Abstract

Purpose: To investigate if i) the risk of ischemia on Myocardial Perfusion Scan (MPS) ii) number of coronary angiographies (CAG) performed iii) necessity for invasive (stent implantation or coronary artery by-pass grefting (CABG)) or medical treatment increased in patients infected with COVID-19.

Methods:

Patients who were referred to MPS between August 2020-April 2021 with a history of active symptomatic Covid-19 infection (confirmed by PCR positivity) in the last 6 months were involved in the study group. Age-and gender matched control group was composed of randomly chosen patients who attended for MPS between January 2019 – September 2019, before pandemic. Frequency of ischemia, CAG, invasive or medical treatments were compared between groups.

Results:

Ischemia was reported more frequently in the study group (p<0.001). In clinical evaluation, regardless of the MPS results, the necessity for invasive evaluation with CAG and treatment (either medical therapy or invasive interventions), was higher in the study group (p=0.006 and p=0.015). It was also true for patients with abnormal MPS results (p=0.008 and p=0.024) but not for the patients with ischemia (p=0.29 and p=0.06).

Conclusion:

There exists a significant increase in the frequency of ischemia on MPS, undergoing CAG, stent implantation or CABG and initiation of medical therapy in patients with a history of Covid-19 infection in the last 6 months. MPS is a reliable method in patients who present with cardiovascular symptoms in the late COVID period.

Introduction

COVID-19 have affected healthcare systems and changed paradigms in the whole world in the last one year. Different from other upper respiratory tract viruses, COVID-19 appears to act on many systems in the body, inducing the inflammatory cascade and thrombotic process. It has been reported that risk of cardiac events has increased after COVID-19 infection [1]. Sudden cardiac death is also reported among young patients, which is soon related with late thrombotic complications. Researchers have demonstrated that there was a significant increase in hospital admission rates due to acute myocardial infarction in the late phase of the first wave of the pandemic, compared to rates before pandemic [2].

Myocardial perfusion scan is the fundamental functional imaging method in evaluation of ischemia and coronary risk assessment. During the pandemic, there have been several reports demonstrating the steep decline in the number of myocardial perfusion studies performed in Nuclear Medicine Departments [3]. However, its use in patients infected with COVID-19 has not been presented yet.
In this study, we investigated if i) the risk of ischemia on MPS ii) number of coronary angiographies performed iii) necessity for invasive (stent implantation or coronary artery by-pass grefting (CABG)) or medical treatment increased in patients infected with COVID-19.

**Materials-methods**

**Patients:**

Following ethics committee approval (2021/117) for this retrospectively designed study, patients who were referred to Nuclear Medicine Department between August 2020-April 2021 with a history of active symptomatic COVID-19 infection in 6 last months were involved in the study group. Age and gender matched control group was composed of randomly chosen patients without history of COVID-19 history who attended for MPS between January 2019 – September 2019, before pandemic. Age, gender, risk factors for coronary artery disease (hypertension, diabetes mellitus, hyperlipidemia, family history for coronary artery disease, obesity) as well as the active symptoms the patients were investigated for were noted in both groups. The history of coronary stent or CABG were also recorded from the hospital registry. Myocardial perfusion SPECT results were categorized in the groups as either normal or abnormal. Abnormal results were then regrouped as i) ischemia either together with infarct or not and ii) infarct only.

**Myocardial Perfusion SPECT:**

Myocardial perfusion Gated-SPECT study was performed by physical or pharmacological stress tests, following recommendations of European Association of Nuclear Medicine [4].

Stress-rest two day protocol was followed. 350–700 MBq Tc-99m methoxyisobutylisonitrile (MIBI) was intravenously administered on two following days, both for stress and rest imaging.

**Stress Protocols:**

For pharmacological stress test, intravenous adenosine was used. 140μg/kg/dk adenosine was infused over 6 minutes. Bolus radiopharmaceutical injection was performed on 3rd minute of infusion. For treadmill exercise stress test, Bruce protocol was followed. Radiopharmaceutical injection was perfomed at at least 85% of age-adjusted maximum predicted heart rate.

**Imaging Protocol:**

Dual head gamma camera equipped by low energy-high resolution collimator (DDD CorCam, Horsholm, Denmark) was used. Stress SPECT images were obtained 45 minutes after radiopharmaceutical injection. Stress SPECT images were acquired over 180° angular sample range, 20 sec/rotation and a total of 64 views from right anterior oblique to left posterior oblique position with detectors positioned at 90° angle, with a non-circular orbit. Rest Gated-SPECT study was performed 60 minutes later than the radiopharmaceutical administration with the same parameters of acquisition. 8-frame gating was used. A beat length acceptance window of 20% was set. Data were recorded in 64X64 matrix.
Image interpretation:

Areas of diminished perfusion were analysed with a software programme (Corridor4DM) visually and quantitatively. Left ventricular ejection fraction (LVEF) and wall motion were examined from Gated images. An even distribution of Tc-99m MIBI in the left ventricle together with a normal LVEF and wall motion is considered normal. An abnormal MPS was defined as existence of abnormal stress perfusion either resolved (ischemia) or remains constant (infarct) in rest images. Abnormal LVEF and/or wall motion was also interpreted as an abnormal scan [4].

Statistics:

Descriptive statistics were presented as mean ± standard deviation for continuous variables and percentage for categorical variables. Categorical variables were expressed as frequencies (percentage) and compared using the Pearson chi-square test. Student’s t-test was performed to compare means and chi-square test for comparison of categorical variables. P values < 0.05 were considered significant. SPSS version 25 was used for statistical analysis.

Results

A total of 179 patients (84F, 95M, mean age 58.28 ± 9.28) were involved retrospectively. 85 patients were included in the study group and 94 in the control group. Mean interval between COVID-19 PCR positivity and MPS was 90.26 ± 47.08 days (min:16 days, max:180 days). Adenosine and exercise stress was performed in 59 (69.4%) and 26 (30.5%) in the study group and in 61 (64.8%) and 33 (35.1%) patients in the control group, respectively (p = 0.52). The study and control groups were matched in terms of age and sex. No significant differences were found in the frequency of risk factors and previous coronary interventions or operations for coronary artery disease between two groups (Table 1).
Table 1
Demographics and clinical characteristics of patients in the study and control groups

|                        | Study group | Control group | P value |
|------------------------|-------------|---------------|---------|
|                        | Mean ± SD   | Mean ± SD     |         |
| Age                    | 58.13 ± 9.07| 58.43 ± 9.42  | 0.98    |
| n (%)                  |             | n (%)         |         |
| Male gender            | 43 (50.5)   | 52 (55.3)     | 0.55    |
| Hypertension           | 59 (69.4)   | 54 (57.4)     | 0.07    |
| Diabetes               | 33 (38.8)   | 36 (38.2)     | 0.53    |
| Hyperlipidemia         | 42 (49.4)   | 43 (45.7)     | 0.37    |
| Prior history of CABG  | 9 (9.5)     | 3 (3.5)       | 0.09    |
| Prior history of stent | 27 (28.7)   | 15 (17.6)     | 0.06    |
| Family History         | 40 (47)     | 52 (57.1)     | 0.23    |
| Smoking                | 35 (41.1)   | 48 (52.1)     | 0.30    |
| Obesity                | 32 (37.6)   | 40 (42.5)     | 0.27    |
| Chest pain             | 48 (56.4)   | 48 (51)       | 0.28    |
| Dispnea                | 35 (41.1)   | 13 (13.8)     | < 0.001 |

In the analysis of the dominant symptom for referral to MPS, dispnea was apparently more common among the patients in the study group compared to the control group (p < 0.001) but the frequency of chest pain did not differ among the groups (p = 0.28) (Table 1). Myocardial perfusion scan was abnormal in 85 patients (45.5%). Ischemia was reported more frequently among patients with a history of COVID-19 infection (p < 0.001) (Table 2).

Table 2
Distribution of frequencies of myocardial perfusion scintigraphy results among the study and control groups.

|                        | Study group | Control group | P value |
|------------------------|-------------|---------------|---------|
|                        | n (%)       | n (%)         |         |
| Abnormal MPS           | 46 (48.9)   | 39 (54.1)     | 0.09    |
| Ischemia               | 39 (45.8)   | 19 (20.2)     | < 0.001 |

When it comes to clinical evaluation, regardless of the MPS results, the necessity for invasive evaluation with coronary angiography and treatment (either medical therapy or invasive interventions, that is, stent
implantation or CABG) was higher in the study group ($p = 0.006$ and $p = 0.015$). The same was true for patients with abnormal MPS results ($p = 0.008$ and $p = 0.024$) but not for the patients with MPS result ischemia ($p = 0.29$ and $p = 0.06$) (Table 3).

Table 3
Follow up results in control and study groups according to MPS results.

| MPS result                | Study group | Control group | P value |
|--------------------------|-------------|---------------|---------|
| Any MPS result           | Necessity for CAG 33 (38.8) | 19 (20.2) | 0.006 |
|                          | Treatment (medical, stent implantation or CABG) | 30 (35.2) | 18 (19.1) | 0.015 |
| Abnormal MPS result      | Necessity for CAG 32 (69.5) | 16 (41.0) | 0.008 |
|                          | Treatment (medical, stent implantation or CABG) | 29 (63.0) | 15 (38.4) | 0.024 |
| Ischemia on MPS          | Necessity for CAG after ischemia on MPS 23 (58.9) | 11 (57.8) | 0.29 |
|                          | Treatment (medical, stent implantation or CABG) | 27 (58.6) | 15 (38.4) | 0.06 |

Among 39 patients with ischemia on MPS in the study group, 11 patients were taken under follow up without coronary angiography and medical therapy was started. 5 patients refused coronary angiography and 23 patients were evaluated with coronary angiography. Stent implantation was performed in 2/23 patients, CABG in 1 patient and in 20/23 patients medical therapy was preferred due to noncritical stenosis in the coronaries. One of the patients with stent implantation had no previous history of coronary artery disease or any risk factors.

Discussion

COVID-19 has appeared as a game changer in the world, affecting millions of people with a wide range of symptoms, as well as late complications some of which are surprisingly frequent and life-threatening. Acute cardiac and vascular involvement in COVID-19 infection was reported in mostly hospitalized cases: myocarditis, acute coronary syndrome, pulmonary thromboembolism, cerebrovascular events etc. Although acute coronary syndrome was relatively rare at initial presentation or during hospitalisation, it could even affect patients with no obstructive coronary disease [5]. Endothelial disfunction, progression of atheromatous plaque formation, emotional factors or hypoxia causing autonomous disfunction, increased sympathetic vasomotor tonus and diminished hemodynamics along with instability of the plaques caused by systemic inflammation were the pathophysiological mechanisms explained so far [6–8].
“Long-COVID” is the term referring to the clinical situation where signs or symptoms of acute COVID-19 have prolonged or new signs or symptoms developed over 12 weeks [9]. Chest pain was also defined as a possible component of “Long COVID” and many imaging studies have demonstrated that myocardial involvement existed in symptomatic patients in the late period [10–16].

Except from direct myocardial involvement, late coronary vascular events have also been demonstrated recently. A young female case has attended to hospital with chest pain 1 month later than recovery from severe respiratory syndrome caused by COVID-19. She had no previous history of cardiac disease or any known risk factors. Authors advocated that, as proven with adenosine stress cardiac myocardial MRI in this case, coronary microvascular ischaemia may have been the mechanism of persistent chest pain after recovery from COVID-19 [17]. Another case report presented a similar scenario on a young male patient, with gradually progressive dispnea on exercise. He was then diagnosed with acute cardiac failure due to nonobstructive coronary artery disease presenting with extensive myocardial infarction [18]. In our study, the indication of MPS was most commonly dispnea, but not chest pain. This finding actually points a gap in the literature. Dispnea may exist as a component of Long COVID in up to 40% of cases [19]. However, its relation to coronary vascular involvement is still unclear.

Myocardial perfusion scintigraphy is the most frequently used functional imaging tool for assessing obstructive coronary artery disease risk. There exists a small amount of articles studying myocardial perfusion scintigraphy in COVID-19 patients.

Hasnie et al have performed stress testing and myocardial perfusion imaging in 15 patients after recovery from COVID-19 and stated that both regadenoson and exercise stress tests were safe and stress myocardial perfusion scan can be used reliably in evaluation of ischemic heart disease after COVID-19 infection [20].

Hasnie et al. and Nappi et al have hypothesized that the percentage of abnormal myocardial perfusion images would increase in the pandemic period, because those who have mild symptoms and a probably normal SPECT MPI would delay their examinations. However, no such significant increase was observed [3, 21].

The aim of this study was different than these previous reports, we focused only on patients with COVID-19 history and documented the increase in the incidence of ischemia demonstrable by MPS, compared to non-infected cohort. Although stent implantation was performed only in 2/39 and CABG in 1/39 patients, ischemia was evident on myocardial perfusion scan in these patients. Keeping all other risk factors constant among the study and control group, COVID-19 has appeared as the possible reason for this difference in the frequency of ischemia between the study and the control group. Demonstration of ischemia reflects the functional changes in myocardial blood flow with stress, which supports the reported clinical cases and previously suggested possible pathophysiological mechanisms affecting myocardial blood flow after COVID-19 infection [5]. One patient with no previous history of coronary artery disease or any mentioned risk factors who come up with ischemia on MPS after recovery from COVID-19 is also meaningful considering the case reports mentioned above. The frequency of obstructive
coronary disease indicating coronary interventions could be expected to be higher after COVID-19, concerning these microvascular endothelial changes, but it was found similar to the control group. Incidence of hospital admissions with acute MI was reported to be higher than the pre-pandemic period, but incidence of ischemia was not studied before [2]. Our results suggest that together with acute coronary syndromes, as a reflection of coronary disfunction after recovery from COVID-19, ischemia on myocardial perfusion scan induced by stress testing is also more frequent compared to non-infected matched group of patients.

In clinical practice, MPS results guide patient evaluation by determining coronary artery risk. In our study, the number of coronary angiographies performed was higher in the study group. Initiation of medical therapy or invasive revascularisation therapies (stent implantation or CABG) were also higher in patients after recovery from COVID-19. We believe that this finding deserves attention as there are no similar results reported before, keeping in mind that obviously we are still lack of evidence to talk about a direct causal relationship between symptomatic COVID-19 infection and coronary artery disease. The reason why we couldn't demonstrate such an increase in patients with ischemia (a statistically nonsignificant increase in frequency of initiation of treatment still exists, with a p = 0.06, Table 3) but generally in the whole study group regardless of the MPS results, may be the five patients in the ischemia group who didn’t accept to undergo CAG.

The main limitation of this study was its retrospective design. Loss of patient data and follow up results led to a relative decrease in the number of subjects included. Further prospective studies are necessary to confirm above mentioned results. Another thing is that COVID-19 is still a matter of debate with multiple unexplained issues in clinical practice. Together with vaccines and treatment methods, diagnosis and imaging remain an important area of clinical investigation to better understand and make provisions against late complications.

**Conclusion**

There is a significant increase in the frequency of ischemia on MPS in patients with a history of COVID-19 infection in the last 6 months. Frequency of undergoing coronary angiography, stent implantation or CABG and initiation of medical therapy is also increased. MPS is a reliable method to investigate ischemia and guide management in patients who present with cardiovascular symptoms in the late COVID period.
