© Springer

Abstract A filament disappearance event was observed on 22 May 2008 during our recent campaign JOP 178. The filament, situated in the southern hemisphere, showed sinistral chirality consistent with the hemispheric rule. The event was well observed by several observatories in particular by THEMIS. One day before the disappearance, H\(\alpha\) observations showed up and down flows in adjacent locations along the filament, which suggest plasma motions along twisted flux rope. THEMIS and GONG observations show shearing photospheric motions leading to magnetic flux canceling around barbs. STEREO A, B spacecraft with separation angle 52.4 degrees, showed quite different views of this untwisting flux rope in He II 304 Å images. Here, we reconstruct the 3D geometry of the filament during its eruption phase using STEREO EUV He II 304 Å images and find that the filament was highly inclined to the solar normal. The He II 304 Å movies show individual threads, which oscillate and rise to an altitude of about 120 Mm with apparent velocities of about 100 km s\(^{-1}\), during the rapid evolution phase. Finally, as the flux rope expands into the corona, the filament disappears by becoming optically thin to undetectable levels. No CME was detected by STEREO, only a faint CME was recorded by LASCO at the beginning of the disappearance phase at 02:00 UT, which could be due to partial filament eruption. Further, STEREO Fe XII 195 Å images showed bright loops beneath the filament prior to the disappearance phase, suggesting magnetic reconnection below the flux rope.

Keywords: Filament disappearance; STEREO; CME; Plasma

1. Introduction

Two types of structures are commonly used to model filaments i.e., arcades structure or twisted flux tubes. Evidence of twisted flux tubes clearly appear during the eruptive phase of prominences (Gary and Moore (2004)), (Török and Kliem (2005)). Most quantitative models assume that the flux rope is in static equilibrium. 3-D magnetic models of filaments by extrapolating photospheric magnetograms into the corona have been developed (Aulanier and Démodin, 1998), (Aulanier, Srivastava, and Martin (2000)), (Dudík et al. (2008), ), (van Ballegooijen (2004)). Such models reproduce helical ropes overlying the polarity inversion line (PIL) and the filament plasma is assumed to be located in dips of the helical field lines. In areas where magnetic parasitic polarity elements are located close to the PIL, the dips extend away from the main body of the filament creating barbs. It is consistent with the findings of the observers (Martin and Echols (1994)), (Martin (1998)) and (Wang (2001)). One of the possible causes of filament eruption is instability (Forbes and Isenberg, 1991), (Isenberg, Forbes, and Demoulin 1993)). Determination of true filament height is an important parameter in studies of filament eruption (Schrijver et al. (2008), ).

Traditionally, this has been a difficult task and only via Hα observations of the limb prominence one could measure the filament height. The disadvantage of this method being: (i) it measures only the projected height, (ii) non-availability of magnetograms due to its location at the limb, (iii) can not be used to follow height evolution for several days and (iv) no continuity of multi-temperature observations. Only recently, with the advent of stereoscopic observations by the twin spacecraft of the Solar Terrestrial Relations Observatory (STEREO) mission called STEREO-A (Ahead) and STEREO-B (Behind), the true height of filament can be measured properly and the heating of the plasma can be tested (Kaiser et al. , 2008); (Gissot et al., 2008); (Liewer et al., 2009).

Here in this paper, we report on the multi-wavelength observations of a filament eruption event using ground as well as space based observatories during a joint observing campaign (JOP-178 from 20 to 25 May 2008). The filament was located in a large filament channel with very weak and diffuse polarities. The weak magnetic polarities in the filament channel are recognized using THEMIS/MTR instrument which has high polarimetric sensitivity and a simultaneous Hα scan. The evolution of these polarities is studied using full-disk GONG line-of-sight magnetograms which are available at a cadence of one minute. Further, we reconstruct the true filament height and eruption velocity using stereoscopic images by SECCHI/EUV instrument in He II 304 Å (∼60-80 ×10^3 K). The He II 304 Å observations are very useful in tracing filaments because (i) the filament spine is much sharper and clearer (Martin, Engvold, and Lin, 2007); (Joshi and Srivastava, 2007), and (ii) the filament can be traced up to higher altitudes compared to Hα images (Joshi and Srivastava, 2007). With the help of stereoscopic observations by STEREO mission we reconstruct the filament geometry and height during the phase. It is difficult to derive the rise velocity by height-time profile as the filament becomes very diffuse during the disappearance phase, however, we try to estimate the projected rise velocity of individual threads from movies. Also, we identify possible reconnected loops below the flux rope.
2. Observations and Results

The JOP 178 observing campaign was carried out during 20-25 May 2008. The observations were targeted on a filament near the polarity inversion line (PIL) in a weak bipolar magnetic region. The region was situated in the southern hemisphere, located at 30° S, 30° E (on 20 May 2008). In Figure 1, a BBSO Hα full-disk context image on 21 May, together with two views of the filament in He II 304 Å by STEREO, is shown. It may be noticed that the filament extends over a large area on the sun. The evolution of the filament was observed extensively using ground based Hα observations also. The Table 1 gives a listing of the various ground based observations relevant to filament disappearance during JOP-178, May 20-25, 2008. These are described in the subsequent sections.

During the eruption, which took place on May 22 around 10:45 UT, a bright structure appears in the filament channel, as shown by arrow in top-right panels in Figure 1. This feature is not visible earlier at 00:05 UT and appears around 06:00 UT. Just few hours before the disappearance phase it is seen prominently at 10:55 UT as shown in Figure 2. A movie showing evolution of the filament in EUV 195 Å wavelength by both STEREO A and B is available in the electronic version [see, movie-195 on http://tinyurl.com/movie-html]. The question is: is it due to heating of the filament plasma? Does this structure correspond to overlying loops or to reconnected loops below the filament-flux rope after reconnection, like post flare loops in flares. The geometry and the inclination of the filament computed in section 2.3.4 leads to the third solution. This structure is visible on the left side of PIL with STEREO B and on the right side of STEREO A, this implies that the structure should be located below the filament and might correspond to sheared reconnected loops. The plasma of the filament itself is not detectable at this temperature.

Further, two views of the filament from widely separated vantage points, observed by STEREO using He II 304 Å images, are shown in Figure 1. The separation angle of the twin spacecraft was about 52.4 degrees during our observations. The images were recorded by SECCHI/EUVI instrument at a cadence of 10 minutes. The STEREO data was reduced using SolarSoft and FESTIVAL libraries under IDL data analysis package. We define various data reduction steps that were followed before our analysis:

(a) co-center the two images,
(b) scale STEREO-B image to STEREO-A image size,
(c) rotate image B to same roll parameters as image A,
(d) orient both images to keep solar north up and overlay Carrington grid. This is useful for comparisons with Earth view. or,
(e) do not orient images for solar north up and overlay spherical grid with diameter equal to diameter of STEREO-A image. This gives epipolar view of the two images with homologous features lying along same line.

In section 2.3 we present analysis of these STEREO images with three different approaches:

(i) Using Movies: visually by looking at the movies of the disappearing filament. The movies were made using FESTIVAL software package (Auchere et al. (2008), ). This involved reduction steps (a), (b), (c) and (d) above.
(ii) Using Grid: by overlaying a spherical grid over the images to identify elevated structures. The data is reduced following steps (a), (b), (c) and (e).

(iii) Using SCC_MEASURE: In order to reconstruct 3D coordinates of filament using SCC_MEASURE routine of the SolarSoft SECCHI library. This routine uses so called “tiepointing” technique, where same feature is manually located in both images to reconstruct the 3D coordinates of the feature (Thompson(2006)). The technique uses “epipolar constraint” to reduce 2D problem to 1D (Inhester(2006)). This approach requires data reduction steps (a), (b), (c) and step (e) without overlaying grids.

2.1. Hα images: Meudon Solar Tower and Udaipur Solar Observatory

The Meudon Solar Tower observed the intensity and velocity field of this region in Hα line using MSDP instrument (Mein, 1977) ; (Mein, 1991). The field of view was 295×460 arcsec with a pixel size of 0.5 arcsec. The morphological evolution of the filament was covered by the Hα filtergams recorded at Udaipur Solar Observatory using Halle birefringent filter with 0.5 Å bandpass filter centered at Hα. Our observing times are summarized in Table 1. Figure 3 shows the evolution of the morphology of the filament during the period 20-22 May. The filament initially had thick spine oriented in North-South direction, later became diffuse and patchy and subsequently disappeared. The disappearing phase was slow and lasted several (~ 10) hours. Figure 4 (right) shows the Hα dopplergram on 21 May at 09:00 UT. The two arrows shows the part of the filament with blue-shifted (black) part corresponding to ~ 200 m s^{-1} and red-shifted (white) part corresponding to ~ 800 m s^{-1}. These elongated areas of blue and red-shifts suggest some twist along the filament body (Schmieder, 1985b). The contours mark the boundary of the filament which is shown in the right panel of Figure 4. We have made movies of the MSDP Hα dopplergrams and notice that the blue-shift is always seen near the southern part of the filament suggesting that the

(09:53, 15:43, 18:12 UT)
(08:38, 18:12 UT)
(09:47 UT)
Figure 1. The filament as seen in BBSO Hα full-disk image on May 21 at 23:50 UT (top left) and SECCHI/EUVI 195 Å in STEREO-A and B views at 10:45 UT (top right panel). Arrows mark the bright loops discussed in the text, which are seen on either side of the filament in A and B views. Global view of the sun and filament during its erupting phase on May 22 at 10:56 UT in He II 304 Å observed by STEREO A (bottom right) and B (bottom left). The images are co-centered, re-scaled to same size and rotated to keep solar north up. The arrows indicate the filament in the two images.
material is escaping from the lower end of the filament. However, we do not see very strong velocities during the filament disappearance in our Hα observations, probably due to slow rise and eruption of the filament. Also, the small value of blue-shift of $\sim 200$ m s$^{-1}$ is consistent with slow disappearance of the filament. However, these are line-of-sight velocities and as shown later in section 2.3.4, that the filament sheet is inclined to solar normal by about $\gamma = 47^\circ$. Thus, applying $1/\cos(\gamma)$ correction to these velocities, we get blue-shifts of $\sim 300$ m s$^{-1}$ and red-shifts of $\sim 1200$ m s$^{-1}$. The white circle in Figure 4 indicates up and downward flows at the end of one feet of the filament. Up and down flows at the feet are frequently observed (Schmieder, Raadu, and Wiik (1991)), suggesting that filament could be formed by plasma injection through the barbs. Unfortunately, it has been difficult to prove that these motions like spicule motions are frequent or continuous enough to feed the prominence. Higher resolution observations may prove it in the future.

Figure 2. The filament as seen in Fe XII 195 Å images by STEREO/EUVI. Top row shows STEREO-A view on 22 May 2008 at 00:05 UT (left panel) and 10:55 UT (right panel). Bottom row shows STEREO-B view of the filament at the same times. The bright loops (banana like structure) seen in EUV Fe XII 195 images are possibly the newly reconnected loops below the filament which are not seen at 00:05 UT and clearly seen at 10:55 UT. They appear around 06:00 UT.
Figure 3. The evolution of the filament from 20 to 22 May 2008, as seen in Hα filtergrams from Udaipur Solar Observatory. The date and time of the images are mentioned in the bottom of the corresponding panel. The filament is vanishing on May 22 (see bottom right image).

Figure 4. The intensity and velocity images in Hα line observed using MSDP instrument at Meudon Solar Tower on 21 May 2008, at 09:00 UT. The left panel shows the line center intensity while the right panel shows the dopplergram overlaid by contours of the filament. The maximum (most white) and minimum (most black) velocities are +800 m s$^{-1}$ and -200 m s$^{-1}$ respectively (positive is redshift). The white circle indicates up and downward flows at the end of one feet of the filament. Elongated areas of blue and redshifts suggest some twist along the filament body.
Figure 5. Top panel shows the position of the filament on the fulldisk Hα image (left) and magnetogram (right) observed by BBSO and SOHO/MDI respectively. The date and time of observations are indicated on the top. The THEMIS/MTR FOV is indicated by a box on the fulldisk images. Middle panel shows the THEMIS MTR scan of 20 May, (Seq. No. 14, 15:43 UT) with filament in Hα (left) and Fe I 6302 Å longitudinal flux (right). The longitudinal flux is scaled between +/- 250 Gauss in the full-disk magnetogram and between +/- 50 Gauss in THEMIS/MTR map. The filament is outlined by white contour. Bottom panel shows the horizontal flow velocity derived by applying Local Correlation Technique (LCT) to the region corresponding to MTR FOV, extracted from GONG full-disk magnetograms at the times indicated on top of the panel.
2.2. THEMIS-MTR and GONG observations

The high resolution spectro-polarimetric observations of the filament were carried out using MTR instrument of THEMIS (Bommier and Rayrole, 2002), (Bommier, Rayrole, and Eff-Darwich, 2005), (Guo et al., 2009). We choose the following three sets from MTR for this analysis (1) 20 May: seq. 14, during the early stable stages of the filament. This gives the contextual information, (ii) 21 May: seq. 16, the filament has evolved into a more diffuse patchy and broad configuration, and (iii) 22 May: seq. 2, the filament is in disappearing phase. The polarities near the feet of the filament which is detaching from the solar surface are studied. The summary of these three sets are shown in Figure 5, 6 and 8 respectively, with top panels showing full-disk Hα images and longitudinal magnetograms. The THEMIS/MTR field-of-view (FOV) is indicated by a box, while middle panels show the Hα and longitudinal magnetic field map derived from THEMIS/MTR scans. The MTR observations of the filament channel were taken in Fe I 6302 Å Hα, Na 5896 Å and Fe 5250 Å lines. The photospheric magnetic field was derived by fitting Fe I 6302 Å lines with the profiles computed using UNNOFIT (Bommier et al., 2007). The transverse magnetic field is too weak and hence is not shown in these inverted maps. The pattern of weak magnetic polarities in the filament channel as seen by high sensitivity of THEMIS/MTR measurements is recognized in full-disk GONG/MDI magnetograms as close in time as...
possible. Since the evolution of magnetic field using spectral scans is not feasible as scans take long time for a single magnetic map, we use full-disk longitudinal magnetograms from GONG instrument to study time evolution of magnetic field in the filament channel.

The evolution of magnetic polarities using GONG magnetogram is studied in these steps:

(1) MTR scans in Hα and Fe I 6302 Å line are automatically co-aligned since these are strictly simultaneous. So, the magnetic polarities of interest (POI), like polarities near filament feet or barbs or parasitic polarities are conveniently located using overlays of MTR Hα over MTR Fe I 6302 Å maps.

(2) These POI are then identified in fulldisk GONG magnetogram by matching the pattern visually. A good correspondence between GONG and MTR magnetogram panels in Figure 5, 6 and 8 is evident. The appropriate region

Figure 7. Evolution of the polarities near the filament feet (shown by arrows 1 and 2) which are recognized in MTR scan in Figure 6 (shown here as white box). The new parasitic polarities are indicated by arrows 3 and 6. The polarities 2 and 1 have evolved into polarities marked by arrows 4 and 5 respectively.
Disappearing filament seen with STEREO

Figure 8. Same as Figure 5 but for 22 May, Seq. No. 2, 09:47 UT.

is then extracted from GONG full-disk magnetograms and co-aligned using cross-correlation technique.

Thus, the co-alignment of ground-based datasets is required only among successive GONG magnetograms for Local Correlation Tracking (LCT) analysis and for making movies. GONG magnetograms are chosen because these are available most of the time in a network of six observing stations. Also, during our campaign the MDI magnetograms are available with large data gaps and therefore not used much in this work.

2.2.1. Evolution of polarities near filament barbs

The feet or the barbs are visible in THEMIS/MTR Hα image shown in Figure 6. Figure 7 shows the evolution of the polarities near the feet of the filament. These polarities are shown in panel 7(a) with arrows 1 and 2. These were identified using THEMIS/MTR scan as shown in Figure 6. This scan is represented by white box in Figure 7. In the panel 7(b) the arrow 3 shows new parasitic polarity (positive) emerging near point 2. In panel 7(c) this parasitic polarity has disappeared. Further, the two negative polarity patches corresponding to arrow 2 coalesce to form the patch shown by arrow 4. Similarly, in panel 7(d) the arrow 5 corresponds to polarity 1, merging with other positive polarity patches. The arrow 6 corresponds to another new parasitic polarity (negative) that has emerged.
in the channel. To visualize the evolution of polarities in the filament channel in general, we made a movie of the LOS magnetic field with these co-aligned GONG magnetograms. These movies are made for the duration 20 May, 09:04 UT to 22 May, 22:34 UT, which covers the entire period of THEMIS observations and also the filament disappearance event. These movies are made available online in the electronic version of this paper [see, movie-1 on http://tinyurl.com/movie-html]. The polarities in THEMIS/MTR FOV as indicated in Figure 7 by the white box, can be recognized in these movies. The magnetic field in the channel is weak, about $\pm 10$ to $\pm 40$ Gauss, and changes over tens of hours. The movie shows parasitic polarities emerging and disappearing in and around the filament channel continuously. These changes can induce the change of the footpoint barb and the untwisting flux rope (Schmieder et al., 2006).

2.2.2. Horizontal flows: Local Correlation Tracking

Further, the plasma flows in the filament channel are studied by computing horizontal flow velocities using local correlation technique (LCT) (Welsch et al., 2004), (Roudier et al., 2008). We use GONG magnetograms, separated half-an-hour apart, for computing these LCT maps during the entire period 20, 21 and 22 May. The flow maps for 20, 21 and 22 May are shown in the lower panels of Figure 5, 6 and 8 respectively, corresponding to the FOV and observing times of THEMIS/MTR. The flow velocity derived by LCT during the observations is of the order of 250 to 350 m s$^{-1}$. The LCT map for 20 May shows the shearing flow pattern, with flow vectors pointing upwards in the right side and downwards on the left side of the map, while the filament is located in between these flows. The flow field is changing continuously and on 21 May, the pattern is like a vortex. For the location of filament see white contour for 21 May THEMIS/MTR FOV. During 22 May, the flow pattern is more or less unidirectional in this small FOV and is oriented towards the remnant filament seen in 22 May THEMIS/MTR FOV. The increase of the shear flow leads to an increase in magnetic shear and destabilizes the filament. The presence of vortex flow favours canceling of magnetic flux at the location of filament feet. These motions could be responsible for canceling of flux, and later on disappearance of the foot-point barbs where the filament is tied to the photosphere and to the eruptions (Raadu et al. 1987, 1988).

2.3. STEREO SECCHI/EUVI He II 304 Å observations

STEREO/SECCHI/EUVI A and B spacecraft continuously observe the Sun in EUVI lines 171 (Fe IX), 195 (Fe XII), 284 (Fe XV) and 304 Å (He II) from two different angles. These images give stereoscopic view of the extended objects like coronal loops and filaments. The angle of separation between STEREO A and B during our observations is around 52.4 degrees. In the following we present analysis of the stereoscopic He II 304 Å observations of the filament using different methods.

2.3.1. Analysis using movies

We use stereoscopic observations from STEREO/SECCHI/EUVI A and B satellite to study evolution of filament dynamics before and during its eruption. We
made movies of the event in both STEREO-A and B observations using He II 304 Å filtergrams which were observed at a cadence of 10 minutes during the campaign. The movie is available in electronic version [see, movie-2 on http://tinyurl.com/movie-html]. The visual analysis of these observations in He II 304 Å of the filament, clearly shows that unlike Hα, the filament is extended over very large distance. We notice that prior to its disappearance the filament splits up into several thin filamentary structures parallel to filament axis, which subsequently disappear. The chirality of the filament appears to be sinistral as inferred by sense of twist of the filament threads during the eruption. The chirality inferred from the Hα data using the direction of barbs (López Ariste et al., 2006) is also sinistral. Also, globally the erupting filament seen in He II 304 Å filtergrams had a long S-shaped PIL. Thus, the filament follows the hemispheric chirality rules for filaments (Pevtsov, Balasubramaniam, and Rogers, 2003). Also from the movies it seems that the filament evolves in two phases, (i) the southern part evolves on 22 May around 2-3 UT, a faint CME reported by LASCO C2 at 02:00 UT could be associated with this part of the filament, and (ii) the north and west part which evolves between 10-12 UT. LASCO was not observing around these times. STEREO COR1 and COR2 were observing and did not detect any CME, which implies either the CME was too faint to be detected or there was no CME at all.

Further, from the movie we notice that the evolving threads observed by STEREO A, have a fan shape and an oscillating nature before disappearing. Before escaping, a few threads (Longitude=260°, Latitude=20°, in right panel of Figure 9), oscillate three times, between 09:56 and 10:16 UT, between 10:46 and 11:06, and between 11:36 and 11:46 UT. Large amplitude oscillations in a filament before disappearance have been reported earlier by Isobe et al., (2007) and Chen, Innes, and Solanki (2008). Further, the topmost threads seem to be rising with a projected velocity of about 100 km s$^{-1}$ with respect to the filament feet as estimated from the movie.

2.3.2. II. Analysis using spherical grid method

Images of He II 304 Å by STEREO/EUVI B (left image) and STEREO/EUVI A (right image) on 22 May, around 10:56 UT are shown in Figure 9. Using the grid one can differentiate the surface features from elevated structures as they do not appear at the same latitude and longitude due to projection effects. In Figure 9, the numbers 1 and 4 indicate the feet of the filament, number 2 and 3 the high-lying threads of the spine. There are clear indications that the filament sheet is not normal to solar surface, but inclined. The following observations support this inference:

(i) Even though the longitude separation between the filament and central meridian (say $\phi$) in frame of STEREO B ($\phi_B=17$ degrees) is smaller compared to that of STEREO-A ($\phi_A=35$ degrees), the width of the filament is broader in STEREO B as compared to STEREO A. Whereas, we know that for a filament sheet which is normal to solar surface, the observed width should increase with $\phi$ and reach maximum at the limb, where it would be seen as prominence.

(ii) If the filament sheet is normal to solar surface then the filament sheet in
The filament as seen in STEREO/EUVI A (right image) and B (left image) on 22 May 2008 at 10:56 UT. Spherical coordinates on a surface of 700 Mm have been drawn for given longitudes and latitudes between 240 and 260 degrees and 0 to 30 degrees respectively. Numbers 1 and 4 indicate the feet of the filament, number 2 and 3 the top threads. Notice the fan shape of the filament.

STEREO-A should be seen projected on the right side of the filament feet. While, we can observe feet 4 in both STEREO A and B images on the same side (on the left of the filament).

Thus, we infer that the filament sheet is inclined. Further, we can use the fact that filament sheet is projected on the same side (towards right) of the filament feet in both STEREO A and B, to put an upper limit on the filament inclination. We know that if the filament sheet is inclined to the line-of-sight then the inclination is equal to angle $\phi$. In which case the filament feet will be difficult to observe as these will be obscured by filament itself. Thus, from observation (ii) above we can say that filament inclination is greater than angle $\phi_A$, that is, 35 degrees. Indeed in section 2.3.4 we measure filament inclination using triangulation technique to be about 47 degrees.

2.3.3. Height measurement using SCC_MEASURE

The height of the filament spine during the eruption at 10:56 UT was reconstructed by using a routine called SCC_MEASURE, which is a part of SolarSoft IDL library for SECCHI data analysis (Thompson(2006)). The routine measures 3D coordinates from two STEREO images. It is a widget based application that allows a user to select with the cursor a common feature in both images. The user identifies a point on one image and then selects the point corresponding to
Disappearing filament seen with STEREO

the same feature on another image. The 3D coordinates are then calculated as longitude, latitude and radial distance from the center of the Sun. The radial distance is used to measure height above the solar surface. Figure 10 gives the various locations on filament spine for which the height is measured by above-mentioned procedure. The longitude, latitude and height of these locations is given in Table 2. Note that the location marked by ‘F’ is the feet of the filament.

It must be mentioned that this technique relies on identification of identical features in STEREO A and B, which is difficult due to very different projections in our case (separation angle 52.4 degrees). However, in SCC_MEASURE routine we first select a point on the filament spine in STEREO-A, and immediately the epipolar line is displayed in the adjacent STEREO-B image. Then we have to select a point along this epipolar line where it intersects the filament spine as viewed in STEREO-B image. This removes possibility of error in locating same feature in one direction (vertical direction), this is called “epipolar constraint” (Inhester(2006)). However, the main source of error that remains is the error in identification of the filament spine in STEREO-B, as it appears quite differently in both images. An estimate of error in determination of height using this technique was given by Liewer et al., (2009). They relate the error in locating the common feature in the image to an error in height by the relation \[ \Delta h \approx \Delta r / \sin \phi \], where \( \Delta r \) is the error in locating common feature in pixels and \( \phi \) is the separation angle of the two spacecraft. During our observations separation angle was about 52.4°, which leads to an error in height determination to about \( \Delta h / R_{\text{sun}} \approx 0.12\% \), taking \( R_{\text{sun}} \) for SECCHI/EUVI pair as \( \approx 1001 \) pixels.

In Figure 10 we can see that except location 2, other locations marked 1, 3, 4, 5 and 6 are clearly identified, thanks to the sharp contrast of the filament spine. The contrast is good enough so as to determine identical feature in both images within 2 to 3 pixels. Taking ± 3 pixels as the worst case error, this translates to an error of \( \approx \pm 2.5 \text{Mm} \) in the determination of height of locations 1, 3, 4, 5 and 6. For location 2, we take worst error to be ± 6 pixels (filament width at location 2 in STEREO-B), which translates to an height error of \( \approx \pm 5 \text{Mm} \). These errors are small as compared to the heights determined in Table 2.

However, one must keep in mind the inherent limitation of line-of-sight integration effect while interpreting reconstructed filaments using EUVI data. Features may look very different from different viewing angles and background features always add to the confusion. The use of scc_measure has been possible only during the eruption when identical structures could be identified in STEREO A and B images. Nevertheless, these reconstructions are the best that can be done and give more information than hitherto studied non-stereoscopic images.

2.3.4. Inclination estimate using SCC_MEASURE

The three dimensional spherical coordinates of the filament determined in Table 2 above are used to calculate the filament inclination \( \gamma \). The two positions marked 'F', the filament feet, and '6' on the filament spine are used to determine the inclination of filament sheet. These two points are chosen because they correspond to same latitude. Thus, choosing these points will yield filament inclination
The filament as viewed in STEREO-B (left panel) and STEREO-A (right panel) and the reconstruction of height along different points on the spine. The height in Mm from solar surface is given for locations marked by yellow ‘+’ marks. The location numbers are marked in blue colors. The height determined from SCC\_MEASURE routine for these locations are mentioned in Table 2. Location marked ‘F’ is the feet of the filament. The latitude of ‘F’ and ’6’ is same and the longitude separation is 8.7°, this is used to determine filament inclination along red arrow in section 2.3.4.

Table 2. 3-D coordinates of the filament spine determined using SCC\_MEASURE routine

| Location | Longitude | Latitude | Height (Mm) |
|----------|-----------|----------|-------------|
| 1        | -12.6     | -22.4    | 50          |
| 2        | -9.4      | -27.6    | 63          |
| 3        | 2.4       | -24.2    | 116         |
| 4        | 5.3       | -21.9    | 123         |
| 5        | 7.5       | -19.6    | 113         |
| 6        | 9.0       | -18.3    | 99          |
| F        | 0.3       | -18.3    | 0           |

along latitudinal direction. Further, these locations have longitudinal separation, $\theta = 8.7°$. Figure 11 illustrates that using the height, $H$, of ‘6’ to be 99 Mm, and $\theta = 8.7°$ we can estimate $d = \theta R_{\text{sun}} = 106$ Mm and thus determine angles $\phi = \tan^{-1} (H/d)$ to be 43°, and thus the inclination, $\gamma$, of the segment of the filament sheet shown by red arrow between ‘F’ and ‘6’, is about 47°.

3. Discussion and Conclusions

A long S-shaped filament composed of several segments and located in the Southern hemisphere was disappearing between May 20-22, 2008. This was observed during a coordinated campaign (JOP-178) involving ground-based instruments, THEMIS on the Canary Islands, MSDP at the Meudon solar tower, GONG magnetograph and Hα telescope in Udaipur, as well as space-based instruments.
Disappearing filament seen with STEREO

Figure 11. The filament inclination is estimated using the 3-D coordinates of locations 'F' and '6' derived in Table 2. The latitude is same, while longitude separation $\theta = 8.7^\circ$, height $H = 99$ Mm, solar radius $R_{\text{sun}} = 700$ Mm, $d = \theta R_{\text{sun}} = 106$ Mm. Thus, using $\tan \phi = H/d$, we get $\phi = 43^\circ$ and $\gamma = 47^\circ$.

SOHO/MDI and SECCHI/EUVI aboard STEREO. H\alpha instruments observed the progressive disappearance of the filament, segment after segment, between May 20 to May 22. It was a long process with some impulsive phases. The last H\alpha segment was visible on May 22 till 10:00 UT while the long spine of the S-shaped filament was observable in He II 304 Å till 15:30 UT. Before disappearing filament segments showed high dynamics in H\alpha with blue and red shifts parallel to the filament axis.

MDI and GONG magnetograms show that the filament is located along the polarity inversion line between two weak magnetic field regions. The magnetic field in the filament channel was weak and rapidly changing. Local correlation tracking techniques applied to GONG polarities showed strong shear between these two regions two days before the eruption, then some vortex pattern and no noticeable motion after the eruption. THEMIS magnetograms allowed us to identify weak minority polarities associated with the filament feet. The canceling flux/polarities in the vicinity of the feet were observed in the GONG movies a few hours before the disappearance of the associated segment. Such cancelation of flux and disappearance of the foot-point barbs where the filament is tied to the photosphere could lead to eruptions (Raadu et al. 1987, 1988).

The angular separation between STEREO A and STEREO B spacecraft was 52.4 degrees during our observations, which gave quite different views of the filament. We used different methods to study the filament disappearance using He II 304 filtergrams: (i) study of filament dynamics and estimation of the projected rise velocity of thread-like structures using He II 304 movies, (ii) by overlaying a spherical grid over the solar surface drawn over a sphere of 700 Mm to identify elevated features and filament feet and put an upper limit on the filament inclination, and (iii) using the triangulation algorithm SCC_MEASURE (part of STEREO data analysis library in Solarsoft package) to compute the altitude and inclination of the filament over the chromosphere during its disappearance phase. These methods give consistent results.

The stereoscopic reconstructions using SECCHI/EUVI observations of 19 May 2007 filament eruption event were reported recently by (Liewer et al., 2009)
and (Gissot et al., 2008). While Liewer et al., (2009) used scc_measure for reconstruction, Gissot et al., (2008) used optical flow method to find displacements between features in stereoscopic pairs of SECCHI/EUVI 304 Å images. The results of these two techniques are in good agreement (Liewer et al., 2009). These results for the 19 May 2007 event showed that the filament eruption was asymmetric and whip-like. The filament disappearance in our case is different from their study in two ways (i) filament was rooted in a weak diffuse bipolar magnetic region not in an active region, and (ii) there was no CME recorded for our filament disappearance event (however, one cannot rule out a CME as it could be below detection threshold). The length of the filament is too large spanning more than 10° in latitude, as seen in He II 304 Å images. We also use scc_measure to derive three-dimensional geometry of the filament which is used to derive its height and inclination. The filament was highly inclined to solar normal by about 47°. Such large inclinations are interesting as theoretical models of filaments consider filament sheet as thin vertical slab. The maximum filament height determined during the disappearance phase around 10:56 UT is estimated to be about 123 Mm in the middle portion of the filament. Determining height evolution of filament during the disappearance phase was difficult as it became quite diffuse, making identification of common features very difficult. The presence of fine threads running parallel to filament spine could be seen in movies. These threads are so tiny that it was difficult to track them over the chromosphere in the later phases, i.e., after around 11:00 UT. Only the EUVI movies allowed us to distinguish them over the chromosphere. The initial dense filament became an untwisting flux rope with multiple threads with a fan-shaped structure which rose and disappeared one by one into the corona. The plasma becomes optically so thin as the flux rope rapidly expands in the corona that it remains no longer visible.

Bright structure observed in STEREO A and B images at 195 Å is interpreted as reconnection loop system, located below the filament (flux-rope). This bright structure is not visible earlier at 00:00 UT and appears during the onset of rapid disappearance phase at about 06:00 UT. The plasma of the filament is less and less dense as the flux rope rises and expands. As the plasma is dispersed it is no more visible in filter 304 Å nor in 195 Å. No CME was reported during this last phase (LASCO was not observing) by COR1 and COR2, the two coronagraphs aboard STEREO. The CME might be too faint to be detected or the magnetic field might be too weak to prevent the plasma’s expansion to undetectable density levels.

Ground based data are very useful to understand the context of the event. Up to now we have the knowledge of eruption phenomena principally by using instruments with low temporal and/or spatial resolution. These observations are still largely used to study the association of filament eruption and CMEs. On the other hand high-cadence instrumentation with high-resolution have made a breakthrough in the nature of the dynamics of filament fine-structures. Non-eruptive filaments show counter-streaming flows along the fine structures and up-and-down flows in the filament-end ((Zirker, Engvold, and Martin(1998)), (Lin et al.(2005), ), (Berger et al.(2008), )). These velocities are lower than 10
Disappearing filament seen with STEREO

km s$^{-1}$. With STEREO and ground-based observations we can find some relationship between the dynamics at large-scale and at small-scale. The Hα doppler velocities associated with the filament, that we measure in the present paper, are relatively small but they confirm previous observations of activated filaments with low spatial-resolution instruments ([Schmieder et al. (1985a), ],[Schmieder, 1985b]). The pair of aligned and elongated regions of oppositely directed velocities are interpreted in terms of a twisted magnetic flux rope. The STEREO observations allow perspective effect to be removed in doppler velocities by taking into account the filament inclination. The corrected velocities are about 1.5 times more. The Doppler-shifts are also lower due to the computation by using the bisector method and not taking account the background chromosphere. In the paper by (Schmieder et al. (1985a), ) and (Schmieder, 1985b), they could derive larger velocities by a factor 2 between the foot-points and of the order of 10 km s$^{-1}$ in the feet using a cloud model method. That is probably what we could expect with our present observations using the cloud model method. The standard method (bisector) indicates the general trend of the velocities with large uncertainty but indicates clearly that the filament is activated. The day before we did not observe such organized velocity pattern.

In the future, development of ground based instruments like dual-beam doppler imaging system, being developed at Udaipur Solar Observatory (Joshi et al. (2009), ) for detecting filament activation using high-cadence Hα dopplergrams, and combined observations with STEREO will lead to further developments in our understanding of the filament eruptions.

Acknowledgements The authors thank CNRS for allocating observing time on THEMIS. THEMIS is a French-Italian telescope installed at Observatorio El Teide, Tenerife, Spain. The observations from BBSO, GONG and SOHO are acknowledged. We thank V. Bommier for providing her UNNOFIT code for inversion of Stokes profiles. We also thank Arturo Lopez Ariste, G. Ruyma and Cyril Delaigue for help in observations and data reductions. Further, SG acknowledges CEFIPRA funding for his visit to Observatoire de Paris, Meudon, France under its project No. 3704-1. Also, SG acknowledges travel support to THEMIS, Tenerife by Observatoire de Paris, Meudon. We thank Frédérique Auchère for the STEREO movies. We also thank G. Molodij, J. Moity for the observations at the solar tower and P. Mein for helping in the MSDP data reduction. This work was supported by the European network SOLAIRE (MTRN_CT_2006_035484).
