(Dated: March 30, 2015)

We investigate the cosmological effects of neutrino lumps in Growing Neutrino Quintessence. The strongly non-linear effects are resolved by means of numerical N-body simulations which include relativistic particles, non-linear scalar field equations and backreaction effects. For the investigated models with a constant coupling between the scalar field and the neutrinos the backreaction effects are so strong that a realistic cosmology is hard to realize. This points towards the necessity of a field dependent coupling in Growing Neutrino Quintessence. In this case realistic models of dynamical Dark Energy exist which are testable by the observation or non-observation of large neutrino lumps.

I. INTRODUCTION

The origin of the observed accelerated expansion of the universe is still unknown [1, 2]. It is usually accounted for by a Dark Energy (DE) component. The simplest possibility consistent with observations is a cosmological constant \( \Lambda \), but a lot of alternatives have been proposed [3]. Prime candidates are dynamical Dark Energy models mediated by a scalar field or modified gravity - the latter being often equivalent to the former [4]. For many alternatives the cosmological constant problem [5, 6] of explaining the small value of \( \Lambda \) persists, however. Also the explanation of why DE becomes important in the present cosmological epoch is often not more convincing than for a cosmological constant.

Growing Neutrino Quintessence (GNQ) [7, 8] offers here some advantages. As a quintessence model [9, 10] the late time acceleration is driven by a scalar field \( \phi \) (the cosmon), employing a mechanism similar to Inflation. It is possible to unify the late and early time acceleration into a single picture [11–13] so that the same field is responsible for DE and Inflation. As an overall description within quantum gravity crossover cosmology [14] GNQ also addresses the cosmological constant problem.

GNQ is able to explain the smallness of the DE component, since the dynamical DE density decays during the cosmic history, just as the other energy densities in the universe. The DE density being small is then just a matter of time - it is small because the universe is old. In contrast to simpler Quintessence models GNQ solves the Why-Now-Problem. No fine tuning of the self interaction potential is needed for this purpose. A coupling between the cosmon and the neutrinos provides a mechanism for stopping the evolution of the cosmon field as soon as the neutrinos become non-relativistic. The phenomenology of a very slowly evolving scalar field resembles a cosmological constant. The transition from relativistic to non-relativistic neutrinos acts as a trigger for the DE domination. For neutrino masses allowed by observations this transition happens in the “recent” past, explaining why DE has become important now.

Despite a background evolution similar to the \( \Lambda \)CDM model for redshift \( z \lesssim 5 \), GNQ has a phenomenology which is distinct from other models. It predicts a time varying neutrino mass and the formation of neutrino lumps, which might be detectable through there gravitational potentials [15]. The formation of lumps is a consequence of the large coupling between neutrinos and the cosmon, which is required for the stopping mechanism. The resulting additional attraction between neutrinos is about \( 10^3 \) times stronger than the gravitational attraction. It can have a natural explanation in a particle physics framework [8].

While the strong coupling on the one hand offers with the lumps a clear and distinct way of testing the model. On the other hand, it renders the model technically difficult to study. In GNQ perturbations in the neutrino density become non-linear already at \( z \approx 1 - 2 \) on very large scales [15]. This has lead to the development of a comprehensive N-body simulation [16, 17] to follow the formation of the neutrino lumps. The simulation is different from the usual CDM-only simulations: In order to include backreaction effects, induced by the highly non-linear nature of the lumps [15], the background is solved simultaneously with the perturbations. Additionally, neutrinos becoming relativistic during the formation of lumps is captured by the simulation. A similar framework for relativistic N-body simulation with focus on the metric perturbations was explored recently in [19]. With our simulation it was possible to draw a consistent picture of neutrino structures within GNQ. For stable lumps the main characteristic features can be understood within an approximation in terms of a non-relativistic fluid of neutrino lumps [20].

In this work we investigate if GNQ can provide a realistic expansion history. Therefore we study the equation of state and the energy density of the cosmon for different model parameters. We aim at finding model parameters for which the backreaction effect remains compatible with an accelerated expansion with \( \Omega_{DE} \approx 0.7 \). At the same time the accelerated expansion of the universe must start early enough to be consistent with observations.
A time dependent neutrino mass related to a scalar Dark Energy field concerns a wider setting than GNQ. Mass varying neutrino scenarios (MaVaNs) have been studied earlier in [24] and share common features with GNQ as the instability of neutrino perturbations [22–24].

This work is organized as follows. We start with a brief review of GNQ in section II. In section III we discuss the formation of lungs and their backreaction on the cosmological expansion. In section IV we describe our simulation, which we use to perform a parameter scan. Results are presented in section V. Finally, we conclude in section VI.

II. GROWING NEUTRINO QUINTESSENCE

A. Basic Concepts

In this section we briefly describe GNQ. The ingredients of GNQ are a scalar field $\varphi$ (the cosmon) and neutrinos. The neutrino mass depends on the value of $\varphi$, thereby coupling the cosmon and the neutrinos. The cosmon itself is described by the standard Lagrangian of a scalar field which takes, using the metric signature $(-, +, +, +)$ and setting the reduced Planck Mass to unity, $8\pi G = 1$, the form:

$$\mathcal{L}_\varphi = \frac{1}{2} \partial_\mu \varphi \partial^\mu \varphi + V(\varphi).$$  \hspace{1cm} (1)

We choose an exponential potential $V(\varphi) \propto e^{-\alpha \varphi}$. As long as the neutrino mass can be neglected the exponential potential leads to scaling solutions of the cosmon field. The background energy density of the cosmon becomes independent of the initial conditions and mimics a constant field. The background energy density of the cosmon is a constant that comes independent of the initial conditions and mimics a constant field. The background energy density of the cosmon is a constant field. The backreaction effect and an overall cosmology consistent with present observations. For a constant $\beta$ large backreaction effects have been observed [16]. We address here the question if the model remains compatible with observations in this case as well.

A constant coupling implies for the neutrino mass:

$$m_\nu(\varphi) = m_\nu e^{-\beta \varphi},$$  \hspace{1cm} (3)

where an additive constant in $\varphi$ is fixed such that $V(\varphi = 0) = 2.915 \cdot 10^{-7}$ eV. The $\varphi$-dependent neutrino mass allows for energy transfer between neutrinos and the cosmon, which is proportional to the trace of neutrino energy momentum tensor:

$$\nabla_\nu T^\mu_\nu(\varphi) = +\beta T^\nu_\nu \dot{\varphi}$$

\begin{equation}
\nabla_\nu T^\mu_\nu(\varphi) = -\beta T^\nu_\nu \dot{\varphi}.
\end{equation}

The trace of the energy momentum tensor $T^\mu_\nu(\varphi) = \rho_\nu + 3P_\nu$ vanishes for ultra-relativistic neutrinos. The coupling between neutrinos and the cosmon is therefore ineffective for relativistic neutrinos. The neutrino energy-momentum tensor also sources the Klein-Gordon equation which governs the evolution of the cosmological expansion.

We will describe neutrinos and dark matter by an N-body simulation. The trajectories of classical neutrinos obey a modified geodesic equation [16]:

$$\frac{d u^\mu}{d\tau} + \Gamma^\mu_{\nu\lambda} u^\nu u^\lambda = \beta u^\nu \partial_\nu \varphi u^\mu,$$  \hspace{1cm} (6)

where $u^\mu$ denotes the four-velocity and $\tau$ the proper time. The left hand side is the usual gravitational motion, with the Christoffel symbols $\Gamma^\mu_{\nu\lambda}$ determined by the metric. Throughout this work we use the Newtonian gauge for the metric:

$$ds^2 = -(1 + 2\Psi) \, dt^2 + a^2 (1 - 2\Phi) \, d\mathbf{x}^2.$$  \hspace{1cm} (7)

We will work to first order in the gravitational potentials $\Phi$ and $\Psi$ and neglect there time derivatives.

The right hand side of equation (6) describes an additional force due to the coupling to the cosmon. It consists of two parts. First, a velocity dependent part $\beta u^\nu \partial_\nu \varphi u^\mu$ compensates changes in the mass for neutrinos moving in a varying cosmological field so that momentum is conserved. A neutrino moving into a region with smaller (larger) values of $\varphi$ will lose (gain) mass. To compensate the loss (gain) of momentum it will be accelerated (decelerated). Second, a velocity independent fifth force $\beta \partial_\nu \varphi$. In the non-relativistic limit it acts as an attractive force about $2\beta^2$ times stronger than gravity [24].

B. Homogeneous Evolution

Let us now turn to the homogeneous limit and discuss how GNQ in its simplest form can lead to an accelerated expansion of the universe. At early times when the neutrinos are relativistic the evolution of the cosmon is
determined by the potential. Therefore the cosmon will evolve towards its scaling solution with the DE density decreasing with $a^{-3}$ during matter domination. In view of the growing mass the neutrinos become non-relativistic rather late. The interaction becomes important once $\alpha V(\varphi) \approx \beta T(\nu) \approx -\beta \rho_\nu$. It acts as an effective potential barrier stopping the time evolution of the energy density of the cosmon-neutrino fluid. The constant energy density then mimics a cosmological constant. Since the energy density of the neutrinos is small compared to the cosmon energy density, the coupling must be rather large. Most of the cosmological parameters as $\Omega_{DE} = \Omega_\varphi +\Omega_\nu$ and $m_\nu$ are approximately independent of the individual values of $\alpha$ and $\beta$, they only depend on the ratio. Demanding a dark energy density of $\Omega_{DE} \approx 0.7$ enforces $-\frac{2}{\alpha} \approx 5$, for a present neutrino mass $m_\nu = O(1 \text{ eV})$, where smaller neutrino masses require larger $-\frac{\beta}{\alpha}$. We note that the usual cosmological bounds on the neutrino mass from CMB and Large Scale Structure observations [30 91] do not apply here, since neutrino masses have been substantially smaller in the past. In the homogeneous limit the neutrino mass is mainly constrained by earth based experiments. Also the scale factor at which the neutrinos stop the cosmon evolution has only a moderate dependence on the individual values of $\alpha$ and $\beta$. The energy density fraction of the cosmon before stopping is given by $\Omega_\varphi \propto \alpha^{-2}$ and hence becomes smaller for larger $\alpha$. The time at which the interaction with neutrinos compensates the self interaction of the cosmon becomes earlier for larger $\alpha$. The onset of dark energy is therefore earlier for larger values of $\alpha$ and $\beta$.

As we will discuss later, strong backreaction effects will alter this simple picture. We will see in section III that backreaction effects always counteract the stopping mechanism and the cosmon will evolve again, so that it is not guaranteed that values for $\alpha$ and $\beta$ which describe a realistic cosmology in the homogeneous limit will also describe a close-to-realistic cosmology including backreaction.

Since backreaction effects can only be important after the neutrinos became non-relativistic the homogeneous description remains valid at early times. Large values for $\alpha$ are preferred by bounds on early dark energy. For large $\alpha$ the stopping mechanism acts earlier, hence also the backreaction becomes important earlier. From these qualitative considerations we already find some tension between reducing the backreaction effects, which spoil the stopping of the cosmon evolution, and satisfying bounds on EDE.

III. BACKREACTION AND EFFECTIVE EQUATION OF STATE

A. Neutrino Lumps

In GNQ it is important to understand structure formation, not only in view of using large scale structure observation as a probe for our cosmological models, especially to test DE models or “measure” the neutrino mass. It is crucial to understand the formation and evolution of neutrino lumps, before being able to judge about the viability of GNQ as a DE model. In this section we shortly review the progress towards an understanding of the neutrino lumps, for details we refer to previous work [15 16 18 20 24 29 32 34]. Our main focus lies on the strong backreaction effects from non-linear perturbations in the neutrino-cosmon fluid.

The large non-linearities have there origin in the large
coupling \( \beta = O(10^2) \). Therefore the additional force between neutrinos will be about \( 10^3 \) times larger than the gravitational interaction between neutrinos and between neutrinos and CDM. In turn the neutrino perturbations grow very quickly as soon as neutrinos become non-relativistic. This implies that the fluctuations in the neutrino energy density become non-linear even at large scales. The scale factor \( a_{NL} \), at which this happens for a neutrino perturbation of a given wavelength \( k^{-1} \) can be estimated by the value of \( a \) at which the linear dimensionless neutrino Power Spectrum \( \Delta_{\nu}(k) = k^3 P_\nu(k)/(2\pi^2) \) becomes order unity. Looking at figure 2 we see that for the particular choice of parameters \( \alpha = 10 \) and \( \beta = -52 \) already at \( a \sim 0.4 \) scales around \( k_{NL,\nu} \sim 0.01 \) h Mpc\(^{-1} \) become non-linear, while today scales around \( k_{NL,\nu} \sim 0.002 \) h Mpc\(^{-1} \) are non-linear. The exact value of the non-linear scale of neutrino-cosmon perturbations depends on the chosen parameters, but it is a generic finding that \( k_{NL,\nu} \) is smaller than the corresponding wave vector for CDM perturbations, \( k_{NL,C,0} \sim 0.1 \) h Mpc\(^{-1} \). These can be traced back to instabilities in the neutrino perturbations already present at linear order. These instabilities are stabilized non-perturbatively by the formation of neutrino lumps.

### B. Backreaction

Usually backreaction in cosmology is assumed to be negligible. In the last years several quantitative estimates \cite{35,36} came to the conclusion that backreaction is indeed small in the ΛCDM-model. In contrast, backreaction effects are crucial in GNQ. We demonstrate this in figure 3 where we compare the numerical results for the clumping neutrinos with the pure background evolution for which the effects of non-linear neutrino perturbations are neglected. We choose the parameters \( \alpha = 10 \) and \( \beta = -52 \) that have often been employed in the literature.

We find two types of backreaction effects. First, the Friedmann equation involves the volume averaged energy density, which we will define below. Second, the average value of the cosmon \( \phi \) can not be obtained by solving the homogeneous equation of motion. The Klein-Gordon Equation needs to be modified to include backreaction effects from the neutrino lumps. The reason is that the typical velocities and masses of the neutrinos do not coincide with the corresponding wave vector for CDM perturbations, \( k_{NL,C,0} \sim 0.1 \) h Mpc\(^{-1} \). These two effects lead to a mismatch between the energy momentum tensor of neutrinos from the homogeneous calculation and its average value, as soon as the formation of lumps has started.

We account for the backreaction effects by using the volume averaged energy momentum tensor. The Klein-Gordon equation for the average field is given approximately by:

\[
\ddot{\bar{\phi}} + 3H \dot{\bar{\phi}} + \alpha V(\bar{\phi}) = -\beta \bar{T}_{(\nu)},
\]

where the volume average is defined as

\[
\bar{T}_{(\nu)} = \frac{1}{V} \int d^3x \sqrt{g^{(3)}} T_{(\nu)} \approx \frac{a^3}{V} \int d^3x (1 - 3\Phi) T_{(\nu)}.
\]

The determinant of the spatial 3-metric up to first order in metric perturbations is given by \( \sqrt{g^{(3)}} \approx a^3(1 - 3\Phi) \). The integration is to be understood over
the whole simulation box. The volume is given by $V \approx a^3 \int d^3 x \ (1 - 3 \Phi)$. Taking backreaction effects consistently into account and evolving the volume averaged field $\bar{\varphi}$ additional modifications arise in the equation. However, we will neglect these terms for the qualitative discussion of backreaction in this section and postpone a more detailed discussing to section IV.

The right hand side of equation (8) can be written as:

$$\beta T_{\nu} = \beta (-\bar{p}_{\nu} + 3\bar{P}_{\nu}) = -\beta \rho_{\nu} (1 - 3w_{\nu}) < -\beta \rho_{\nu},$$

where the energy density and pressure are understood as volume averages. We use them to define the equation of state $w_{\nu}$. The neutrino pressure is positive ($w_{\nu} \geq 0$) such that pressure effects lower the effective potential barrier which stops the cosmon evolution. As a consequence, the time at which the cosmon evolution stops is postponed towards the future. If the evolution has already stopped the effective reduction of the barrier can have the effect that the cosmon will evolve again. The weaker interaction between the neutrinos and the cosmon after the formation of lumps, can also be interpreted as a lower effective coupling $\beta_1$, which gets renormalized by integrating out short wavelength modes [20]. In a qualitative sense $\beta_1$ can be interpreted as the effective coupling between a fluid of neutrino lumps and the homogenous cosmon field. The smaller value of $\beta_1$ as compared to $\beta$ is the dominant backreaction effect in our model.

We next turn to the backreaction effect for the evolution of the background metric. One needs to replace the background density of neutrinos and the cosmon by their volume average, such that the Friedmann equation becomes:

$$H^2 = \bar{\rho}_{\text{CDM}} + \bar{\rho}_{\nu} + \bar{P}_\varphi. \quad (11)$$

In the presence of lumps $\rho_{\nu}$ has contributions from the neutrino velocities, and $P_\varphi$ involves additional gradient contributions. The observable DE component is the combined neutrino-cosmon fluid $\rho_{\text{DE}}$. The neutrinos are typically subdominant but still contribute a significant fraction $\frac{\rho_{\nu}}{\rho_{\text{DE}}} \sim 0.1$. With an equation of state $w_{\nu} \sim 0.1$ the neutrinos lift the dark energy equation of state away from $w \approx -1$ to some higher value.

The volume average of the cosmon energy density is given by:

$$\bar{\rho}_\varphi = \frac{1}{2} \varphi^2 + \frac{1}{2a^2} (1 + 2\Phi) (\partial_i \varphi) (\partial_j \varphi) \delta^{ij} + V(\varphi), \quad (12)$$

where we only keep metric perturbations up to first order, neglected their time derivatives and use that the volume average of the gravitational potentials vanishes $\bar{\Phi} = \bar{\Psi} = 0$. Also assuming that time derivatives of the cosmon perturbation $\delta \varphi$ are small allows us to approximate $\bar{\rho}_\varphi \approx \bar{\varphi}^2$. Using the quasi static approximation is justified although the individual neutrino velocities are large. For the quasi static approximation to hold it is sufficient that the energy-momentum tensor for all neutrinos does not evolve fast, so that there are no fast varying sources for the cosmon. A non-zero $\delta \varphi$ results in a positive contribution to the pressure, making it even harder to achieve an almost constant energy density for the cosmon-neutrino fluid.

Without the gradient term one has the usual competition between potential and kinetic energy. The potential energy should be dominant in order to have an accelerated expansion. The averaged potential energy $\bar{V}(\varphi)$ differs from the potential energy $V(\varphi)$ of the averaged field $\bar{\varphi}$ only by a few percent, such that no major backreaction effect arises from this source. In contrast, the gradient term can be almost as large as the the potential energy. From the expression for the pressure

$$\bar{P}_\varphi \approx \frac{1}{2} \bar{\varphi}^2 - \frac{1}{6a^2} (1 + 2\Phi) (\partial_i \varphi) (\partial_j \varphi) \delta^{ij} - V(\varphi), \quad (13)$$

we see that a gradient term dominated equation of state would be $w_{\nu} = -\frac{1}{2}$. We emphasize that all backreaction effects individually lead to an evolving energy density of neutrino-cosmon fluid and typically push $w$ away from $-1$.

For models with constant $\beta$ the lumps have the tendency to stabilize and to remain present once formed. The neutrino-cosmon fluid can be understood as an effective fluid of nearly virialized neutrino lumps with parameters differing from the microscopic ones [20]. The observable DE is then the sum of a neutrino lump fluid and a homogenous background field. For virialized lumps the pressure between relativistic neutrinos and cosmon gradients is expected to cancel [20]. Therefore the equation of state of the lump fluid is close to zero, similar to the fluid of non-relativistic neutrinos. The backreaction effect that remains even in this limit is the reduced effective coupling $\beta_1$ between neutrino lumps and the cosmon background field. Due to the not completely virialized lumps the pressure contribution from the neutrinos and the cosmon gradients do not cancel exactly, adding a small but relevant additional backreaction effect. This is different to gravitationally bound objects, for which a non-renormalization theorem states that small virialized objects decouple completely from the background evolution and there is no backreaction effect from small virialized objects at all [30].

### IV. N-BODY SIMULATION

The highly non-linear nature of the neutrino lumps makes their description non-amenable to standard perturbative techniques. Instead we use a N-body simulation specially designed for GNQ. The N-Body simulation solves the background and the inhomogeneities simultaneously and therefore allows us to study the backreaction effect of lumps on the homogeneous background evolution. Concept and many details of the simulation were
already described in [16][17], we focus here on the equation of motion for the average cosmon field \( \bar{\phi} \) and its perturbation \( \delta \phi \).

In our simulation we follow the usual motion of non-relativistic CDM particles and there clustering due to gravity. In contrast to the standard picture of structure formation the two gravitational potentials differ, \( \Phi \neq \Psi \), because of the anisotropic stress from the neutrinos. This is accounted for by solving the Poisson equation for \( \Phi - \Psi \), which yields \( \Phi \) ones the Newtonian potential \( \Psi \) is known. The Poisson equation for \( \Psi \) is sourced by the energy density of CDM, neutrinos and to a small part by the one of the cosmon perturbations.

The neutrinos are evolved using equation (6). The cosmon evolution is governed by the Klein-Gordon equation (5). We split the cosmon into the volume average \( \bar{\phi} = \int d^3x \sqrt{\gamma} \phi \) and a perturbation \( \delta \phi = \phi - \bar{\phi} \). Neglecting time derivatives of the gravitational potentials, time derivatives commute with the process of averaging \( \dot{\bar{\phi}} \approx \dot{\phi} \). The averaged equation (5) is:

\[
\dot{\bar{\phi}} + 3H \bar{\phi} + \alpha (1 + 2\Psi) V(\phi) = -\beta (1 + 2\Psi) T(x) + a^{-2}\delta ij \partial_i \partial_j \delta \phi (1 + 2\Psi)
+ \alpha \left( (1 + 2\Psi) V(\phi) - (1 + 2\Psi) V(\bar{\phi}) \right) = -\beta \left( (1 + 2\Psi) T(x) - (1 + 2\Psi) T(x) \right),
\]

where we expanded up to first order in metric perturbations. Equation (14) is the full version of equation (5). As already discussed in section III the most important difference as compared to a naive homogeneous calculation is the use of the actual average of the neutrino momentum tensor. Including the gravitational potential in the average gives only a minor correction. Also the averaged potential term agrees up to a few percent with the homogeneous estimate. The gradient terms is roughly one order of magnitude smaller than the potential term and therefore only subdominant. Nevertheless, our numerical code includes all these effects.

By subtracting equation (14) from the the Klein-Gordon equation (5) we find the equation for the perturbation:

\[
\delta \phi + 3H \dot{\delta \phi} - a^{-2} \delta ij \partial_i \partial_j \delta \phi (1 + 2\Psi)
- a^{-2} \delta ij (\partial_i (\Psi - \Phi)) (\partial_j \phi) + a^{-2} \delta ij (\partial_i \Psi) (\partial_j \phi)
+ \alpha \left( (1 + 2\Psi) V(\phi) - (1 + 2\Psi) V(\bar{\phi}) \right) = -\beta \left( (1 + 2\Psi) T(x) - (1 + 2\Psi) T(x) \right).
\]

This equation is a non-linear wave equation, which is, due to the averaging, non-local in position space. To be able to solve this equation we need to make some approximations. We employ a quasi static approximation for the cosmon perturbation for which we neglect the second order time derivative \( \delta \dot{\phi} \). Simply neglecting all time derivatives is not a consistent approximation. Doing so the resulting equation does not ensure that the perturbation has a vanishing mean \( \overline{\delta \phi} = 0 \). This can be seen by averaging equation (15). Taking into account the \( \Phi \) dependence in the volume element and only keeping terms to first order in the metric perturbations all terms except the time derivatives cancel:

\[
\ddot{\delta \phi} + 3H \dot{\delta \phi} = 0.
\]

This relation ensures that if the average vanishes initially it will vanish at all times. This is still true if we neglect the second time derivative while keeping the first one. This approximation is consistent with the approximation for kinetic term of the average energy density and pressure

\[
\overline{\phi^2} = \dot{\phi}^2 + \frac{\delta \phi^2}{2}.
\]

where we neglected the \( \overline{\delta \phi^2} \)-term. So we neglected all terms which are second order in the time derivatives of the cosmon perturbations these terms are smaller than those with only one time derivative.

If one instead neglects the second derivative with respect to conformal time the Hubble damping changes \( 3H \rightarrow 2H \), we compared both possibilities and found only a small difference. We interpret this a sign that the quasi static approximation is justified.

To solve the equation for \( \delta \phi \) we use a Newton-Gauß-Seidel (NGS) multigrid relaxation method, already applied to the varying coupling model [17] and originally developed for modified gravity [38]. The quasi static approximation is crucial for applying the NGS method, which is not applicable to wave like equations, but can be applied to diffusion like equations [39]. The idea of the NGS solver is to rewrite the equation to be solved into a functional form:

\[
\mathcal{L}[\delta \phi] = D \delta \phi - F[\delta \phi] = 0,
\]

with some differential operator \( D \) and a non-linear functional \( F \). The root of \( \mathcal{L}[\delta \phi] = 0 \) can be obtained by a newton-like iterative procedure:

\[
\delta \phi^{(n+1)} = \delta \phi^{(n)} - \mathcal{L}[\delta \phi^{(n)}] \left( \frac{\partial \mathcal{L}[\delta \phi^{(n)}]}{\partial \delta \phi^{(n)}} \right)^{-1},
\]

the derivative is taken at each point individually, the coupling between different points, induced by the derivatives, is taken into account solely by the iterative procedure. The derivative of the differential operator \( \frac{\partial \mathcal{L}[\delta \phi]}{\partial \delta \phi} \) is defined by the discretisation rule used in the simulation. We define the gradient and the laplacian by relating a grid point to its neighbors in \( j \)-direction by a Taylor expansion: \( \delta \phi(x_i) \pm \Delta x \delta_{ij} \) where \( \Delta x \delta_{ij} = \frac{\partial^2 \delta \phi(x_i)}{\partial x^2} + \Delta x \) with \( \Delta x \) the spacing between two grid points. The laplacian is then approximated by a seven-point stencil and the derivative is \(-6/\Delta x^2\). The derivative of the gradient vanishes.

In principle this method can be applied even in the presence of the non-local terms present in equation [15]. In practice this not possible because calculating the non-local terms involves an integration over the full simulation box in each iteration step. We account for these
terms iteratively. The difference between the values of the average terms of two time steps is small. So we use at a given time step the average terms of the proceeding step as first approximation and apply the NGS solver a few times to correct for the difference.

V. RESULTS AND DISCUSSION

Using the N-Body simulation described in section IV we perform a parameter scan and search for parameters describing a realistic universe with accelerated expansion. For the details on the formation of lumps and there characteristics we refer to previous work [16, 20]. We use a simulation box with a comoving volume of \( V = (600 \, h^{-1} \, Mpc)^3 \), which we divide into \( N_c = 128 \) cells. The number of effective CDM particles \( N_{C} \) and neutrino particles \( N_{\nu} \) is chosen to be equal to the number of cells \( N_c = N_C = N_{\nu} \). The initial power spectrum has a spectral index of \( n_s = 0.96 \) and an amplitude of \( A_s = 2.3 \cdot 10^{-9} \) at the pivot scale \( k_{\text{pivot}} = 0.05 \, Mpc^{-1} \). We start our simulation with the CDM particles only at a given time step the average terms of the proceeding time step the average terms of two time steps is small. So we use\( \alpha \)

\[ \approx \begin{cases} 0 & \text{if } |w| < 0.9, \\ -0.7 & \text{if } 0.9 \leq |w| < 1.0, \\ -1.0 & \text{if } |w| \geq 1.0. \end{cases} \]

\[ \Omega_{\text{DE}} \approx 0.75 \]

with \( \Omega_{\text{DE}} \approx 0.75 \) the benchmark value of \( \Omega_{\text{DE},0} \approx 0.7 \). On the other hand for \( \alpha = 5 \) one has \( \Omega_{\text{DE}} \approx 0.7 \), but the equation of state is \( w_0 \approx -1.0 \). Although we could not find parameters for which \( w_0 \) and \( \Omega_{\text{DE},0} \) match the benchmark values precisely, our results are not too far from those values either. It might be that varying also the mass parameter \( m_i \) could bring them into agreement with observations.

The equation of state is not constant in time, it can even possess oscillating features, see figure [4]. It may happen that the present time coincides with a minimum (maximum) of \( w \) during an oscillation. In this case the cosmic evolution is actually better described by an average value somewhat larger (smaller) than \( w_0 \). The time evolution of the equation of state is shown in figure [6] for a range of parameters \( \alpha \) and \( \beta \) in the region not too far from the benchmark values. One typically observes a first stop of the scalar field (\( w \approx -1) \). Due to backreaction this is followed by a slow decrease of the dark energy, typically with \( -0.9 \lesssim w \lesssim -0.8 \).

Only looking at the energy density and the equa-
FIG. 5. Present energy density $\Omega_{DE,0}$ and equation of state $w_0$ of the cosmon-neutrino fluid. Realistic values ($w_0 \approx -1$, $\Omega_{DE,0} \approx 0.7$) are found for small values of $\alpha$. It is hard to get both values “correct” simultaneously, for sufficiently large $\alpha$.

FIG. 6. Equation of state as a function of the scale factor. The model parameters are chosen such that $w$ and $\Omega_{DE,0}$ are near the benchmark values. Values $w_0 \lesssim -0.9$ are only reached before backreaction effects become important. Thus $w \approx -0.99$ for $\alpha = 5$ and $\beta = -52$ is not accompanied by large negative $w$ at redshifts relevant for supernova observations.

FIG. 6 shows the generic evolution of the equation of state: It drops down after the neutrinos became non-relativistic followed by a few damped oscillations. In the homogeneous evolution these oscillations are damped away quickly and the equation of state assumes an almost constant value rather close to $w = -1$. In fact the equation of state grows again due to the backreaction and typically reaches values $w \approx -0.8$. An equation of state of $w_0 \lesssim -0.9$ is only reached before or shortly after backreaction becomes important. This simply means that lumps had not enough time to grow large enough for being able to induce significant backreaction effects.

From these results we conclude that GNQ with a constant coupling $\beta$ is probably not a viable DE model. Realistic values for $w_0$ and $\Omega_{DE,0}$ seem only possible if the cosmon evolution is stopped late, so that backreaction effects have no time to become important. Stopping the cosmon evolution late is in some tension with supernova data and involves a large amount of EDE, probably not consistent with observations.

VI. CONCLUSION

We have performed a numerical analysis of Growing Neutrino Quintessence with a constant cosmon-neutrino coupling $\beta$. Due to strong backreaction effects from the formation of large neutrino lumps these models have difficulties to be compatible with the observed properties of dark energy.

A specific choice for the model parameters $\alpha$, $\beta$ and
dependence \( m_\nu \), which appears to be compatible with observations at the homogenous level, is typically no longer viable if backreaction is included. Our parameter scan reveals regions for which the backreaction effects are small enough to allow a slowly evolving cosmon and consequently an almost constant DE density. However, this is only possible if the neutrino lumps form late so that backreaction effects are still small today. In this case an accelerated expansion is only possible for scale factors \( a \gtrsim 0.6 \), in tension with an almost constant equation of state for scale factors \( a \lesssim 0.5 \), as preferred by supernova data. Furthermore, the parameter region for which the equation of state is close to \(-1\) and the DE density is not too far from 0.7, requires \( \alpha \lesssim 5 \). This contradicts constraints on early dark energy for which \( \alpha \gtrsim 10 \) is necessary. We conclude that growing neutrino quintessence with a constant coupling \( \beta \) is probably not a viable DE model.

These results for a constant coupling should be contrasted with models where \( \beta \) increases with \( \varphi \). For this second class of models the backreaction effect is found to be small since the neutrino lumps form and disrupt periodically \cite{D15}. At the present stage this second class of models seems compatible with observations. In certain parameter ranges it may even be hard to detect a difference from the \( \Lambda \)CDM models and its variants.

These two classes of models may be seen as particular points in a larger class of models where \( \beta \) is allowed to vary with \( \varphi \). Having established points that are viable with only rather small deviations from \( \Lambda \)CDM, as well as other points where the deviations are so strong that the model is no longer acceptable, we can conclude by continuity that in between there will be models which are still compatible with observations today, but also offer highly interesting prospects of finding deviations from \( \Lambda \)CDM. Finding large neutrino lumps, thereby observing the cosmic neutrinos directly, would be a direct hint for GNQ. Even for models with small neutrino perturbations we expect observable deviations from the \( \Lambda \)CDM model, due to the different evolution of the neutrino sector. First, the transition of relativistic to non-relativistic standard massive neutrinos is imprinted in the CMB fluctuations with a specific scale dependence \cite{K7}. The signal differs for constant or time-varying neutrino masses. Second, free-streaming standard massive neutrinos attenuate the growth of matter perturbations on small scales and therefore add an additional scale dependent effect to the matter distribution. Observing these scale dependent effects as predicted for standard neutrinos with a constant mass would be a strong argument for the \( \Lambda \)CDM model and against GNQ.

The result for models with constant \( \beta \) presented in this note as well the results on the varying \( \beta \) model presented in \cite{W08} suggest that only those models are viable in which the small scale non-linear neutrino perturbations have only a moderate effect on the large scale dynamics. Nevertheless, the neutrino lumps can have an observable effects on larger scales. One possibility to account for these effects is to construct an effective fluid for the long wavelength perturbations by averaging over small scales non-linearities as proposed in reference \cite{S09}. A similar route has already been taken in \cite{S15} to describe the large scale dynamics of virialized neutrino lumps in the constant \( \beta \) model by means of an effective lump fluid. These ideas where already successfully applied to the mildly non-linear regime of structure formation in the form of the Effective Field Theory of Large Scale Structure \cite{W12, S07}, see also \cite{W06}. Adopting these ideas to GNQ we hope that it will become possible to study the dynamics of perturbations in GNQ on large scales qualitatively. It might even become possible to study some effects of lumps on the CMB, without running time consuming simulations.

**ACKNOWLEDGMENTS**

The authors are thankful to Youness Ayaita, Valeria Pettorino and Santiago Casas for numerous inspiring discussions and ideas. They would also like to thank Ewald Puchwein for providing his NGS code and David Mota for providing his numerical implementation of linear perturbation theory in GNQ. FF acknowledges support from the IMPRS-PTFS and the DFG through the TRR33 project “The Dark Universe”.
