validity of the above results.

If $\alpha_2$ is independent of $b$, then there is no gray area since the entropy achieves its maximum at $b = 0$ fm. However, if $\alpha_2 = \alpha_2(b)$, then the gray area can emerge, being noted by the absence of the Tsallis entropy at $b = 0$ fm, indicating a hollow in this region.

The Tsallis entropy obtained from the presented approach to the leading Regge pole, despite its simplicity, can help to distinguish if the main contribution for the collision is central

| set | $\alpha_0$ | $\beta$ (mb) | $\chi^2/ndf$ |
|-----|------------|---------------|--------------|
| 1   | 0.93 ± 0.19 | 10.04 ± 4.58  | 1.48         |
| 2   | 1.05 ± 0.05 | 7.54 ± 0.92   | 1.26         |
or peripheral, based on the behavior of $\alpha_2$. A small value for the slope $\alpha'$ may indicate a small $t$-dependence of $\alpha_2$ (in this linear approach), which implies a contribution near the hadron core as being dominant over the peripheral one. A non-linear contribution for $\alpha_2$ can be considered (not presented here), resulting in a more complicated scenario.

4. Critical remarks

One obtains an approximation for the scattering angle, whose main result is a hadron-hadron total cross section arising from the asymptotic leading Regge pole, obeying the Froissart-Martin bound. It is important to stress, however, that $\sigma_{\text{tot}}$ used in the present analysis comes from a scattering amplitude without subtractions, which implies that Cauchy integral theorem may not be satisfied. Nonetheless, this is a natural consequence of the Regge approach for wave expansion, which result in a scattering amplitude not necessarily satisfying such a theorem. The advantage of the present approach over the well-known Donnachie and Landshoff model, for example, is the preservation of unitarity, as well as the Froissart-Martin bound.
The introduction of subtractions, however, can be easily performed preserving the Cauchy integral theorem, unitarity, and Froissart-Martin bound, resulting in \( \sigma_{\text{tot}}(s) \approx s^7 \ln(s/s_0) Y_{\alpha}(0) \), \( \gamma < 0 \). On the other hand, the natural consequence of that is the decreasing of the total cross section above some \( \sqrt{s_0} \), as \( s \to \infty \). Of course, the mnemonic relation \( \gamma = 0 \) cannot be identified with the simple Regge trajectory, being more similar to a Regge cut term. The analysis of this case will be performed otherwise.

The approximation implemented is valid for \( 0 \leq \cos \theta \leq 1 \) and \( |t| \ll s \), which includes the forward collision case as well as the cases where the inequality holds. In a first moment, the \( pp \) total cross section was analyzed only for \( \sqrt{s} \geq 1.0 \) TeV, including the cosmic-ray data. The fitting procedure results in a pomeron intercept \( \alpha_P = 0.93 \pm 0.19 \), indicating the presence of a soft pomeron. In a second moment, the experimental data for \( \sigma_{\text{tot}}^{pp} \) above 1.0 TeV were added to the \( pp \) data in an attempt to compensate the absence of \( pp \) experimental data in the energy range 1.0 TeV \( < \sqrt{s} < 2.0 \) TeV. The main goal of this procedure was to enhance the statistical description of the data resulting in \( \alpha_P = 1.05 \pm 0.05 \). These values for \( \alpha_P \) indicates the dominance of two gluon exchange and a very slow rising \( \sigma_{\text{tot}}^{pp} \) above 1.0 TeV.

Using the proposed parameterization for the fitting procedure, one obtains the Tsallis entropy in the \( b \)-space. A simple mathematical approximation was implemented, allowing the use of a logarithmic representation for the entropic index \( w \). Due to this approximation, emerges a free parameter analyzed as being \( b \)-independent and \( b \)-dependent. In the first case, the entropy reveals that the main contribution to the elastic scattering pattern is central since the entropy achieves its maximum at \( b = 0 \) fm. In the later case, one assumes \( \alpha(b) \) given by the simple change of \( |t| \to b^{-3} \) in the linear form of \( \alpha(t) \). This assumption results in a Tsallis entropy mainly generated in the region \( b \sim 0 \) up to the hadron edge. Of course, the mnemonic relation \( b^2 \to |t|^{-1} \) implies \( b = 0 \) only for \( |t| \to \infty \), which cannot occurs without violation of the mandatory condition \( |t| \ll s \). However, if one considers the present-day range for \( |t| \), then the obtained results are valid as an approximation, working better for \( \sqrt{s} \) above the TeV scale. Indeed, the momentum transfer for the \( pp \) collisions is restricted to \( |t| < 15 \) GeV \(^2 \ll s \) resulting in \( b \approx 0.05 \) fm, very close to the forward collision.

It is interesting to note that the leading Regge pole is obtained in asymptotic conditions (\( s \to \infty \)). Thus, it would be expected to work only for very high energies. Yet, it is surprising that it works in the energy range one has nowadays, far from the concept of asymptotia. The Pomeronchuk theorem, in the original and modified versions, had predicted the existence of an exchange particle that does not differ particle-particle and particle-antiparticle scattering at very high energies. This theorem also seems to be valid at the present-day energy scale. At a low energy scale, on the other hand, the total cross section for \( pp \) and \( p\bar{p} \) have different patterns. Furthermore, the presence of the odderon seems inevitable to fill up the dip in the \( pp \) and \( p\bar{p} \) differential cross section [35].

The BFKL equation is the perturbative mechanism driving the growth of the total cross section [45, 46], and the BFKL pomeron can be calculated from its series expansion [55]. The hard pomeron describes processes dominated by small transverse distance, whereas the soft pomeron describes large transverse distances (\( \sim \) the proton radius). Although the BFKL equation was not created for the soft pomeron, there are interpolating methods being developed about a possible BFKL approach for the soft pomeron [56] (and references

---

**Figure 3.** The Tsallis entropy for the leading Regge pole using the critical energy \( \sqrt{s} = 25.0 \) GeV, \( \alpha_P = 1.05 \) and \( \alpha' = 0.25 \) GeV \(^2 \). The solid-line is for \( \sqrt{s} = 14 \) TeV, dashed-line is for \( \sqrt{s} = 7 \) TeV and dotted-line is for \( \sqrt{s} = 600 \) GeV.
therein). The comparison between the results obtained here and this BFKL approach will be presented elsewhere.

It is important to stress that the term soft pomeron emerges in the context of $\sigma_{tot}(s) \sim s^{\alpha_0}$, for $\alpha_0 \gg 1$. The hard pomeron appears when the Regge phenomenology is used, by analogy, to explain the small-$x$ data for $F_2(x, Q^2)$. Thus, applying the present formalism to diffractive processes may result in an intercept higher than the one obtained here.

As a complimentary question, one must to say that the pomeron intercept depends on the renormalization scheme and scale for the running coupling constant $[57-59]$. However, the Regge pole should not depend on this arbitrary choice, since it has a phenomenological basis, the Chew-Frautschi plot. Thus, the definition of a renormalization group for the Regge theory is an important question to be solved in the future.
