COMPUTING WITH ALMOST PERIODIC FUNCTIONS

R.V. MOODY, M. NESTERENKO, AND J. PATERA

Abstract. The paper develops a method for discrete computational Fourier analysis of functions defined on quasicrystals and other almost periodic sets. A key point is to build the analysis around the emerging theory of quasicrystals and diffraction in the setting on local hulls and dynamical systems. Numerically computed approximations arising in this way are built out of the Fourier module of the quasicrystal in question, and approximate their target functions uniformly on the entire infinite space.

The methods are entirely group theoretical, being based on finite groups and their duals, and they are practical and computable. Examples of functions based on the standard Fibonacci quasicrystal serve to illustrate the method (which is applicable to all quasicrystals modeled on the cut and project formalism).

1. Introduction

In this paper we consider the problem of discrete methods for dealing with functions that are intrinsically almost periodic, but not actually periodic. Quasicrystals, quasicrystalline photonic crystals, Faraday wave experiments, and other physical phenomena arising from the interaction of incommensurate frequencies, all display the features of almost periodicity. As a typical example one may think of a potential field of a physical quasicrystal. The salient features of quasicrystals are highly structured long-range order (represented by pure point or near pure point diffraction) but no periodic order. Thus the potential is not a periodic function, but rather belongs to the domain of almost periodic functions.

Here we put forth a method for finite discrete analysis of almost periodic functions that has the following main features:

- It is entirely based on group theoretical methods, primarily finite groups and their duals.
- The discretely computed Fourier approximants are themselves almost periodic and uniformly approximate their target functions over their entire domains.
- The Fourier frequencies involved in the approximation lie in the module of Fourier frequencies of the target function.

A standard approach to modeling such structures is to take a finite part of it, impose periodic boundary conditions, rationalize and reduce the object to a periodic approximant, and then apply usual crystallography. Although this type of periodization is used routinely and successfully for many modelling problems in the theory of quasicrystals, it is not entirely satisfactory. Almost periodic order goes beyond periodic order in fundamental ways, its essence appearing as a underlying incommensurability which pervades every part of the theory. For instance, a key feature of quasicrystals appears in the Fourier module which parameterizes the Bragg spectrum and always has rank higher than (typically double) the dimension of the ambient space of the quasicrystal. Periodization destroys this, and by its nature can only produce results that can fit data over the finite range specified by the imposed periodization boundaries, whereas the essence of the material is that its order is long-range. The present paper does not involve any periodization and avoids these issues.

The theory of almost periodic functions was initiated by H. Bohr [7], on the basis of earlier work on uniform approximation of functions by trigonometric polynomials by P. Bohl. It was greatly extended by the work of A. Besicovitch [3], S. Bochner, J. von Neumann, [3, 5, 6], N. Wiener [24], H. Weyl [23], and others [9, 15, 1]. The advent of quasicrystals and aperiodic tilings instigated a revival of the field, and led to extensive study of the cut and project formalism and the theory of pure point diffraction [16, 17, 11, 22] which have become the mainstays of experimentalists and theorists alike. An important component of this is the use of dynamical systems and dynamical hulls. These are ideally suited to the phenomenon of almost periodicity, which appears in the dynamics as recurrence, and provide a natural setting for the Fourier analysis that is used to study it.

Although our study is of almost periodic functions, their importance in the subject of quasicrystals is that they arise from functions whose behaviour is dominated by the local environments of the quasicrystal in question. The way in which this happens is mostly taken for granted, but in fact there are some interesting assumptions involved, and for this reason we begin by formally defining local functions with respect to a given point set \( \Lambda \), and showing how it is that they are connected with almost periodic functions.
We can create a dynamical hull \((X, \mu)\) from \(\Lambda\). This is a compact space that arises from \(\Lambda\) and its translations, and it lies at the heart of the Fourier analysis of local functions on \(\Lambda\). One assumes (in many important cases it is forced) a probability measure \(\mu\) on which \(\mathbb{R}^d\) acts in a measure preserving way. A local function \(f\) lifts to some new function \(F\) on \((X, \mu)\), and this is an \(L^2\) function. Now the analysis of \(f\) can be related directly to the analysis of \(F\), and for this we have a powerful tool in the form of the action of \(\mathbb{R}^d\) on \(L^2(X, \mu)\), which is unitary. All of this material is explained in §2.

To go further, we next place ourselves in the situation of the cut and project formalism, which is the standard method of modeling used in the study of quasicrystals. The set \(\Lambda\) is now assumed to be a model set (cut and project set). In this setting the hull \((X, \mu)\), and more particularly \(L^2(X, \mu)\), can be described explicitly in terms of a higher dimensional torus (higher dimensional periodicity!), and it is a straightforward matter to carry out Fourier analysis of \(F\). It is the restriction of this Fourier analysis back to \(f\) that provides the required Fourier analysis of \(f\). By its very nature this is almost periodic and captures the full aperiodic nature of \(\Lambda\), including the correct Fourier module in which physical information actually appears. This is the content of §3. Readers familiar with the cut and project method who do not wish to go through the theory of local hulls and local functions may read §§3.1 and 3.4 and then continue starting at §4.

This theoretical analysis is based on higher dimensional structures that are not explicitly computatable, as well as the usual array of countably many Fourier coefficients, each of which is the outcome of integration. To be a practical tool, the analysis has to be reduced to finitely many objects that are explicitly computable entirely in the context of the given function \(f\). The resulting approximants are trigonometric polynomials (quasi-periodic functions) whose frequencies come from the Fourier module of the original function. In §4 we outline the method of discretization, which depends primarily on the construction of a refinement lattice of the lattice of the cut and project scheme and, along with it, its dual lattice. Together these produce two finite groups which are in \(\mathbb{Z}\)-duality to each other. The selection of data points and appropriate Fourier frequencies is governed by these two groups.

This is best illustrated by examples and for this we have chosen two local functions based on one of the famous Fibonacci point sets. This has the advantage of being straightforward to construct and easy to visualize, while at the same time containing all the essential features of more general model sets. §5 prepares the mathematics of the Fibonacci cut and project scheme, and §6 shows some explicit computations for the particular local functions we have chosen. As is evident from the examples, the main effort required is in the creation of the data points. Once this is done, the same set of data points and Fourier frequencies will work for any almost periodic function arising from the same cut and project scheme.

The results are striking in two ways. First of all, the approximating functions are remarkably good, given the amount of data from which they are produced. Second, the approximating functions are not just local approximations they are also global approximations, in the sense that they provide finite Fourier series that approximate \(f\) throughout its entire domain (namely \(\mathbb{R}\)). Of course this was to be expected, but it is impressive to see it in action.

The numerical methods we introduce here are designed to be efficient and, of course, to utilize the inherent almost periodicity. In the development of the theory we provide error estimates that can be worked out specifically in the cases of interest. We note that the primary weakness in the error estimates is not one that is due to the aperiodic nature of the problem, but one that always appears in Fourier analysis, namely how well can one approximate a function if one uses only finitely many of its Fourier coefficients.

## 2. Continuous functions on aperiodic point sets

### 2.1. Local hulls.

We work in \(\mathbb{R}^d\), a real Euclidean space of finite dimension \(d\). For \(r > 0\), let \(D_r(\mathbb{R}^d)\), be all point sets \(\Lambda \subset \mathbb{R}^d\) for which the distance \(|x - y| \geq r\) for all \(x, y \in \Lambda\). This means that \(D_r\) consists of all discrete point sets with minimal separation \(\geq r\) between their points.

The local topology on \(D_r(\mathbb{R}^d)\) can be intuitively introduced as follows. Two sets \(\Lambda_1\) and \(\Lambda_2\) of \(D_r(\mathbb{R}^d)\) are ‘close’ if, for some large \(R\) and some small \(\epsilon\), one has:

\[
\Lambda_1 \cap B_R \subset \Lambda_2 + B_\epsilon, \\
\Lambda_2 \cap B_R \subset \Lambda_1 + B_\epsilon,
\]

\(^1\)More generally a compact Abelian group
where $B_R$ (resp. $B_\epsilon$) is the ball of radius $R$ (resp. $\epsilon$) around 0. Thus for each point of $\Lambda_1$ within the ball $B_R$, there is a point of $\Lambda_2$ within the distance $\epsilon$ of that point; and vice versa. Pairs $(\Lambda_1, \Lambda_2)$ satisfying are called $(R, \epsilon)$-close.

![Figure 1. Two sets $\Lambda_1$ and $\Lambda_2$ of $D_r(\mathbb{R}^d)$ that are close.](image-url)

The local topology is actually a metric topology, although we make no use of this fact here.

**Definition 1.** For $\Lambda \in D_r(\mathbb{R}^d)$ the local hull of $\Lambda$ is

$$X(\Lambda) = \{ t + \Lambda : t \in \mathbb{R}^d \} \subset D_r(\mathbb{R}^d),$$

i.e. take all translates of $\Lambda$ and take their closure in the local topology.

**Proposition 2.1.** [21] The translation action of $\mathbb{R}^d$ on $\Lambda$ lifts to a translation action on $X(\Lambda)$. The local hull $X(\Lambda)$ is compact and the $\mathbb{R}^d$-action on it is continuous.

**Example 1.** Let $\Lambda$ be the lattice $\mathbb{Z}^d$ in $\mathbb{R}^d$. Then $X(\Lambda) = \mathbb{R}^d/\mathbb{Z}^d$ is the $d$-torus (with its usual topology). Intuitively we translate the lattice around with $\mathbb{R}^d$. But translation by an element of $\mathbb{Z}^d$ leaves $\Lambda$ invariant. So $\mathbb{R}^d/\mathbb{Z}^d$ parameterizes all distinct positions of $\Lambda$ under translation.

**Example 2.** Let $\Lambda$ be any Penrose tiling. Then $X(\Lambda)$ is the set of all Penrose tilings that are locally indistinguishable from some translate of $\Lambda$. $X(\Lambda)$ contains considerably more than just the translations of $\Lambda$. In fact $X(\Lambda)$ consists of all Penrose tilings based on the same pair of Penrose rhombs and the same orientations as appearing in $\Lambda$.

Generally one may think of $X(\Lambda)$ as some sort of local indistinguishability class of $\Lambda$.

### 2.2. Continuous functions on $X(\Lambda)$

We assume that $\Lambda \subset D_r(\mathbb{R}^d)$ and $X(\Lambda)$ are as in [2.1].

Consider a function

$$F : X(\Lambda) \rightarrow \mathbb{C}.$$  

(3)

We can define from it a function

$$f : \mathbb{R}^d \rightarrow \mathbb{C}.$$  

by

$$f(t) = F(t + \Lambda).$$  

(4)

If $F$ is continuous then we note that for all $t_1, t_2 \in \mathbb{R}^d$,

$$t_1 + \Lambda, t_2 + \Lambda \text{ are close} \quad \Rightarrow \quad F(t_1 + \Lambda), F(t_2 + \Lambda) \text{ are close} \quad \Rightarrow \quad f(t_1), f(t_2) \text{ are close}.$$  

Thus continuity of $F$ implies continuity of $f$, and we see that $f$ is local, or almost periodic, with respect to $\Lambda$ in the following sense:
Definition 2. A function \( f : \mathbb{R}^d \to \mathbb{C} \) is called local with respect to a set \( \Lambda \in D_T(\mathbb{R}^d) \), or \( \Lambda \)-local, if for all \( \epsilon' > 0 \) there exist \( R \) and \( \epsilon \) so that whenever \( t_1, t_2 \in \mathbb{R}^d \) satisfy that \( t_1 + \Lambda \) and \( t_2 + \Lambda \) are \((R, \epsilon)\)-close then
\[
|f(t_1) - f(t_2)| < \epsilon'.
\]

The intuitive meaning of this is that \( f \) has the very natural property, at least from the perspective of physical systems, that it looks very much the same at places where the local environment looks the same. Local functions are easily seen to be continuous on \( \mathbb{R}^d \).

Using locality, we can go in the opposite direction. Let \( \Lambda \in D_T(\mathbb{R}^d) \) and let \( f : \mathbb{R}^d \to \mathbb{C} \) be local with respect to \( \Lambda \). Define
\[
F : \{ t + \Lambda : t \in \mathbb{R}^d \} \to \mathbb{C}
\]
so that \( F \) is a function on a part of \( D_T(\mathbb{R}^d) \) by
\[
F(t + \Lambda) = f(t).
\]
Then \( F \) is continuous on \( \{ t + \Lambda : t \in \mathbb{R}^d \} \) with respect to the local topology. In fact it is uniformly continuous. The reason for this is that the continuity condition which defines the local-ness of \( f \) is based on the uniformity (i.e. the notion of \((R, \epsilon)\)-closeness) defining the local topology of \( \{ t + \Lambda : t \in \mathbb{R}^d \} \).

It follows that \( F \) lifts uniquely to a continuous function \( X(\Lambda) \) on the local hull \( X(\Lambda) \).

Proposition 2.2. For each local function \( f \) with respect to \( \Lambda \) there is a unique continuous function \( \tilde{X}(\Lambda) \) on the local hull, whose restriction to the orbit of \( \Lambda \) is \( f \). Every continuous function on the local hull of \( \Lambda \) arises in this way.

Thus we see that a locality with respect to \( \Lambda \) and the existence and continuity of an extension function on \( X(\Lambda) \) amount to the same thing.

In the situation that \( X(\Lambda) \) is equipped with an \( \mathbb{R}^d \)-invariant probability measure \( \mu \) (i.e. a positive Borel measure \( \mu \) with \( \mu(t + \Lambda) = \mu(\Lambda) \) for all Borel sets and with \( \mu(X(\Lambda)) = 1 \), the action of \( \mathbb{R}^d \) on \( X(\Lambda) \) leads to unitary action \( T \) of \( \mathbb{R}^d \) on \( L^2(X(\Lambda), \mu) \). Namely for all \( F \in L^2(X(\Lambda), \mu) \) and for all \( t \in \mathbb{R}^d \), \( T_t F \) is the function defined by \( T_t F(\Gamma) = F(-t + \Gamma) \) and with
\[
\langle F | G \rangle := \int_{X(\Lambda)} F \overline{G} \, d\mu
\]
we have
\[
\langle T_t F | T_t G \rangle = \langle F | G \rangle.
\]

In principle the spectral theory of \( L^2(X(\Lambda), \mu) \) should allow one analyze \( \Lambda \)-local functions \( f : \mathbb{R}^d \to \mathbb{C} \) by analyzing their corresponding functions \( F \) on \( L^2(X(\Lambda), \mu) \).

For one very important class of subsets \( \Lambda \) this can actually be carried out in detail – namely the class of model sets, which we now introduce.

3. Local functions on model sets

3.1. Cut and project schemes, model sets and torus parametrization. An important class of point sets \( \Lambda \subset \mathbb{R}^d \) for which we know a considerable amount about the corresponding hulls \( X(\Lambda) \) is the class of cut and project sets, or the model sets as they are often called \([16, 17]\).

Consider the cut and project scheme
\[
\mathbb{R}^d \leftarrow \begin{array}{c|c}
\mathbb{R}^d \times \mathbb{R}^d & \rightarrow \mathbb{R}^d \\
\cup & \\
\downarrow & \\
\begin{array}{c}
1-1
\end{array} & \begin{array}{c}
\tilde{L}
\end{array}
\end{array} \quad \text{dense image}
\]
and a window \( \Omega \). Here \( \tilde{L} \) is a lattice in \( \mathbb{R}^d \times \mathbb{R}^d \) which is oriented so that the projections into \( \mathbb{R}^d \) are \( 1-1 \) and dense respectively.

In (5) the left-hand \( \mathbb{R}^d \) is physical space, the space in which \( \Lambda \) is going to lie. The right-hand \( \mathbb{R}^d \) is internal space, the one that will be used to control the projection of the lattice \( \tilde{L} \) into physical space. The image of \( \tilde{L} \) under projection into physical space is denoted by \( L \). Since this projection is one-one, \( L \simeq \tilde{L} \) as groups, so \( L \) is a free Abelian group of rank \( 2d \), i.e. it has a \( \mathbb{Z} \)-basis of \( 2d \) elements. However, it necessarily has accumulation points, and the typical situation is that \( L \) is dense in physical space.
It is convenient to use notation like $\tilde{x}, x, x'$ for the elements of $\tilde{L}$ and their respective left and right projections. Then $\tilde{x} = (x, x')$ where $x$ runs through $L$. This implies existence of the mapping $(\cdot)': L \to L'$ defined by $x \mapsto x'$, which passes from physical to internal space.

Note that this mapping $(\cdot)'$, as given, is only defined on $L$. It cannot be extended in any canonical way to a mapping $\mathbb{R}^d \to \mathbb{R}^d$. However it does extend canonically to the rational spans of the objects in question, and we shall make use of this later.

We choose a subset $\Omega$ in internal space. This window is assumed to be compact, equal to the closure of its interior, and to have boundary of measure 0. Using it we define

$$\Lambda = \Lambda(\Omega) = \{x : \tilde{x} \in \tilde{L}, x' \in \Omega\}.$$  \hspace{1cm} (6)

Sets of the form $t + \Lambda(\Omega)$, $t \in \mathbb{R}^d$, are called cut and project sets or model sets.\footnote{Model sets can be taken more generally with any locally compact Abelian group as the internal space.} In particular, for each $(x, y) \in \mathbb{R}^d \times \mathbb{R}^d$ we may define

$$\Lambda_{(x,y)} = x + \Lambda(-y + \Omega).$$  \hspace{1cm} (7)

If $(x, y) \equiv (x', y') \ (\mod \tilde{L})$, then $x + \Lambda(-y + \Omega) = x' + \Lambda(-y' + \Omega)$, as can be verified directly from the definitions. Thus these model sets are parameterized by the torus of dimension $2d$,

$$\left(\mathbb{R}^d \times \mathbb{R}^d\right)/\tilde{L} \simeq (\mathbb{R}/\mathbb{Z})^d =: \mathbb{T}.$$  \hspace{1cm} (8)

We note, though, that the parametrization need not necessarily be 1 - 1, i.e., in general, $\Lambda_{(x,y)} = \Lambda_{(x',y')}$ \hspace{1cm} (9)

$(x, y) \equiv (x', y') \ (\mod \tilde{L})$. In the sequel, for simplicity, we shall usually write $(x, y)_L$ for the congruence class $(x, y) \ (\mod \tilde{L})$.

There is a natural measure, the Haar measure, $\theta_\mathbb{T}$ on $\mathbb{T}$. This measure is the obvious ‘area’ measure in the case of $\mathbb{T}^2$, and ‘length’ measure for $\mathbb{T}^1$. It is invariant under the $\mathbb{R}^d$-action: $\mathbb{R}^d$ acts on $\mathbb{R}^d/\tilde{L}$ by

$$t + (x, y)_L = (t + x, y)_L.$$  \hspace{1cm} (10)

Of particular importance to us is natural embedding (see Fig. 2.)

$$\mathbb{R}^d \rightarrow \mathbb{T} \quad t \mapsto (t, 0)_L,$$  \hspace{1cm} (11)

which lies behind the connection between almost periodicity in physical space and periodicity in some higher dimensional setting. The image of this mapping is easily established to be dense in $\mathbb{T}$.

Now start with $\Lambda = \Lambda_{(0,0)} = \Lambda(\Omega)$, and translate it by elements $t \in \mathbb{R}^d$:

$$t + \Lambda(\Omega) = t + \Lambda(0 + \Omega) = \Lambda_{(t,0)}.$$  \hspace{1cm} (12)

Form the local hull $X(\Lambda)$, the closure of the set of all translates $\Lambda_{(t,0)}$ of $\Lambda$ under the local topology.\footnote{Model sets can be taken more generally with any locally compact Abelian group as the internal space.}

**Proposition 3.1.** \cite{22} There is a continuous mapping,

$$\beta : X(\Lambda) \rightarrow \mathbb{T},$$  \hspace{1cm} (13)

called the torus parametrization, such that

1) $\beta$ is onto;

2) $\beta$ is 1 - 1 almost everywhere, seen from the perspective of Haar measure on $\mathbb{T}$;

3) for all $t \in \mathbb{R}^d$, for all $\Lambda' \in X(\Lambda)$, one has $\beta(t + \Lambda') = t + \beta(\Lambda')$.

4) $\beta(t + \Lambda) = (t, 0)_L$ for all $t \in \mathbb{R}^d$. $\square$

$X(\Lambda)$ and $\mathbb{T}$ are both compact spaces with natural $\mathbb{R}^d$ action, and $\beta : X(\Lambda) \rightarrow \mathbb{T}$ is an onto $\mathbb{R}^d$ mapping. But $X(\Lambda)$ and $\mathbb{T}$ are subtly different. Although $t + \Lambda \in X(\Lambda)$ and $t + \Lambda \rightarrow \Lambda_{(t,0)}$ for all $t$, not every element of $X(\Lambda)$ is a $\Lambda_{(x,y)}$ for some $(x,y)$. Rather, when $\{-y + \partial \Omega\} \cap L' \neq \emptyset$, then for all $x \in \mathbb{R}^d$ there are always $\Lambda_1 \neq \Lambda_2$ of elements of $X(\Lambda)$ that are mapped by $\beta$ to the same $(x, y)_L$. When $\tilde{z} = (z, z') \in \tilde{L}$ with $z' \in \{-y + \partial \Omega\}$ then there will always be $\Lambda_1, \Lambda_2 \in X(\Lambda)$ with $\beta(\Lambda_1) = \beta(\Lambda_2) = (x, y)_L$, yet $x + z \in \Lambda_1$, $x + z \notin \Lambda_2$. In other words, there are ambiguities regarding the lattice points that project onto the boundary $\partial \Omega$ of $\Omega$. An example of this is shown in the footnote appearing in [5, 3]. The fact that $\beta$ is 1 - 1 almost everywhere is due to our assumption that the boundary of $\Omega$ has measure 0.

When we say that $\beta$ is 1 - 1 almost everywhere, we mean that the set $A$ of points $\xi$ in $\mathbb{T}$, for which there is more than one point set over $\xi$, satisfies $\theta_\mathbb{T}(A) = 0$.

There is a unique $\mathbb{R}^d$-invariant ergodic measure $\mu$ on $X(\Lambda)$ with $\mu(X(\Lambda)) = 1$. In fact $\beta$ relates $\mu$ and $\theta$:

$$\beta(\mu) = \theta.$$  \hspace{1cm} (14)
Or more specifically, \( \theta(A) = \mu(\beta^{-1}A) \) for all measurable subsets \( A \) of \( \mathbb{T} \). With \( \mu \) in hand, we can introduce the space \( L^2(X(\Lambda), \mu) \) of square integrable functions on \( X(\Lambda) \). As already pointed out, the natural action of \( \mathbb{R}^d \) on this is unitary.

### 3.2. From hulls to tori.

Square integrable functions on \( X(\Lambda) \) and square integrable functions on \( \mathbb{T} \) can be identified,

\[
L^2(X(\Lambda), \mu) \simeq L^2(\mathbb{T}, \theta). \tag{14}
\]

The isomorphism is easy to understand:

\[
X(\Lambda) \xrightarrow{\beta} \mathbb{T}
\]

\[
\begin{array}{c}
\uparrow \quad \downarrow \\
G \circ \beta \quad G
\end{array}
\]

gives us a map

\[
L^2(\mathbb{T}, \theta) \longrightarrow L^2(X(\Lambda), \mu).
\]

Since \( \beta \) is almost everywhere 1 - 1, the map is a bijection.

This allows us to analyze functions on \( X(\Lambda) \) by treating them as functions on \( \mathbb{T} \). The advantage of this is that functions in \( L^2(\mathbb{T}, \theta) \) have Fourier expansions

\[
\tilde{F}(z) = \sum_{k \in \mathbb{L}} a_k e^{2\pi i (\tilde{k} \cdot z)}, \quad z \in \mathbb{T}, \ a_k \in \mathbb{C}. \tag{15}\]

Here \( \langle \cdot, \cdot \rangle \) is the natural dot product on \( \mathbb{R}^d \times \mathbb{R}^d = \mathbb{R}^{2d} \) and \( \mathbb{L}^\circ \) is the lattice which is \( \mathbb{Z} \)-dual to \( \mathbb{L} \):

\[
\tilde{k} \in \mathbb{L}^\circ \iff \langle \tilde{k} \mid \tilde{x} \rangle \in \mathbb{Z}, \quad \text{for all} \quad \tilde{x} \in \mathbb{L}.
\]

Assuming that the dot product is rational valued on \( \mathbb{L} \), this new lattice is in the \( \mathbb{Q} \) span of \( \mathbb{L} \) and its elements \( \tilde{k} \) have the same type of decompositions \( \tilde{k} = (k, k') \) as elements of \( \mathbb{L} \). In particular, for each \( \tilde{k} \) there is a unique \( k \in \mathbb{R}^d \). We prepare for the ultimate reduction of everything to the physical space by already using the symbols \( a_k \) rather than \( a_{\tilde{k}} \) for the coefficients of the Fourier expansion. We shall write \( \mathbb{L}^\circ \) for the projection of \( \mathbb{L}^\circ \) on the physical side, so we can just as well write \( k \in \mathbb{L}^\circ \) as \( \tilde{k} \in \mathbb{L}^\circ \). We will call \( \mathbb{L}^\circ \) the dual (or \( \mathbb{Z}[\tau] \)-dual) of \( \mathbb{L} \). The mapping \( (\cdot)^\prime : \mathbb{L}^\circ \to \mathbb{R}^d \) here is compatible with the one on \( \mathbb{L} \), indeed \( \mathbb{Q}\mathbb{L}^\circ = \mathbb{Q}\mathbb{L} \).

The corresponding functions on \( X(\Lambda) \) have similar expansions. This works as follows: If \( F : X(\Lambda) \to \mathbb{C} \) corresponds to \( \tilde{F} : \mathbb{T} \to \mathbb{C} \) then, for \( \Lambda_1 \in X(\Lambda) \) with \( \beta(\Lambda_1) = (x, y) \mathbb{L} \), we have as \( L^2 \)-functions

\[
F(\Lambda_1) = \tilde{F}((x, y) \mathbb{L}) = \sum_{k \in \mathbb{L}^\circ} a_k e^{2\pi i \langle \tilde{k} \mid (x, y) \rangle}. \tag{16}\]

### 3.3. Local functions on model sets.

Let \( \Lambda \) be a model set arising from the cut and project scheme of \( [31] \). Let \( \mathbb{T} = \mathbb{T}^{2d} = (\mathbb{R}^d \times \mathbb{R}^d)/\mathbb{L} \) be the torus with torus parametrization

\[
\beta : X(\Lambda) \longrightarrow \mathbb{T}.
\]

Then we have the identification \([12]\) of the corresponding \( L^2 \) spaces. Each element \( \Lambda' \in X(\Lambda) \) maps by \( \beta \) to a point \( \beta(\Lambda') \) in \( \mathbb{T} \). We also know \( \beta(\Lambda) = (0, 0) \mathbb{L} \), and \( \beta(t + \Lambda) = (t, 0) \mathbb{L} \). So we know how \( \beta \) works on \( \mathbb{R}^d + \Lambda \).

Suppose \( f \) is a local function with respect to the model set \( \Lambda \). From the local function \( f \) we have its extension \( \tilde{F} \in L^2(X(\Lambda), \mu) \) which is continuous. Then we obtain \( \tilde{F} \in L^2(\mathbb{T}, \theta) \), where

\[
\tilde{F}((t, 0) \mathbb{L}) = \tilde{F}(\beta(t + \Lambda)) = F(t + \Lambda) = f(t), \tag{17}\]

and we can write

\[
\tilde{F}(\cdot) = \sum_{k \in \mathbb{L}^\circ} a_k e^{2\pi i \langle \tilde{k} \mid \cdot \rangle},
\]

where \( \mathbb{L}^\circ \) is the dual of \( \mathbb{L} \).

**Definition 3.** The *Fourier-Bohr expansion* of the local function \( f \) is

\[
f(t) = F(t + \Lambda) = \tilde{F}((t, 0) \mathbb{L}) = \sum_{k \in \mathbb{L}^\circ} a_k e^{2\pi i \langle \tilde{k} \mid (t, 0) \rangle} = \sum_{k \in \mathbb{L}^\circ} a_k e^{2\pi i \langle k \mid t \rangle}. \tag{18}\]
Our study of almost periodic functions on $\Lambda$ becomes the study of functions on $T$ and their restrictions to the ‘spiral’ orbit $\mathbb{R}^d + \Lambda$ in $T$ given by the embedding (10), i.e. restriction to $(\mathbb{R}^d, 0)_L$.

3.4. Fourier coefficients.

Let us continue with the situation in §3.3. For all $x \in T$, 
\[
\tilde{F}(x) = \sum_{k \in L^d} a_k e^{2\pi i \langle k | x \rangle} \quad (19)
\]
where 
\[
a_k = \int_T e^{-2\pi i \langle \tilde{k} | x \rangle} \tilde{F}(x) \, d\theta_T(x). \quad (20)
\]
Unfortunately, we don’t have total control over $\tilde{F}$. We know it only on $(\mathbb{R}^d, 0)_L$. To compute $a_k$ out of $f$ alone, we use the Birkhoff ergodic theorem: for all continuous functions $\tilde{G}$ on $T$,
\[
\int_T \tilde{G}(x) \, d\theta_T(x) = \lim_{R \to \infty} \frac{1}{\text{vol } B_R} \int_{B_R} \tilde{G}((t,0)_L) \, dt. \quad (21)
\]
Thus
\[
a_k = \lim_{R \to \infty} \frac{1}{\text{vol } B_R} \int_{B_R} e^{-2\pi i \langle \tilde{k} | (t,0)_L \rangle} \tilde{F}((t,0)_L) \, dt
\]
\[
= \lim_{R \to \infty} \frac{1}{\text{vol } B_R} \int_{B_R} e^{-2\pi i \langle k | t \rangle} f(t) \, dt. \quad (22)
\]
Here we use $F((t,0)_L) = f(t)$ and $\tilde{k} = (k, k')$, so 
\[
\langle \tilde{k} | (t,0) \rangle = \langle k, t \rangle + \langle k', 0 \rangle = \langle k, t \rangle.
\]
The averaging sequence $\{B_R\}$ that we have employed here can be replaced by any unbounded ascending sequence $\{A_n\}$, where $A_n \subset \mathbb{R}^d$ is compact, $\bigcup A_n = \mathbb{R}^d$, and the boundary of $A_n$ has measure 0 for all $n$. In actual practice one should adapt the averaging sequence to the problem at hand.

4. Discretization

4.1. Main components. Our objective is to devise a discrete method by which to estimate the coefficients $a_k$ of (22) of a local function $f$ with respect to a model set $\Lambda = \Lambda(\Omega)$. This means replacing the integral by a finite sum of values of the integrand. The problem is to do this in such a way that it respects the cut and project scheme in which the model set lives, can be guaranteed to converge in the limit to the required integral, and can be carried out efficiently from a computational point of view.

There are three components to this:

(i) deciding on a suitable domain of integration (what should we use for $B_R$?);
(ii) creating the points of evaluation of the integrand, including how many there should be;
(iii) deciding to which set of Fourier coefficients (which values of $k$) we should restrict our attention.

\[3\]It is hard to find convenient references for the Birkhoff ergodic theorem in the form we need it. Most references prove it over $\mathbb{Z}$ or $\mathbb{R}$. In [12] there is a proof over $\mathbb{Z}^d$ which is easy to adapt to $\mathbb{R}^d$. 

Figure 2. A fragment of the orbit of $\Lambda$ as seen in the torus parametrization.
A key feature of discrete methods involving periodic functions is the use of finite groups arising from refinements of the period lattice and quotients of its dual lattice, e.g. [20]. We need to translate this concept into the context of cut and project schemes. The set of points on which the integrand is evaluated is created out of the same cut and project process that creates the original model set. The ingredients are a choice of a suitable lattice \( \mathbb{L}_N \supset \mathbb{L} \), which then gives rise to the finite group \( \mathbb{L}_N / \mathbb{L} \). The data points in \( \mathbb{R}^d \) at which computations of our functions will be made come by projection into physical space of a suitable set of coset representatives of \( \mathbb{L}_N \) modulo \( \mathbb{L} \). The corresponding frequencies (wave vectors) \( k \) are chosen from the dual lattice \( \mathbb{L}^\circ \). The choice of values of \( k \) at which we should evaluate the Fourier coefficients \( a_k \) come by selecting suitable representatives of \( \mathbb{L}^\circ \) modulo \( \mathbb{L}_N \). The key point is the duality \( \langle \cdot, \cdot \rangle : \mathbb{L}^\circ / \mathbb{L}_N \times \mathbb{L}_N / \mathbb{L} \to \mathbb{N} / \mathbb{Z} \).

4.2. Outline of the discretization process. In this section we give more precise details as to how the goals of §4.1 can be achieved. The process necessarily involves a number of decisions, which can only be made in the context of the situation at hand. In §4.3 and §5 we shall see how this looks in particular examples.

It should be noted that although getting the computational details set up is somewhat involved, these details depend only on the cut and project scheme and the degree of accuracy required from the computation. Once this is established the data points and choices of frequencies are already determined, and they suffice for the Fourier analysis of all functions that arise out of the same almost periodic family, and are algorithmically easy to compute.

We begin with the cut and project scheme (5) with torus \( \mathbb{T} \) and note the natural extension of the mapping \( \langle \cdot \rangle' \) to the rational span of the module \( \mathbb{L} \):

\[
\mathbb{Q} \mathbb{L} \xrightarrow{1-1} \mathbb{Q}\mathbb{L} \quad \langle \cdot \rangle' : \mathbb{Q}\mathbb{L} \to \mathbb{Q}\mathbb{L}'
\]

(23)

We assume that \( \mathbb{R}^{2d} \simeq \mathbb{R}^d \times \mathbb{R}^d \) is supplied with the standard dot product (denoted \( \langle \cdot, \cdot \rangle \)), and then define the dual lattice:

\[
\tilde{\mathbb{L}}^\circ = \{ Y \in \mathbb{R}^d \times \mathbb{R}^d : \langle Y | \tilde{x} \rangle \in \mathbb{Z} \text{ for all } \tilde{x} \in \tilde{\mathbb{L}} \}.
\]

Then \( \tilde{\mathbb{L}}^\circ \) is a \( \mathbb{Z} \)-module of the same rank as \( \tilde{\mathbb{L}} \), namely \( 2d \). There is a cut and project scheme dual to (5) of which \( \tilde{\mathbb{L}}^\circ \) is the lattice \( \mathbb{L} \):

\[
\mathbb{R}^d \xrightarrow{1-1} \mathbb{R}^d \times \mathbb{R}^d \xrightarrow{\perp} \mathbb{R}^d \quad \cup
\]

\[
\mathbb{L}^\circ \xrightarrow{1-1} \tilde{\mathbb{L}}^\circ \xrightarrow{\text{dense image}} (\tilde{\mathbb{L}}^\circ)'
\]

(24)

We shall use the same type of notation as in (23) for this scheme too. It arises by taking the Pontryagin duals of all the groups in (23), whereupon \( \tilde{\mathbb{L}}^\circ \) appears as the dual of the torus \( \mathbb{T} \). For more on dual cut and project schemes see [17].

Dualizing can be considerably simplified if the inner product on \( \mathbb{R}^d \times \mathbb{R}^d \) is rational valued on the lattice \( \tilde{\mathbb{L}} \). This quite often happens in actual practice. For instance, it happens in the Fibonacci example below, where the inner product arises from the trace form on \( \mathbb{Q}[\sqrt{5}] \). When this happens one can identify \( \tilde{\mathbb{L}}^\circ \) as a subset of \( \mathbb{Q}\tilde{\mathbb{L}} \) and thereby avoid having to find the new \( \langle \cdot \rangle' \) mapping. However, in the general situation such simplifications need not exist, and we do not assume them here.

In reading what follows it is good to keep in mind the equation

\[
e^{2\pi i \langle \hat{k} | \hat{s} \rangle} = e^{2\pi i \langle k | s \rangle} e^{2\pi i \langle k' | s' \rangle}
\]

(25)

which lies at the bottom of the approximation. The discrete Fourier analysis is accomplished by a dual pair of finite groups from which the \( \hat{k} \) and the \( \hat{s} \) will come. The actual values of \( \hat{k} \) and \( \hat{s} \) are important only modulo the lattices \( \mathbb{L}_N \) and \( \tilde{\mathbb{L}} \) respectively, and this freedom lies at the heart of the process.

The values of \( s \) should be in the range \( A \) of our integration, and ideally we would have the corresponding \( s' = 0 \) since the \( \hat{s} \) are supposed to be representing points of the physical space \( \mathbb{R}^d \). However, the latter is not possible, so we attempt to choose the \( s \in A \) along with \( s' \) as small as possible. The approximation then works by throwing away the term which involves \( k', s' \) in (25). The set of values of \( \hat{k} \) is constrained primarily by the requirement that the values of \( |k| \) should be small, see the discussion after Step 5 below.
4.3. The six steps. Step 1: Choose a finite subgroup of $\mathbb{T}$ of order $N$. This appears in the form $\tilde{L}_N/\bar{L}$ where $\tilde{L}_N \supset \bar{L}$ is a lattice refining $\bar{L}$. The number $N$ will determine the number of points of evaluation in approximating the integrals by sums. We have $\tilde{L}_N \subset \mathbb{Q}\bar{L}$ and it has a $\mathbb{Z}$-dual $\tilde{L}_N^o \subset \bar{L}^o$ which is of index $N$ in $\bar{L}^o$.

This affords the natural pairing
\[
\tilde{L}^o/\tilde{L}_N^o \times \tilde{L}_N/\bar{L} \longrightarrow \frac{1}{N} \mathbb{Z}/\mathbb{Z}
\] (26)
induced by $\langle \cdot | \cdot \rangle$ (and still denoted by $\langle \cdot | \cdot \rangle$). Using the $\langle \cdot \rangle'$ mappings, we obtain, in the obvious notation, the $\mathbb{Z}$-modules $L_N \supset L$, $\tilde{L}_N/\bar{L} \simeq L_N/L$, $\tilde{L}^o_L/\tilde{L}^o_N \simeq \bar{L}/\tilde{L}_N$, and an induced pairing
\[
\langle \cdot | \cdot \rangle : \tilde{L}^o_L/\tilde{L}^o_N \times L_N/L \longrightarrow \frac{1}{N} \mathbb{Z}/\mathbb{Z}.
\]
Replacing $\bar{L}$ by $\tilde{L}_N$, we have the refined cut and project scheme
\[
\mathbb{R}^d \leftarrow \mathbb{R}^d \times \mathbb{R}^d \longrightarrow \mathbb{R}^d \\
\bigcup
\]
\[
L_N \xrightarrow{1-1} \tilde{L}_N \leftarrow L_N' \tag{27}
\]
and similarly its dual.

Step 2: Choose a fundamental domain $C$ for $\bar{L}$. A canonical choice would be the Voronoi cell of $\bar{L}$ at 0, but any other choice is allowable. In the examples below we use the parallelogram defined by a pair of basis vectors of $L$. Cover $(\mathbb{R}^d, 0) \subset \mathbb{R}^{2d}$ with a set of translates $\tilde{t} + C$ of $C$ by elements of $L$. The projection of these cells into the physical space $\mathbb{R}^d$ covers it, though in general the projected $\tilde{t} + C$ have many overlaps.

Step 3: Form $\tilde{S} := \tilde{L}_N \cap C$. This provides a complete set of representatives in $\tilde{L}_N$ for the group $\tilde{L}_N/\bar{L}$.

Step 4: Choose a region $A$ which will be the delimiting the range over which the Fourier coefficients of $f$ will be estimated in the form
\[
a_k = a_k^\sim \simeq \frac{1}{\operatorname{vol} A} \int_A e^{-2\pi i (k | t)} f(t) \, dt.
\]
These integrals have to be computed for values of $k$ that come from $L^o/L_N^o$.

Take as $A$ the image of a finite set of the translates of $C$ appearing in Step 2, i.e.
\[
A = \left( \bigcup_{\tilde{t} \in \tilde{T}} \tilde{t} + C \right)^{\parallel}
\]
for some finite subset of $\tilde{T}$ elements of $\bar{L}$. The choice of $A$ is again determined by the problem at hand.

We need next to determine a set of data points in $\mathbb{R}^d$ which will serve to replace the integrals of Step 4 by finite sums. This is the purpose of the next step.

As we pointed out above, we are free to translate the elements of $\tilde{S}$ by $\bar{L}$ as we please, and we wish to do this so that the projected images are in our region of integration $A = \bigcup_{\tilde{t} \in \tilde{T}} (\tilde{t} + C)^{\parallel}$. We also keep in mind that we wish to do this so as to minimize the size of the corresponding $s'$.

Step 5: For each $\tilde{s} = (s, s') \in \tilde{S}$ find a $t(s) \in \tilde{T}$ for which $|s' + t(s)|$ is minimal. Then the set of data points is
\[
D := \{ s + t(s) : \tilde{s} \in \tilde{S} \}.
\]

At this point, for each $k \in L^o$ we have
\[
a_k := \frac{1}{\operatorname{vol} A} \sum_{u \in D} e^{-2\pi i (k | u)} f(u)
\]
and the resulting approximation of $f$ is
\[
f(x) \simeq \sum_{k \in K} a_k e^{2\pi i (k | x)}.
\]

The set $K$ is to run over a complete set of representatives of $L^o/L_N^o$. The choice seems free, but one may assume that in most cases the lower frequencies (smaller $|k|$) are most essential in approximating $f$ by using only finitely many of its frequencies. For this reason we have:

Step 6: Choose $k$ for each class of $L^o/L_N^o$ with $|k|$ taken as small as possible.
This concludes the broad description of the algorithm.

5. A Fibonacci example

To make all this more concrete we work through the details of a one dimensional example, the well-known Fibonacci sequence, where the cut and project scheme lives in two dimensions and the geometry of the data set $D$ and the set of translates $T$ via a refinement lattice and new windows are easily visualized. This involves first setting up the cut and project scheme in detail, §5.1 and §5.2 and then describing a Fibonacci point set arising from the standard Fibonacci substitution in terms of it, §5.3 We then follow Steps 1 through 6 of §5.3 which provide the data points and corresponding frequencies that will work for the analysis of any local function that we may choose. In §6 we apply this information to two simple examples of local functions to see how well the methods actually work.

One of the great virtues of the cut and project method is that it is primarily an algebraic tool and does not require great geometric insight to use it. Given that for aperiodic structures in dimension greater than 1 we almost always in the situation of lattices of rank greater than 3, and hence forced into spaces in dimensions greater than 3, this type of algebraic formalism is of enormous value. However, in the Fibonacci example, in which everything can be done in 2-dimensions, it is useful to see the underlying geometry explicitly. Thus greater than 3, this type of algebraic formalism is of enormous value. However, in the Fibonacci example, in which everything can be done in 2-dimensions, it is useful to see the underlying geometry explicitly. Thus we have gone to some effort to show the geometric meaning of the central feature of the method, that is, the creation of the data points, and to show what the approximations look like and how good they are in comparison with exact computation. In actual practice all this is unnecessary. The only part of the algorithm that requires any serious insight into the geometry (and it is actually trivial in the Fibonacci example) is the selection of the fundamental domain and the translates of it that are to be used. It is their projection to see how well the methods actually work.

5.1. The Fibonacci cut and project scheme. Let $\tau := \frac{1}{2}(1 + \sqrt{5})$ and let $Z[\tau] = \mathbb{Z} + \mathbb{Z}\tau$. Then $Z[\tau]$ is the ring of integers of the field $\mathbb{Q}[\tau] = \mathbb{Q}[\sqrt{5}]$ and $\tau^2 = \tau + 1$. Let $(\cdot)'$ on $Z[\tau]$ and $\mathbb{Q}[\tau]$ be the conjugation that interchanges $\sqrt{5}$ and $-\sqrt{5}$.

We define

$$\widetilde{Z}[\tau] := \{(x, x') : x \in Z[\tau]\} \subset \mathbb{R} \times \mathbb{R}. \tag{27}$$

$\widetilde{Z}[\tau]$ is a lattice in $\mathbb{R} \times \mathbb{R}$ and its natural projections

$$\mathbb{R} \mapsto \mathbb{R} \times \mathbb{R} \mapsto \mathbb{R}$$

into $\mathbb{R}$ provide the set-up for the Fibonacci cut-and-project scheme:

$$\mathbb{R} \quad \underset{\cup}{\overset{\cup}{\overset{\cup}{\leftarrow}}} \quad \mathbb{R} \times \mathbb{R} \quad \underset{\cup}{\overset{\cup}{\overset{\cup}{\rightarrow}}} \quad \mathbb{R} \tag{28}$$

$Z[\tau] \quad \underset{\cup}{\overset{\cup}{\overset{\cup}{\leftarrow}}} \quad \widetilde{Z}[\tau] \quad \underset{\cup}{\overset{\cup}{\overset{\cup}{\rightarrow}}} \quad Z[\tau]$

$$x \quad \leftarrow \quad \widetilde{x} = (x, x') \quad \rightarrow \quad x'.$$

A natural basis of $\widetilde{Z}[\tau]$ is $\{(1, 1), (\tau, \tau')\}$ and the standard inner product on $\widetilde{Z}[\tau]$ is defined by

$$(\widetilde{x} \mid \widetilde{y}) = (2x \cdot y)_Z = \delta xy + (\delta xy)', \tag{29}$$

where $(\cdot)_Z$ indicates taking the rational component $a$ of $2x \cdot y \in Z[\tau] =: a + b\tau$, and

$$\delta = (\tau\sqrt{5})^{-1} = (\tau(\tau - \tau'))^{-1} = \frac{1}{\tau + 1}, \quad \delta' = (-\tau'\sqrt{5})^{-1} = (\tau'(\tau' - \tau))^{-1} = \frac{1}{\tau' + 1}. \tag{30}$$

In particular,

$$(\widetilde{1} \mid \widetilde{1})_Z = 2, \quad (\widetilde{\tau} \mid \widetilde{\tau})_Z = (2\tau^2)_Z = 2, \quad (\widetilde{1} \mid \widetilde{\tau}) = (2\tau)_Z = 0.$$

The geometry of the fundamental cell for the lattice $\widetilde{Z}[\tau]$ is illustrated in Fig. 3. More details of the material here can be found in [10].
5.2. The dual lattice. The inner product \( \langle \cdot \mid \cdot \rangle \) allows us to identify \( \mathbb{Z}[\tau]^\circ \) inside the rational span of \( \mathbb{Z}[\tau] \) and to express \( \langle \cdot \mid \cdot \rangle \) in terms of \( \langle \cdot \mid \cdot \rangle \). The basis dual to \( \{(1,1)\} \) is given by
\[
\tilde{\omega}_1 = \frac{1}{\tau} (1, \frac{1}{\tau}) , \quad \tilde{\omega}_2 = \frac{1}{\tau} (\frac{1}{\tau}, 1)
\]
and the dual lattice is
\[
\mathbb{Z}[\tau]^\circ = \mathbb{Z}\tilde{\omega}_1 + \mathbb{Z}\tilde{\omega}_2 = \frac{1}{\tau} \mathbb{Z}[\tau].
\]
The elements of \( \mathbb{Z}[\tau]^\circ \) are always of the form \( \tilde{k} = (k, k') \) and we can write
\[
\mathbb{Z}[\tau]^\circ := \{ k : \tilde{k} = (k, k') \in (\mathbb{Z}[\tau])^\circ \}
\]
Then
\[
\mathbb{Z}[\tau]^\circ = \mathbb{Z}\tilde{\omega}_1 + \mathbb{Z}\tilde{\omega}_2 = \{ \tilde{k} : k = (k, k') \in \mathbb{Z}[\tau]^\circ \},
\]
and \( \langle \tilde{k} \mid \tilde{x} \rangle \) becomes \( \langle k \mid x \rangle \), which is more useful notation for the sequel.

The 2-torus \( T \) of the cut-and-project scheme \( \{28\} \) is then
\[
T = (\mathbb{R} \times \mathbb{R})/\mathbb{Z}[\tau].
\]
Fourier series on \( T \) are expressed in terms of the characters \( \chi_{\tilde{k}} \), namely
\[
\chi_{\tilde{k}}(\tilde{x}) = e^{2\pi i \langle \tilde{k} \mid \tilde{x} \rangle} , \quad \text{where} \quad \tilde{k} = (k, k') \in \mathbb{Z}\tilde{\omega}_1 + \mathbb{Z}\tilde{\omega}_2 .
\]
Here \( \tilde{x} \) can be arbitrary in \( \mathbb{R} \times \mathbb{R} \), but we shall need to compute only with \( \tilde{x} \in \mathbb{Q}\tilde{\omega}_1 + \mathbb{Q}\tilde{\omega}_2 \) for which \( \tilde{x} \) is well-defined \( \{28\} \). For these elements \( \langle \tilde{k} \mid \tilde{x} \rangle = (2k \cdot x) \mathbb{Q} \).

The product \( \langle \cdot \mid \cdot \rangle \) extends to \( \mathbb{R} \times \mathbb{R} \), but care has to be taken. For a typical element \( a\tilde{1} + b\tau, a, b \in \mathbb{R} \) of our superspace \( \mathbb{R} \times \mathbb{R} \) the inner product is calculated as
\[
\langle (a\tilde{1} + b\tau) \mid (c\tilde{1} + d\tau) \rangle = 2ac + 2bd ,
\]
where
\[
a\tilde{1} + b\tau = a(1,1) + b(\tau, \tau') = (a + br, a + br') \in \mathbb{R} \times \mathbb{R} .
\]
Consider
\[
\tilde{k} = a\tilde{\omega}_1 + b\tilde{\omega}_2 = \frac{a}{\tau} \tilde{1} + \frac{b}{\tau^2} \tilde{\tau} = \left( \frac{a + br}{2}, \frac{a + br'}{2} \right) = (k, k') \in \mathbb{Z}[\tau]^\circ ,
\]
where \( a, b \in \mathbb{Z} \). Suppose we want to compute \( \langle \tilde{k} \mid (t,0) \rangle, t \in \mathbb{R} \). From
\[
(1,0) = \frac{\tau}{\sqrt{3}} \tilde{1} + \frac{1}{\sqrt{3}} \tilde{\tau} = \delta \tilde{1} + \tau \delta \tilde{\tau} ,
\]
\[
(0,1) = \tau^2 \delta \tilde{1} - \tau \delta \tilde{\tau} = \delta' \tilde{1} + \tau' \delta' \tilde{\tau} ,
\]
where \( \delta, \delta' \) are from \( \{30\} \), we have
\[
\langle \tilde{k} \mid (1,0) \rangle = 2\delta k ,
\]
and so,
\[
\langle \tilde{k} \mid (t,0) \rangle = 2\delta kt , \quad \text{for all} \quad t \in \mathbb{R} .
\]
We are interested in model sets \( \Lambda \) coming from the cut and project scheme \( \{28\} \). In the context of \( \{28\} \), the Fourier-Bohr expansion \( \{18\} \) assumes the simpler form
\[
f(t) = F(t + \Lambda) = \tilde{F}(t,0) = \sum_{k \in \mathbb{Z}[\tau]^\circ} a_k e^{2\pi i 2\delta k t} .
\]
We shall use the \( a_k \) computed in the form
\[
a_k = \lim_{R \to \infty} \frac{1}{R} \int_0^R e^{-2\pi i 2\delta k t} f(t) dt .
\]
For future use note that
\[
\langle \tilde{k} \mid (0,1) \rangle = \langle (\frac{a + br}{2}, \frac{a + br'}{2}) \mid \delta' \tilde{1} + \tau' \delta' \tilde{\tau} \rangle = 2k' \delta'
\]
\[
\langle \tilde{k} \mid (0,u) \rangle = 2uk' \delta' .
\]
5.3. The Fibonacci model set.

The standard 2-letter Fibonacci sequence is the fixed point of the substitution $a \rightarrow ab$, $b \rightarrow a$: namely, $abaababa \ldots$.

With tile lengths $\tau$ for $a$ symbols and 1 for $b$ symbols, and starting at 0, we get the sequence of tiles that cover the non-negative part of the real line. The left-hand ends of these tiles,

$$0, \tau, \tau + 1, 2\tau + 1, 3\tau + 1, 3\tau + 2, 4\tau + 2, 4\tau + 3, 5\tau + 3, \ldots$$

form an infinite sequence of points on the non-negative real line. This set appears explicitly as the non-negative part of the model set

$$\Lambda = \Lambda([-1, 1])$$

arising from the cut and project scheme \[28\] \(\Lambda\) decomposes as $\Lambda_a = \Lambda([-\frac{1}{\tau^2}, 1])$ and $\Lambda_b = \Lambda([-1, -\frac{1}{\tau^2}])$, which give the left-hand end points of the $a$ and $b$ points respectively.

![Figure 3. The fundamental cell $C$ of the lattice $\widetilde{Z}[\tau] = \mathbb{Z}(1, 1) + \mathbb{Z}(\tau, \tau')$ is shown in terms of the standard coordinate system for $\mathbb{R} \times \mathbb{R}$. When $C$ is imagined as a torus by identifying opposite sides and the physical space is wrapped onto it using these identifications, then the $a$ and $b$ regions shown here indicate which parts of the physical space are lying in $a$ or $b$ tiles respectively.](image)

A useful and commonly used way to visualize the distribution of $a$ and $b$ points is to view them on the torus $T$ after the embedding \[10\] of $\mathbb{R}$ in $T$. The fundamental cell, see Fig. 3, with opposite edges identified is $T$. To see $\Lambda$ itself being formed, we start at $(0, 0)$ and trace out $(t, 0)$, $t \in \mathbb{R}$, with the usual rules for exiting and re-entering the fundamental cell. We move continuously. Our moving point has three ‘whiskers’ attached to it.

- $a(1)$: a whisker of length $\frac{1}{\tau}$ facing vertically upwards;
- $a(2)$: a whisker of length $\frac{1}{\tau}$ facing down;
- $b(1)$: a whisker of length $\frac{1}{\tau}$ that faces down, but has an initial gap of size $\frac{1}{\tau^2}$.

The rule is this. As our point moves along the line on the fundamental cell, if the $a(1)$ whisker hits $(1, 1)$ (i.e. $(1, 1)$ is close enough to get cut by this whisker), we get an $a$-point of $\Lambda$. If the $a(2)$ whisker hits the point $(\tau, \tau')$, we also get an $a$-point of $\Lambda$. If the $b(1)$ whisker hits the point $(\tau, \tau')$, we get a $b$-point.

\[4\] Alternatively one can use $\Lambda((-1, 1])$, which differs from $\Lambda$ in the two points coming from the ends of the interval $[-1, 1]$. This is an example of a pair of sets that map to the same place in $T$. This ambiguity shows up in an interesting way later on, see \[6, 8\].
Essentially the window, represented by the whiskers, is carried along with the moving point, and exits and re-enters the fundamental cell with the moving point.

The advantage of this point of view is that it allows us to divide the fundamental cell into regions which deliver the \( a \)- and \( b \)-points, and thus to see what our function \( f(t) \) looks like on the fundamental cell.

In Fig. 3 the vertical dotted lines are the key thing. Our moving point moves to the right and every time it crosses a dotted vertical line, we get a new point of \( \Lambda \), thus starting a new interval. We stay on that interval until the next crossing.

The \( a \) and \( b \) regions are indicated in the Fig. 3.

5.4. Discretization.

We now go into the details of how to deal with the Fourier analysis using discrete methods. Here we follow the six steps outlined in \[4.3\].

Write \( L \) for \( \mathbb{Z}[\tau] \), so \( \overline{L} = \mathbb{Z} \mathfrak{I} + \mathbb{Z} \tau \). Let \( C := \{ u \mathfrak{I} + v \tau : 0 \leq u, v > 1 \} \) be a fundamental region for \( \overline{L} \). Its volume is equal to \( \sqrt{5} \).

Fix any \( N \in \mathbb{Z}_+ \). We want to create a lattice \( \overline{L}_N \) that is a refinement of \( \overline{L} \). In the \[4.3\] we took \( \overline{L}_N \supset \overline{L} \) with \( [\overline{L}_N : \overline{L}] = N \). In our present situation we use the most obvious lattices, namely \( \frac{1}{N} L \). These actually have index \( N^2 \), so there are some slight notational differences between this section and \[4.3\]. Since \( NL_N \subset \overline{L} \), so \( \overline{L}_N \subset \mathbb{Q} \mathfrak{I} + \mathbb{Q} \tau \).

Let \( \tilde{S} := L_N \cap C \), so \( \tilde{S} \) is a complete set of representatives of \( L_N \mod L \).

Together this completes steps 1, 2, 3 of \[4.3\].

For understanding the approximations better we also introduce a fundamental region \( C_N \) for \( L_N \), chosen so that
\[
C = \bigcup_{\tilde{s} \in \tilde{S}} \tilde{s} + C_N.
\]

For Step 4 we choose as our delimiting range in \( \mathbb{R} \) an interval \([0, R]\) where \( R \) is a positive real number taken so that \((R, 0)\) taken modulo \( \overline{L} \) is on the boundary of \( C \). Following along the path \((t, 0), t \in \mathbb{R}_{>0}\), and wrapping around \( C \) as indicated in Fig. 4, this amounts to stopping at some point \( R \) where the path is just exiting \( C \), so that we have an exact number of passes of \( C \). Thus the path \((t, 0), 0 \leq t \leq R\) involves an explicit set of translates \( \tilde{t}_i + C, i = 1, \ldots, M \) of \( C \). Let \( \widehat{T} = \{ \tilde{t}_1, \ldots, \tilde{t}_M \} \).

Let \( f : \mathbb{R} \to \mathbb{C} \) be any continuous local function with respect to the model set \( \Lambda = \Lambda([\mathbb{Z}, \frac{1}{N}]) \), and let \( \overline{F} : \mathbb{T} \to \mathbb{C} \) be its extension to a continuous function on \( \mathbb{T} = \mathbb{R}^2/\overline{L} \). Generally we are interested in Fourier decomposition of \( \overline{F} \) and along with it the corresponding decomposition of \( f \). Thus we wish to compute things like
\[
\int_{\mathbb{T}} \overline{F}(x) e^{-2\pi i \tilde{k} \cdot x} d\theta_x(x).
\]

Here \( \overline{F}(\cdot) e^{-2\pi i \tilde{k} \cdot x} \) is just some other continuous function on \( \mathbb{T} \) that is local with respect to \( \Lambda \). So it suffices to deal with some general continuous function \( G \) on \( \mathbb{T} \) and its restriction \( g(t) = G((t, 0)) \) to the line \((\mathbb{R}, 0) \mod \overline{L} \).

Let
\[
\varepsilon_N := \sup_{i=1,\ldots,N^2} \sup_{x \in \tilde{s}_i + C_N} |\overline{G}(x) - \overline{G}(\tilde{s}_i)|.
\]

Our first estimate is
\[
\int_{\mathbb{T}} \overline{G} d\theta_x \sim \frac{\sqrt{5}}{N^2} \sum_{i=1}^{N^2} \overline{G}(\tilde{s}_i).
\]

Since \( \text{vol} C_N = \frac{\sqrt{5}}{N^2} \), the error in this is estimated by
\[
\left| \int_{\mathbb{T}} \overline{G} d\theta_x - \frac{\sqrt{5}}{N^2} \sum_{i=1}^{N^2} \overline{G}(\tilde{s}_i) \right| = \sum_{i=1}^{N^2} \int_{\tilde{s}_i + C_N^2} \left( \overline{G}(x) - \overline{G}(\tilde{s}_i) \right) d\theta_x(x)
\leq \sum_{i=1}^{N^2} \int_{\tilde{s}_i + C_N} \varepsilon_N d\theta_x = \sum_{i=1}^{N^2} \varepsilon_N \text{vol} C_N = \sqrt{5} \varepsilon_N,
\]

\[4.3\]
i.e. the error in our approximation is bounded by $\sqrt{5}\varepsilon_N$. In practice $L_N$ and $N$ would be chosen so as to provide a suitably \textit{a priori} assigned value of $\varepsilon_N$.

5.5. \textbf{Restriction to $f$.}

In order to be useful, the computation must be restricted to values of the function $f$, since this is all that one is given in practice. We wish to use an approximation of the form

$$
\frac{1}{R} \int_{0}^{R} g(t) \, dt = \frac{1}{R} \int_{0}^{R} \tilde{G}(t,0) \, dt \sim \int_{T} \tilde{G} \, d\theta, 
$$

in accordance with (21).

In this section we indicate the geometry behind Step 5. Again, it should be pointed out that in the final analysis much of the detail that appears here need not appear at all in the actual algorithm.

The path $\{(t,0) \mid 0 \leq t \leq R\}$, wrapped around $C$, is divided by $C$ into segments $l_1, \ldots, l_M$.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure4.png}
\caption{Ten crossings of $C$ by the path $\{(t,0)_L \mid 0 \leq t \leq R\}$ are shown in the torus. (Opposite sides of the parallelogram coincide.)}
\end{figure}

Let $b_1 < b_2 < \ldots < b_M$ be the projections onto internal space of the boundary cutting points of $\{(t,0) : 0 \leq t \leq R\}$. Define

$$
c_0 = \tau', \quad c_1 = \frac{b_1 + b_2}{2}, \ldots, \quad c_{M-1} = \frac{b_{M-1} + b_M}{2}, \quad c_M = 1.
$$

The strips $S_i$ formed by passing the interval $[c_{i-1}, c_i]$ in internal space through $C$ in the direction of the physical axis, form a partition of $C$. Through each strip in $C$ runs a part $l_i$ of our line $\{(t,0)_L : 0 \leq t \leq R\}$. The idea is to use the intervals $[c_{i-1}, c_i]$ as windows and the line segments $l_i$ as (part of) the physical space for a model set construction based on the lattice $L_N$. This will then produce the points on $l_i$ which will be our data points for the evaluation of the functions $\tilde{G}$, and then $g$. In other words, we are implicitly using the partial model sets $\Lambda^*_{L_N}(S_i) \cap l_i$.

Let $m(R) := \max\{|c_i - c_{i-1}|\}$ and

$$
\bar{\varepsilon}_N' := \sup_{i} \sup_{(x,v),(x,u) \in S_i} \left| \tilde{G}(x,v) - \tilde{G}(x,u) \right|, \quad i = 1, \ldots, M.
$$

Each $\tilde{s}_j \in \tilde{S}_i$ lies in exactly one strip $S_i$. Let $(p_j, q_j)$ be its projection onto the line segment $l_i$. Then $(p_j, q_j) \equiv (u_j, 0)_L$ for some $u_j \in [0, R]$. Thus we obtain $\{(u_1, 0), \ldots, (u_{N^2}, 0)\}$ on our path $\{(t,0)_L : 0 \leq t \leq R\}$.

We have the estimate (23). Moreover,

$$
\sqrt{\frac{\varepsilon}{N^2}} \sum_{i=1}^{N^2} \tilde{G}(\tilde{s}_i) = \sqrt{\frac{\varepsilon}{N^2}} \sum_{i=1}^{N^2} (\tilde{G}(\tilde{s}_i) - \tilde{G}(p_i, q_i)) + \sqrt{\frac{\varepsilon}{N^2}} \sum_{i=1}^{N^2} g(u_i),
$$

since

$$
\tilde{G}(p_i, q_i) = \tilde{G}((u_i, 0)) = g(u_i).
$$
The projections $b_1, \ldots, b_M$ into internal space of the boundary cutting points of the path. The points $c_0, \ldots, c_M$ mark the boundaries of the smaller windows into which the original window $[\tau', 1)$ is partitioned.

The points $\tilde{s}_j$ lying in the strip $S_i$ formed by the window $[c_{i-1}, c_i)$ are projected onto the segment $l_i$ of the path $\{(t, 0)_L : 0 \leq t \leq R\}$ producing data points $u_j$, shown here as small crosses.

Thus

$$\left| \frac{\sqrt{5}}{N^2} \sum_{i=1}^{N^2} \tilde{G}(\tilde{s}_i) - \frac{\sqrt{5}}{N^2} \sum_{i=1}^{N^2} g(u_i) \right| \leq \frac{\sqrt{5}}{N^2} \sum_{i=1}^{N^2} \varepsilon'_N = \sqrt{5} \varepsilon'_N, \quad \text{(39)}$$

since $\tilde{s}_i$ and $(p_i, q_i)$ both have second component in the same interval $[c_{i-1}, c_i)$.

Combining (38) and (39), we have

$$\left| \int_\mathbb{T} \tilde{G} \, d\theta - \frac{\sqrt{5}}{N^2} \sum_{i=1}^{N^2} g(u_i) \right| < \sqrt{5} (\varepsilon_N + \varepsilon'_N). \quad \text{(40)}$$
This provides a method of estimating the integral \( \int_{\mathbb{R}} \tilde{G} \, d\theta \) using only \( g \) on \([0, R]\) along with well chosen points in the interval. The two parameters \( N \) and \( R \) control the estimates.

In spite of the apparent complexity of strips, what is going on is easy to implement. For each \( \tilde{s}_i = (s_i, s'_i) \) there is a translation vector \( \tilde{t}_j \in \tilde{T} \) for which \( |s'_i + t'_j| \) is minimal. The corresponding data point is then \( u_i := s_i + t_j \). This is Step 5 of \([4.2]\).

6. Two Explicit Examples

6.1. Computation of Fourier coefficients. In this section we apply the methods outlined above to two almost periodic functions \( f : \mathbb{R} \to \mathbb{R} \), both local with respect to the model set \( \Lambda = \Lambda([-1, 1/2]) \) of \([5.3]\). The first is the distance-to-the-nearest neighbour function

\[
 f(t) = \text{the distance of } t \text{ to the nearest point of } \Lambda. \tag{41}
\]

This is a continuous and piecewise linear function that is local with respect to \( \Lambda \).

The second is the function

\[
 f : f(x) = \begin{cases} 
 1, & \text{if } x \text{ is in a long interval} \\
 -1, & \text{if } x \text{ is in a short interval},
\end{cases} \tag{42}
\]

which local, but only piecewise continuous with breaks wherever \( x \) switches from a long to a short interval.

Graphs of these functions are shown (solid lines) in Fig. 8 and Fig. 13 respectively.

Our objective is to see how well the approximations we have discussed compare with the actual functions when the calculations are done with specific choices of data points.

We approximate each of the two functions by a finite number of terms of its Fourier-Bohr expansion \([18]\), which in our setting here reads:

\[
 f(x) = \sum_{k \in \mathbb{Z}[	au]} a_k e^{2\pi i (k|x|)}, \quad x \in \mathbb{R}. \tag{43}
\]

For the two functions \( f \) chosen here, it is easy to determine the corresponding functions \( \tilde{F} \) on the torus \( \mathbb{T} = (\mathbb{R} \times \mathbb{R})/\mathbb{L} \) and hence to compute the Fourier-Bohr coefficients \( a_k \) exactly by \([19]\), see \([6.2]\). For the nearest neighbour function these are given explicitly in \([50]\).

On the other hand, the approximation depends on the choice of the refinement lattice \( \mathbb{L} \), which shall now always be of the form \((1/N)\mathbb{L} = (1/N)\mathbb{Z}[\tau]\) (so the index \([\mathbb{L}_N : \mathbb{L}]\) is \( N^2 \)). This determines both the points that will eventually be projected into our data points and also the values of \( k \) which shall be included in approximating the sum \([43]\), namely a set \( \tilde{K} \) of \( \tilde{k} = (k, k') \in \mathbb{Z}[	au] \) chosen as representatives of the group \( \mathbb{Z}[	au]/N\mathbb{Z}[	au] \) dual to the group \((1/N)\mathbb{Z}[\tau]/\mathbb{L}\). Our choice is take the \( \tilde{k} \) with \( |k| \) as small as possible, so \( K \) consists of elements \( k \in \mathbb{Z}[	au] \), one for each congruence class of \( \mathbb{Z}[	au] \) modulo \( N\mathbb{Z}[	au] \), chosen so that \( |k| \) is minimal in its class. We denote by \( f^{\text{exact}}(x) \) the finite series, taken from \([43]\), approximating \( f(x) \), \( x \in \mathbb{R} \):

\[
 f^{\text{exact}}(x) = \sum_{k \in \tilde{K}} a_k e^{2\pi i (k|x|)}, \quad x \in \mathbb{R}. \tag{44}
\]

Next we replace the coefficients \( a_k \) in \( f^{\text{exact}}(x) \) by their approximations

\[
 a_k^{\text{int}} := \frac{1}{R} \int_0^R f(x) e^{-2\pi i (k|x|)} \, dx \tag{45}
\]

following from \([22]\), and denote the resulting function by \( f^{\text{int}}(x) \). We shall use various values of \( R \), all of which correspond to a set of complete passes across the fundamental region, as illustrated in Fig. 5.

The integrals \([46]\) are to be estimated by reducing them to finite sums where the integrand is computed on the finite set of data arising as projections \( \{u_1, \ldots, u_{N^2}\} \) of the \( N^2 \) points in \( \mathbb{C} \), as explained in \([43]\).

The resulting approximation to \( f^{\text{exact}}(x) \) is denoted \( f^{\text{sum}}(x) \). This is the approximation that we have been working towards. Written out in full it reads:

\[
 f^{\text{sum}}(x) = \sum_{k \in \tilde{K}} \left\{ \frac{1}{N^2} \sum_{j=1}^{N^2} f(u_j) e^{-2\pi i (k|u_j|)} \right\} e^{2\pi i (k|x|)}. \tag{47}
\]
It is computed out of data points in \( \mathbb{R} \), is a finite sum of exponential functions whose frequencies come from the Fourier module of \( f \), and utilizes discrete groups arising out of the periodic setting of the underlying cut and project scheme. By its form, \( f^{\text{sum}} \) is almost periodic and approximates the function \( \tilde{F} \) everywhere on the real line as it lies wrapped around the torus.

Thus we have four functions: \( f, f^{\text{exact}}, f^{\text{int}}, f^{\text{sum}} \), all defined for all \( x \in \mathbb{R} \). The three approximation functions depend on the number \( M \) of passes of the real line going through the fundamental region \( C \) (see \( \S 5.4 \) and \( \S 5.5 \) for details), and on the number \( N^2 \) of lattice points of \( \tilde{L}_N \) found in \( C \). Each of them restricts the full summation of the Fourier-Bohr expansion to the same finite set \( K \) of frequencies. They differ due to the ways in which the Fourier-Bohr coefficients are obtained: they are exact in the first case (or at least as exact as real computation on computers can be), are derived from the integral approximation in the second, and come from the finite sum approximation to the integral in the third. The calculations and graphs shown below allow one to compare these functions. The exact coefficients and their approximations by integrals are sufficiently close as to make little difference to the graphs, so the figures are restricted to comparing \( f, f^{\text{int}}, f^{\text{sum}} \).

By way of comparison, there is one further Fourier approximant, of the type that we are obtained by periodically extending \( f \) from its values on a fixed finite interval \( I \) of \( \mathbb{R} \) to the entire space \( \mathbb{R} \). Thus we introduce

\[
f^{\cos}(x) = \sum_{k=0}^{n} a_k \cos\left(\frac{1}{2}k\pi x\right), \quad \text{where} \quad a_k = \frac{1}{2} \int_0^2 f(x) \cos\left(\frac{1}{2}k\pi x\right) dx.
\] (48)

Needless to say, \( f^{\cos} \) cannot be expected to have much relationship to \( f \) outside \( I \), and it doesn’t. In fact, \( f^{\cos} \) does not appear to be a good choice even on the limited domain \( I \).

6.2. Computing the exact Fourier-Bohr coefficients. It may be of interest to indicate how we computed the exact Fourier-Bohr coefficients. We can reorganize Fig. 3, translating the \( a \) and \( b \) regions into single blocks (see Fig. 7), a procedure that is familiar from the kloz construction see \( \S 7 \) often used in studying cut and project sets. \[13\].

It is then straightforward to understand the corresponding function \( \tilde{F} \) on the 2-dimensional torus, i.e. a genuinely periodic function for which \( f(t) = \tilde{F}(t,0) \mod \mathbb{Z}[\tau] \).

Furthermore, it is easy to compute the ‘exact’ Fourier coefficients of \( \tilde{F} \). Let \( \tilde{k} = a\tilde{\omega}_1 + b\tilde{\omega}_2 \in \mathbb{Z}[\tau]^\circ \), where \( a, b \in \mathbb{Z} \). Then

\[
(\tilde{k} \mid (x,y)) = x (\tilde{k} \mid (1,0)) + y (\tilde{k} \mid (0,1)) = 2xk\delta + 2yk'\delta',
\]
where
\[ k = \frac{a + b\tau}{2}, \quad k' = \frac{a + b\tau'}{2}. \]

The Fourier coefficient for \( \tilde{k} \) is
\[ a_k = \int_{\tau} \tilde{F}(w) e^{-2\pi i (k|w|)} dw = \int_0^1 \int_0^1 \tilde{F}(u, v) e^{-2\pi i (k|u\tau + v\tau'|)} du dv. \quad (49) \]

Writing
\[ u\tau + v\tau' = (u + v\tau, u + v\tau') =: (x, y), \]
we have
\[ (\tilde{k} | u\tau + v\tau) = 2kx\delta + 2k'y\delta'. \]

Making the change from the variables \( u \) and \( v \) to \( x \) and \( y \), and using the definition of \( \tilde{F} \), we obtain
\[ a_k = \frac{1}{\sqrt{5}} \int_{x}^{0} \int_{y}^{0} \left( \frac{1}{2} - \left| x + \frac{1}{2} \right| \right) e^{-4\pi i (kx\delta + k'y\delta')} dx dy + \frac{1}{\sqrt{5}} \int_{x'}^{0} \int_{y'}^{0} \left( \frac{1}{2} - \left| x - \frac{1}{2} \right| \right) e^{-4\pi i (kx\delta + k'y\delta')} dx dy. \quad (50) \]

Note that the factor \( \frac{1}{\sqrt{5}} \) comes from \( x = u + v\tau, \ y = u + v\tau' \).

\[ \begin{pmatrix} 1 \\ \tau \\ 1 \\ \tau' \end{pmatrix} = \tau' - \tau = -\sqrt{5}. \]

6.3. Shadows of singularities. Inspection of the aperiodic approximations shows that they are remarkably faithful to the originals. But there is apparently a strange fuzziness in the approximation in the interval \( [-\tau^2, 0] \). The explanation for this is quite interesting and shows that the approximation method we use here is sensitive to quite subtle qualities of the aperiodicity.

The particular Fibonacci set that we have used in our example is singular, that is to say, it is one at which the torus parametrization is not one-one. As pointed out in footnote of 5.3, \( \Lambda \) is but one of two distinct sets in \( X(\Lambda) \) that map to the same point on the torus \( T \) under the torus map. The other one differs from \( \Lambda \) only in that it contains \( \{-\tau\} \) but not \( \{-1\} \). The Fourier analysis takes place on \( T \) and treats these two sets equally. However the nearest neighbour functions of the two sets are different. This is a difference that it immaterial to \( \tilde{F} \), which our function \( f^{\text{sm}} \) is approximating, but which the original function \( F \) can see. What we see is the Fourier analysis hedging between the two scenarios.

Further refinements of the lattice will never improve the situation on this interval. However, if we had used an element of \( X(\Lambda) \) at which the torus map were \( 1 - 1 \) (and this is the case with probabilistic certainty if one chooses randomly from \( X(\Lambda) \)) then this phenomenon would not occur and the approximation would be uniformly valid over the entire space. All one need do is to shift the window so that its end points do not lie in the set \( \mathbb{Z}[\tau] \), e.g. \( \frac{1}{2} + [-1, \frac{1}{2}] \).

7. Final Comments

We should point out that there is considerable scope for adapting the scenario sketched out here. It is possible to arrange things so that they are related to tilings. One elegant tiling method is the klotz construction [13, 14]. One begins with the decomposition into Voronoi cells of the lattice \( \mathbb{L} \) in \( \mathbb{R}^d \times \mathbb{R}^d \), and along with it the corresponding dual cell decomposition into Delone cells. For each pair of \( P, Q \) consisting of intersecting \( d \)-dimensional faces \( P \) and \( Q \) from a Voronoi cell and a Delone cell respectively, form the klotz \( P^L \times Q^L \) in \( \mathbb{R}^d \times \mathbb{R}^d \). The set of these klotze form a tiling of \( \mathbb{R}^d \times \mathbb{R}^d \). Furthermore the intersection of \( (\mathbb{R}^d, 0) \) with this tiling produces a tiling of physical space. (If one chooses instead to do the projections the other way around, one gets a different tiling). Several of these klotze can be combined to form a fundamental region for \( \mathbb{R}^d \times \mathbb{R}^d \), as we see in Fig. 7, and this type of choice should lead to computational methods that are adapted to the these tilings. For instance, the region \( A \) of integration might well be chosen as the union of a finite number of tiles. For more on determining Voronoi and Delone cells in the context of high symmetry, see [19].

The method advocated here is based on the idea of local functions, the extending of them into the context of compact Abelian groups, and the discretization of the resulting Fourier analysis by the use of finite groups.
In the 1D setting that was explored in detail here, the only symmetries involved arise from translational symmetry (which is at the base of the almost periodicity). In higher dimensions, especially those of interest to the quasicrystal community, decagonal, icosahedral, or other symmetries appear. In these cases there are a number of ways of utilizing the symmetry to greatly improve the efficiency of the computation, in the same spirit as [LS]. As we have pointed out, the preparations required for this depend largely on the cut and project scheme and not so much on the actual model set involved. Fortunately the cut and project schemes for these settings are essentially canonical and their strong algebraic nature makes this program quite feasible.

Finally, although we have not spelled it out here, the way in which finite groups and their duals are used here makes the process amenable to the technique of the fast Fourier transform. Details will appear later.

Figure 8. The solid line is the graph of \( f \) of (41). The dotted curve shows the \( f^{\text{sum}} \) approximation and the dashed curve shows the \( f^{\text{int}} \) approximation. Both approximations were calculated using a total of \( N^2 = 49 \) lattice points in \( C \) and \( M = 11 \) path passes in \( C \), corresponding to an interval of integration \( R \approx 23,30 \).

Figure 9. The function \( f \) and approximants of (41) are drawn with the same conventions as in Fig. 8, but for refined parameters: \( M = 17, N^2 = 121 \), and \( R \approx 37,43 \). See subsection 6.3 for an explanation of the misfit of approximations in the region \([-\tau^2, 0]\).

Figure 10. The function \( f \) of (41) is graphed for parameters: \( N^2 = 9 \) lattice points from \( C \), \( M = 10 \) passes of the fundamental domain, and corresponding interval of integration given by \( R \approx 21,64 \). Also the periodic approximation \( f^{\text{cos}} \) is shown. The number of cosine terms used is \( n = 50 \) and coefficients are calculated by formula (48). Here the dotted curve corresponds to the \( f^{\text{sum}} \) approximation, the dashed curve corresponds to \( f^{\text{exact}} \) approximation, and the thin line represents \( f^{\text{cos}} \) approximation.

Figure 11. Here we graph the same approximations as in Fig. 10, but the functions are now drawn on the interval \([200, 215]\). Observe how the aperiodic approximants continue to follow the graph of \( f \) while the periodic approximant now has no relation to it.
Figure 12. The approximations are presented with the same conventions as on Fig. 10 but the functions are drawn in the interval $[-115, -100]$.

Table 3. Comparison of the calculated coefficients $a_k$ in the approximations $f_{exact}$, $f_{int}$, and $f_{sum}$. The parameters are as in Fig. 14.

| $k$           | $a_k^{exact}$       | $a_k^{int}$       | $a_k^{sum}$       |

Figure 13. The solid line is the graph of $f$ of (42). The dotted and dashed curves correspond to the $f^{\text{sum}}$ and $f^{\text{int}}$ approximations. Both approximations were calculated using a total of $N^2 = 81$ lattice points in $C$, $M = 17$ passes of $C$, and corresponding interval of integration given by $R \approx 37.01$.

Figure 14. The function $f$ of (42) is drawn for parameters: $N^2 = 49$, $M = 11$, $R \approx 23.30$. Also the periodic approximation $f^{\text{cos}}$ is shown as thin line. The number of cosine terms used is $n = 50$ and coefficients were calculated by (48). Here the dotted curve corresponds to the $f^{\text{sum}}$ approximation and the dashed curve corresponds to $f^{\text{exact}}$ approximation.

Figure 15. Here we adduce the same approximations as in Fig. 14, but the functions are drawn on the interval $[200, 215]$.

Figure 16. The approximations are drawn with the same conventions as on Fig. 14, but on the interval $[-115, -100]$.
