Received 3 July 1997/Returned for modification 5 September 1997/Accepted 10 October 1997

Helicobacter pylori NCTC 11637 lipopolysaccharide (LPS) expresses the human blood group antigen Lewis x (Le\(^a\)) in a polymeric form. Le\(^b\) is \(\beta\)-D-galactose-(1-4)-(\(\alpha\)-D-fucose-(1-3))-\(\beta\)-D-acetylmuraminic acid. Schematically the LPS structure is (Le\(^a\))\(_n\)-core-lipid A. In this report, we show that Le\(^a\) expression is not a stable trait but that LPS displays a high frequency (0.2 to 0.5%) of phase variation, resulting in the presence of several LPS variants in one bacterial cell population. One type of phase variation implied the loss of \(\alpha\)-1,3-linked fucose, resulting in variants that expressed nonsubstituted polyglycosamines (also called the i antigen), i.e., Le\(^a\) minus fucose; LPS: (lactosamine)\(_n\)-core-lipid A. The switch of Le\(^a\) to i antigen was reversible. A second group of variants arose by loss of polymeric main chain which resulted in expression of monomeric Le\(^b\); LPS: (Le\(^b\))\(_n\)-core-lipid A. A third group of variants arose by acquisition of \(\alpha\)-1,2-linked fucose which hence expressed Le\(^b\) plus Le\(^a\); LPS: (Le\(^b\))(Le\(^a\))\(_n\)-core-lipid A. The second and third group of variants switched back to the parental phenotype [(Le\(^a\))\(_n\)-core-lipid A] in lower frequencies. Part of the variation can be attributed to altered expression levels of glycosyltransferase levels as assessed by assaying the activities of galactosyl-, fucosyl-, and N-acetylgalactosaminyltransferases. Clearly this phase variation increases the heterogeneity of H. pylori, and this process may be involved in generating the very closely related yet genetically slightly different strains that have been isolated from one patient.

Helicobacter pylori is involved in the pathogenesis of gastritis, gastric glandular atrophy, duodenal and gastric ulcer, gastric adenocarcinoma, and mucosa-associated lymphoid tissue lymphoma (12). How bacteria belonging to a single species can give rise to such a diversity of disease entities is currently under investigation. H. pylori is genetically very diverse (9): strains from different sources are all different from each other at the DNA level (15). This genetic heterogeneity is in part due to the natural competence of H. pylori that renders this bacterium naturally transformable (24). In addition, it has been reported that recombinational events involving insertion elements occur (7). A mechanism used by other mucosal pathogens like Haemophilus influenzae (19) and Neisseria spp. (30) to increase diversity is phase variation. Phase variation (also called antigenic variation) is the reversible on-and-off switching of surface epitopes, e.g., those present on adhesins or lipopolysaccharide (LPS). Switch frequencies of 0.1% in these species are common. Genetically, this is paralleled by on-and-off switching of specific genes coding for surface structures, such as the glycosyltransferase genes involved in LPS biosynthesis. Often, those glycosyltransferase genes contained oligonucleotide repeats in the 5' end, and one mechanism for phase variation involved replication errors due to slipped-strand base pairing in the repeat region. Recently, oligonucleotide repeats have been identified in the fucosyltransferase (FucT) genes of H. pylori (8, 16, 23). The result of phase variation is a more versatile, more heterogeneous microorganism that can cope better with a variety of different environments: with one set of genes switched on, the microorganism may be able to adhere to mucosal cells of the nasopharynx but not to survive complement attack in serum; with that particular set switched off, the reverse may apply.

H. pylori LPS O antigen expresses Lewis x and/or y (Fig. 1), and only 15% of the strains tested lacked these blood group antigens (22). The surface localization of the bacterial Lewis antigens was demonstrated by immunoelectron microscopy (6, 21). The enzymatic activity of two enzymes involved in LPS O-antigen biosynthesis (\(\alpha\)-1,3-FucT and \(B1,4\)-galactosyltransferase [GalT]) has been demonstrated (1, 21), but it is not clear by what mechanisms serotype diversity is generated.

Thus, the H. pylori O antigen expresses structures identical to that of the corresponding human blood group antigens present in the gastric mucosa (molecular mimicry) (2–4, 6, 21, 22). The identity of these LPS epitopes with molecules of the host may play a role in the induction of H. pylori-associated autoantibodies (1, 17, 18) and facilitate persistence in the gastric niche of humans (31).

We now report that expression of H. pylori LPS in a given strain is not a stable trait and that H. pylori LPS displays phase variation. From a single strain, we isolated various serotypes, all expressing different LPS structures and having different glycosyltransferase levels, which demonstrates that also in H. pylori, phase variation contributes to increased heterogeneity.

MATERIALS AND METHODS

Bacterial strains and cultivation procedures. We investigated three strains, all expressing Lewis x: the laboratory strain NCTC 11637; strain 92-1152, isolated from a patient with gastric carcinoma; and strain 3B3, isolated from the oral cavity of a patient with gastritis (1, 22). Bacteria were stored at −80°C in 20% glycerol and were subcultured on solid medium (blood agar base plus Dent supplement) before growth in the fluid phase (brucella broth with 3% fetal calf serum) under microaerobic conditions (1, 22). Apart from B1,3 (see below), none of the strains autoagglutinated.

MAbs. The following murine immunoglobulin M monoclonal antibodies (MAbs) were used: MAb 54.1F6A, specific for Lewis x (G. van Dam, Leiden, The Netherlands [25]); MAb 18S2, specific for Lewis y (R. Negrini, Brescia, Italy [1, 17, 18]); MAb 19-O-Le, specific for H type 2 and Lewis y (Bioprobe, Amstelveen, The Netherlands).
Phase variation in an H. pylori LPS mutant. Following UV irradiation, an LPS mutant (named B1.5) that lacked Lewis x expression and was strongly positive for Lewis y was isolated (for further characterization, see below). A colony blt of this mutant, probed with MAB 4D2, specific for H type 1, is shown in Fig. 2A. There are completely nonreactive colonies, colonies with reactive sectors only, and completely reactive (dark) colonies; this pattern indicates a spontaneous high-frequency clonal on switching of the H type 1 epitope.

Isolation of LPS variants from nonirradiated bacterial cells and demonstration of reversibility. Nonirradiated cells of strain NCTC 11637 and the two clinical isolates investigated also displayed phase variation behavior (Fig. 2B) but at a lower frequency, Figures 1 and 2B shows that NCTC 11637, which expresses Lewis x, has the ability to switch spontaneously to the expression of i antigen; strains expressing the i antigen did not express Lewis x (Table 1). Several of the colonies reactive with the anti-i MAb but nonreactive with anti-Lewis x, including variant K4.1, were subcultured. K4.1 was tested again to detect whether it could switch back to phenotype of the parent strain NCTC 11637. Indeed, K4.1 spontaneously switched to variants that reacted with anti-Lewis x MAbs but not with the anti-i MAb. The frequency of switching from Lewis x to i was determined in multiple experiments and equaled 49/11,080 (0.44%); the switchback frequency was 17/3,095 (0.55%). One of the switchback variants (strain K5.1 [Table 1]) was isolated. Switching from Lewis x to i-antigen expression also took place in the two clinical isolates tested (not shown). Forty percent of the 106 clinical isolates tested proved positive for the i antigen. Parallel colony blots of NCTC 11637 probed with 19-O-Le (anti-Lewis y) and 54.1F6a (anti-Lewis x) (Fig. 2C and D, respectively) showed the presence of two other variants, i.e., variants that strongly expressed both Lewis x and y (for example, strain 1b [see below]; frequency, 1.5%). The majority of the colonies strongly expressed Lewis x and reacted weakly with the anti-Lewis y MAb. Three such colonies (2a, 2b, and 3c) were subcultured and characterized. Their reactivity pattern was identical to that of the parental strain (Table 1).

Immunochromatographic analysis of variants. Immunochromatographic data for all mutants and variants isolated by us from strain NCTC 11637 are shown in Table 1 and in Fig. 3 and 4. Variant K4.1 (Fig. 3a) expressed an LPS similar to that of the parent strain: the O antigen expressed Lewis x, not i antigen. The frequency of switching from Lewis x to i was determined in multiple experiments and equaled 49/11,080 (0.44%); the switchback frequency was 17/3,095 (0.55%). One of the switchback variants (strain K5.1 [Table 1]) was isolated. Switching from Lewis x to i-antigen expression also took place in the two clinical isolates tested (not shown). Forty percent of the 106 clinical isolates tested proved positive for the i antigen. Parallel colony blots of NCTC 11637 probed with 19-O-Le (anti-Lewis y) and 54.1F6a (anti-Lewis x) (Fig. 2C and D, respectively) showed the presence of two other variants, i.e., variants that strongly expressed both Lewis x and y (for example, strain 1b [see below]; frequency, 1.5%). The majority of the colonies strongly expressed Lewis x and reacted weakly with the anti-Lewis y MAb. Three such colonies (2a, 2b, and 3c) were subcultured and characterized. Their reactivity pattern was identical to that of the parental strain (Table 1).

Immunochromatographic analysis of variants. Immunochromatographic data for all mutants and variants isolated by us from strain NCTC 11637 are shown in Table 1 and in Fig. 3 and 4. Variant K4.1 (Fig. 3a) expressed an LPS similar to that of the parent strain: both in ELISA and in blot analysis, K4.1 (Fig. 3b) reacts with the anti-i MAb but not with anti-Lewis x. Variant K5.1, a switchback variant isolated from K4.1, behaves serologically like the parent strain: the O antigen expressed Lewis x, not i antigen. The frequency of switching from Lewis x to i was determined in multiple experiments and equaled 49/11,080 (0.44%); the switchback frequency was 17/3,095 (0.55%). One of the switchback variants (strain K5.1 [Table 1]) was isolated. Switching from Lewis x to i-antigen expression also took place in the two clinical isolates tested (not shown). Forty percent of the 106 clinical isolates tested proved positive for the i antigen. Parallel colony blots of NCTC 11637 probed with 19-O-Le (anti-Lewis y) and 54.1F6a (anti-Lewis x) (Fig. 2C and D, respectively) showed the presence of two other variants, i.e., variants that strongly expressed both Lewis x and y (for example, strain 1b [see below]; frequency, 1.5%). The majority of the colonies strongly expressed Lewis x and reacted weakly with the anti-Lewis y MAb. Three such colonies (2a, 2b, and 3c) were subcultured and characterized. Their reactivity pattern was identical to that of the parental strain (Table 1).
antigen. We hypothesized that the switch from parent to K4.1 implied the loss of α1,3-fucose, which was regained upon switching from K4.1 to K5.1. Serologically, the mutants K1.4, K2.1, and K3.1 were identical to the K4.1 variant. Figure 4 shows that variant 1b had lost its polymeric main chain and now synthesized a low-molecular-mass LPS expressing Lewis y but not Lewis x. Serologically, mutants B1.5 and B2.1 are identical to variants B3.1 and 1b. Strain 1c expressed a polymeric Lewis x ladder, runs of the ladder being capped with Lewis y and with slightly more runs in the lower-molecular-weight zone compared to the parent. Variant 3a reacted less than the parent or not at all with 4D2 in ELISA or blot analysis, respectively. This variant expressed LPS that upon SDS-PAGE yielded a smear instead of a ladder (see silver stain and blot in Fig. 4).

Additional data on switch frequencies of *H. pylori* NCTC 11637, LPS mutants, and variants are shown in Table 2. The switching behavior of mutants was similar to that of the variants: mutant K1.4 (Lewis x⁻, i⁺) switched back to Lewis x⁺, i⁻ at a frequency of 0.2%. One K1.4 derived switchback variant (called K6.1 [data not shown]) was isolated and found to be able to switch to Lewis x⁺, i⁻, which is further proof of the reversibility of the Lewis x-to-i-antigen switch. In contrast, mutants and variants that were Lewis x⁻, Lewis y⁺ did not switch back (mutant B1.5, variant B3.1) or did so in extremely low frequencies (variant 1b, switchback frequency, 1/1,400). We also did not find switchbacks of variant 1c (Lewis x⁻, Lewis y⁻). The serotype that most often is expressed by colonies of NCTC 11637 (strong Lewis x⁻, weak Lewis y⁻; variants 2b and 3c) switched to strong expression of Lewis y⁺ at frequencies of 0.28 to 1%.

**Glycosyltransferase assays.** To study the enzymatic basis for the phenotypic differences observed, the activities of three relevant glycosyltransferases were assayed in some of the variants. Various activities were found (Table 3), with highest GalT activity in the parental strain (NCTC 11637) and highest FucT activity in variant 1c, while the activity of GlcNAcT was below the detection limit in variant 1b. Except for the latter

FIG. 2. (A) Colony blot of LPS mutant B1.5 probed with MAb 4D2 Mab (anti-H type 1). (B) Colony blot of nonirradiated strain NCTC 11637 probed with MAb NAM61-1A2 (anti-i). (C) Colony blot of nonirradiated strain NCTC 11637 probed with MAb 19-O-Le (anti-Lewis y). (D) Colony blot of nonirradiated strain NCTC 11637 probed with MAb 54.1F6A (anti-Lewis x). Variant 1c (●) expresses both Lewis x and y; variant 1b (►) expresses Lewis y but lacks Lewis x.
TABLE 1. Characterization of *H. pylori* NCTC 11637 LPS mutants and variants

| Strain     | ELISA reactivity with MAbsa |  |
|------------|----------------------------|---|
|            | Anti-Lewis y | Anti-Lewis x | Anti-H type 1 | Anti-i |

| 3c         | +           | ++          | +            | +     |
| 3a         | –           | ++          | +            | +     |

a. ++, optical density (OD) < 0.3; +, 0.3 < OD < 1.3; ++, 1.3 < OD < 2.3; +++, OD > 2.3.

b. D1.1 was isolated as an anti-H type 1-negative variant of the K3.1 mutant.
c. OD < 0.35.
d. OD < 0.8.

In this report, we show that *H. pylori* LPS displays phase variation. Reversible Lewis x-to-i-antigen switching was observed, at frequencies of about 0.4%. We also observed switches implying loss of polymeric main chain (Lewis x⁺⁻, Lewis y⁻⁻; for example, variant 1b) as well as switches implying strong expression of Lewis y (Lewis x⁺⁺, Lewis y⁺⁺; for example, variant 1c). By chemical means, strain NCTC 11637 was shown to express Lewis x (2), but in the past we have described the presence of low amounts of Lewis y in this strain as measured by serology (1); this finding was confirmed in this study. We assume that serology is more sensitive than structural-chemical methods. The presence of nonfucosylated polylactosamine stretches (i.e., the i antigen) has already been demonstrated by chemical methods (2). Our report is the first one on phase variation in *H. pylori* LPS; however, Bukholm et al. (5a) have reported the occurrence of reversible variants in colony morphology.

In previous reports (1, 18), we have suggested a pathogenic role for *H. pylori* LPS-induced anti-Lewis antibodies that cross-react with gastric mucosal antigens of the host. To further study the role of Lewis x, we isolated UV-induced Lewis x⁻⁻ mutants (Table 1). By serendipity, we discovered that a mutant (B1.5 [Fig. 2A]) displayed clonal expression of the epitope recognized by MAb 4D2, specific for H type 1 antigen. However, no H type 1 antigen can be detected in LPS of strain NCTC 11637 by structural-chemical means, and possibly the reactivity with strain 11637 represents a cross-reaction. Due to these uncertainties, we did not study phase variation of this epitope any further.

In contrast, the events taking place during phase variation of Lewis x to i antigen (and vice versa) can be understood at the molecular level, based on serological data (Table 1; Fig. 3) and on the primary structure of the LPS of *H. pylori* NCTC 11637 (Fig. 1). We postulate that the Lewis x antigen of strain 11637 switches to the i antigen by loss of the 1,3-linked fucose. A summary of the postulated LPS structures of the various variants and their possible interrelationships is shown in Fig. 5. The chemical structures of the LPS of the variants is under investigation. The presence of FucT enzymatic activity in *H. pylori* has been reported (1, 6), and hence it was conceivable that this Lewis x-to-i-antigen switch actually involved the on and off switching of the gene coding for *H. pylori* α3-FucT. Variant K4.1 shows FucT activity yet is Lewis x negative.

DISCUSSION

In this report, we show that *H. pylori* LPS displays phase variation. Reversible Lewis x-to-i-antigen switching was observed, at frequencies of about 0.4%. We also observed switches implying loss of polymeric main chain (Lewis x⁻⁻, Lewis y⁻⁻; for example, variant 1b) as well as switches implying strong expression of Lewis y (Lewis x⁺⁺, Lewis y⁺⁺; for example, variant 1c). By chemical means, strain NCTC 11637 was shown to express Lewis x (2), but in the past we have described the presence of low amounts of Lewis y in this strain as measured by serology (1); this finding was confirmed in this study. We assume that serology is more sensitive than structural-chemical methods. The presence of nonfucosylated polylactosamine stretches (i.e., the i antigen) has already been demonstrated by chemical methods (2). Our report is the first one on phase variation in *H. pylori* LPS; however, Bukholm et al. (5a) have reported the occurrence of reversible variants in colony morphology.

In previous reports (1, 18), we have suggested a pathogenic role for *H. pylori* LPS-induced anti-Lewis antibodies that cross-react with gastric mucosal antigens of the host. To further study the role of Lewis x, we isolated UV-induced Lewis x⁻⁻ mutants (Table 1). By serendipity, we discovered that a mutant (B1.5 [Fig. 2A]) displayed clonal expression of the epitope recognized by MAb 4D2, specific for H type 1 antigen. However, no H type 1 antigen can be detected in LPS of strain NCTC 11637 by structural-chemical means, and possibly the reactivity with strain 11637 represents a cross-reaction. Due to these uncertainties, we did not study phase variation of this epitope any further.

In contrast, the events taking place during phase variation of Lewis x to i antigen (and vice versa) can be understood at the molecular level, based on serological data (Table 1; Fig. 3) and on the primary structure of the LPS of *H. pylori* NCTC 11637 (Fig. 1). We postulate that the Lewis x antigen of strain 11637 switches to the i antigen by loss of the 1,3-linked fucose. A summary of the postulated LPS structures of the various variants and their possible interrelationships is shown in Fig. 5. The chemical structures of the LPS of the variants is under investigation. The presence of FucT enzymatic activity in *H. pylori* has been reported (1, 6), and hence it was conceivable that this Lewis x-to-i-antigen switch actually involved the on and off switching of the gene coding for *H. pylori* α3-FucT. Variant K4.1 shows FucT activity yet is Lewis x negative.

| Strain     | MAb       | Estimated no. of colonies on blots | No. (%) of positive colonies |
|------------|-----------|-----------------------------------|-----------------------------|
| K1.4 mutant | Anti-Lewis x | 3,000                            | 5 (0.2)                     |
| K6.1 variant | Anti-i     | 5,000                            | 39 (0.78)                   |
| B1.5 mutant | Anti-Lewis x | 900                              | 0 (0)                       |
| B3.1 variant | Anti-Lewis x | 6,386                            | 0 (0)                       |
| 1b variant  | Anti-Lewis x | 1,400                            | 1 (0.07)                    |
| 2b variant  | Anti-Lewis y | 1,850                            | 19 (1)                      |
| 3c variant  | Anti-Lewis y | 6,400                            | 18 (0.28)                   |
| 1c variant  | Anti-Lewis x | 3,200                            | 0b                          |
| 1c variant  | Anti-Lewis y | 3,200                            | 0b                          |

a. K6.1 is a phase variant (Lewis x⁺⁺, i⁻⁻) isolated from K1.4 mutant.
b. Number of negative colonies.
Whether the measurement of FucT activities of a value in this respect is not clear, because in the past it has been shown that strains strongly positive for Lewis x may have lower FucT activities than strains expressing less Lewis x (6). It is also conceivable that genes coding for enzymes of the pathway leading to the donor substrate for FucT, GDP-Fuc, are involved in the Lewis x-to-i phase variation.

We observed the occurrence of i antigen to Lewis x switches first in strains that had been obtained from NCTC 11637 after UV irradiation (strains K1.4, K2.1, and K3.1). Later, switches were shown to occur also in nonirradiated cells. The reversibility of the phenomenon was investigated extensively, and we demonstrated that both spontaneous Lewis x-to-i-antigen switches and i antigen-to-Lewis x switches occurred at the same frequency, 0.44 and 0.55%, respectively. By using our colony blot procedures, we succeeded in isolating variants that had spontaneously switched from Lewis x to i antigen (e.g., K4.1) and a variant (K5.1) that had switched back again from i antigen to Lewis x. Mutants K1.4, K2.1, and K3.1 (all i+) also switched back spontaneously to Lewis x-positive cells, and one Lewis x-positive variant (K6.1 [data not shown]) that again switched to i+ at a frequency of 0.78% was isolated. In short, phase variation in the Lewis x to i antigen is reversible.

The presence in human sera of antibodies to the i antigen has been reported; these antibodies belong to the group of so-called cold agglutinins (CAs) (20). CAs recognize epitopes on erythrocytes and cause agglutination. As many H. pylori strains express the i antigen, it is possible that they induce CAs.

Second, we also studied mutants and variants that strongly expressed Lewis y and were negative for Lewis x (B1.5, B2.1, B3.1, and 1b [Table 1; Fig. 4]). Analysis of the lengths of these LPSs by SDS-PAGE showed that the polymeric main chain was lost. Apart from the core, only a single band could be seen. Strains that express Lewis y only, as determined both by chemical-structural analysis and by serology, have been described before (strain MO19 [4] and serotype O6 [1b]), and likely strains B1.5, B2.1, B3.1, and 1b are similar to MO19 and serotype O6 (Fig. 1). The single, Lewis y-expressing band (lanes 2 in Fig. 4a and 5b) likely represents a single Lewis y unit, covalently linked to the core. In contrast to the readily detected reversible phase variation Lewis x to i antigen, the switch from Lewis y to Lewis x was nondenotable in mutants B1.5 and variant B3.1 and with only one observed event of backswitching in strain 1b (Table 2). Again the similarity of the mutant and the variants is striking, and it is possible that those strains that we classified as mutants because they were isolated after UV irradiation simply are spontaneous phase variants.

In variant 1b, the switch from poly lactosamine with multimeric Lewis x to a single, Lewis y-carrying lactosamine unit appears to be due to a complete turn off of a chain-elongating GlcNAcT, as no activity was found with a substrate specific for such an enzyme. In mammals, the GlcNAcTs that link GlcNAc residues to the core regions of protein- and lipid-linked glycans differ from the aglycon-nonspecific β3-GlcNAcT that is involved in the elongation of lactosamine chains (26, 27). Because in variant 1b only one lactosamine unit is present, it is likely that also in H. pylori the attachment of a GlcNAc to the α-D-glycero-d-manno-heptose unit of the LPS core is catalyzed by a GlcNAcT that differs from the elongating enzyme. Likely, the high expression of Lewis y by variant 1b is caused by the absence of the GlcNAcT, which may compete with the α2-FucT for linking a glycosyl group to galactose. In addition, a preferred action of the α2-FucT on short lactosamine chains rather than elongated ones is possible.

Third, a switch from Lewis x to Lewis x plus Lewis y was

| Strain or variant | Glycosyltransferase activity | GalT (mU/10^10 cells) | GlcNAcT (mU/10^10 cells) | FucT (mU/10^10 cells) |
|------------------|-----------------------------|------------------------|-------------------------|------------------------|
| NCTC 11637       | 20.0                        | 33.8                   | 46.0                    |
| K4.1             | 9.3                         | 59.4                   | 15.3                    |
| K5.1             | 6.7                         | 28.2                   | 3.6                     |
| 1b               | 2.8                         | <0.1                   | 19.6                    |
| 1c               | 7.3                         | 29.9                   | 216                     |

The presence of antibodies to the i antigen has been reported; these antibodies belong to the group of so-called cold agglutinins (CAs) (20). CAs recognize epitopes on erythrocytes and cause agglutination. As many H. pylori strains express the i antigen, it is possible that they induce CAs.

Second, we also studied mutants and variants that strongly expressed Lewis y and were negative for Lewis x (B1.5, B2.1, B3.1, and 1b [Table 1; Fig. 4]). Analysis of the lengths of these LPSs by SDS-PAGE showed that the polymeric main chain was lost. Apart from the core, only a single band could be seen. Strains that express Lewis y only, as determined both by chemical-structural analysis and by serology, have been described before (strain MO19 [4] and serotype O6 [1b]), and likely strains B1.5, B2.1, B3.1, and 1b are similar to MO19 and serotype O6 (Fig. 1). The single, Lewis y-expressing band (lanes 2 in Fig. 4a and 5b) likely represents a single Lewis y unit, covalently linked to the core. In contrast to the readily detected reversible phase variation Lewis x to i antigen, the switch from Lewis y to Lewis x was nondenotable in mutants B1.5 and variant B3.1 and with only one observed event of backswitching in strain 1b (Table 2). Again the similarity of the mutant and the variants is striking, and it is possible that those strains that we classified as mutants because they were isolated after UV irradiation simply are spontaneous phase variants.

In variant 1b, the switch from poly lactosamine with multimeric Lewis x to a single, Lewis y-carrying lactosamine unit appears to be due to a complete turn off of a chain-elongating GlcNAcT, as no activity was found with a substrate specific for such an enzyme. In mammals, the GlcNAcTs that link GlcNAc residues to the core regions of protein- and lipid-linked glycans differ from the aglycon-nonspecific β3-GlcNAcT that is involved in the elongation of lactosamine chains (26, 27). Because in variant 1b only one lactosamine unit is present, it is likely that also in H. pylori the attachment of a GlcNAc to the α-D-glycero-d-manno-heptose unit of the LPS core is catalyzed by a GlcNAcT that differs from the elongating enzyme. Likely, the high expression of Lewis y by variant 1b is caused by the absence of the GlcNAcT, which may compete with the α2-FucT for linking a glycosyl group to galactose. In addition, a preferred action of the α2-FucT on short lactosamine chains rather than elongated ones is possible.

Third, a switch from Lewis x to Lewis x plus Lewis y was

|------------------|-----------------------------|------------------------|-------------------------|------------------------|
| NCTC 11637       | 20.0                        | 33.8                   | 46.0                    |
| K4.1             | 9.3                         | 59.4                   | 15.3                    |
| K5.1             | 6.7                         | 28.2                   | 3.6                     |
| 1b               | 2.8                         | <0.1                   | 19.6                    |
| 1c               | 7.3                         | 29.9                   | 216                     |
observed (strain 1c [Table 1; Fig. 4]). This variant expressed polymeric Lewis x, forming a ladder structure like its parent strain but with a much stronger expression of Lewis y; i.e., terminal α1,2-linked fucose is strongly increased. Strains with this phenotype, as determined by structural analysis and serology, have been described before (strain P466 [4] and serotype O3 [1b]). We did not observe backswitches of 1c to the parent phenotype. The mechanism involved may be a switching from low to high levels of expression of α2-FucT. It is known that in H. influenzae LPS, phase variation may involve both off-to-on switches and switches from low to high levels of expression (10).

The substrate used to assay FucT activity [Galβ1→4GlcNAcβ-O-(CH₂)₆-COMe] did not allow us to discriminate between α2- and α3-FucT. Previously it has been shown that using the same acceptor substrate the FucT in several strains of H. pylori only catalyzed the transfer of Fuc to GlcNAc in α1→3 linkage to yield the Lewis x structure (6). The high FucT activity in variant 1c might, however, in part be due to a strongly enhanced activity of an α2-FucT leading to the high expression of Lewis y. No such transfer could be demonstrated in assays using a substrate (Galβ-O-para-nitrophenol) that is known as a specific acceptor for mammalian α2-FucTs (data not shown). It has, however, been suggested that in the formation of Lewis y in H. pylori, α2-fucosylation may have to precede α3-fucosylation (16). Thus, it is conceivable that the high FucT activity in variant 1c reflects the consecutive transfers of Fuc residues in α1→3 and α1→2 linkage. Thus, α2-FucT may be involved in the switch from parental type to variant 1c. H. pylori FucT genes have been identified (8, 16, 23) and exons have been described before (strain P466 [4] and serotype O3 [16]. Structures of a class of lipopolysaccharides with reference to the location of oligomeric units of β-glucuron-α-n-mannopyranosyl residues. Eur. J. Biochem. 248:592–601.
