ABSTRACT
Using the almost all-sky 2MASS Photometric Redshift catalogue (2MPZ) we perform for the first time a tomographic analysis of galaxy angular clustering in the local Universe (\(z < 0.24\)). We estimate the angular auto- and cross-power spectra of 2MPZ galaxies in three photometric redshift bins, and use dedicated mock catalogues to assess their errors. We measure a subset of cosmological parameters, having fixed the others at their Planck values, namely the baryon fraction \(f_b = 0.14^{+0.09}_{-0.06}\), the total matter density parameter \(\Omega_m = 0.30^{+0.06}_{-0.06}\), and the effective linear bias of 2MPZ galaxies \(b_{\text{eff}}\), which grows from \(1.1^{+0.3}_{-0.4}\) at \(\langle z \rangle = 0.05\) up to \(2.1^{+0.3}_{-0.5}\) at \(\langle z \rangle = 0.2\), largely because of the flux-limited nature of the dataset. The results obtained here for the local Universe agree with those derived with the same methodology at higher redshifts, and confirm the importance of the tomographic technique for next-generation photometric surveys such as Euclid or LSST.

Key words: cosmology - large-scale structure of Universe - observations - cosmological parameters, galaxies: photometry

1 INTRODUCTION
Cosmological probes like the baryonic acoustic oscillations (BAO; e.g. Eisenstein & Hu 1998; Eisenstein et al. 2005; Cole et al. 2005; Sánchez et al. 2008; Anderson et al. 2014) and redshift-space distortions (RSD; e.g. Kaiser 1987; Szalay et al. 1998; Hamilton 1998; Guzzo et al. 2008) can be used to simultaneously trace the expansion history of the Universe and the growth of cosmic structures. These probes, together with the measurements of the temperature fluctuations in the cosmic microwave background (CMB) (e.g. Hinshaw et al. 2013; Planck Collaboration et al. 2016) and distance measurements to Supernovae Type Ia (e.g. Kowalski et al. 2008), are exploited not only to constrain the fundamental cosmological parameters, but also to reveal the nature of dark energy and to tests the validity of General Relativity on cosmic scales (e.g. Taruya et al. 2014; Beutler et al. 2014).

BAOs and RSDs are inferred from the two and three-point statistics of mass tracers, both in configuration and in Fourier space (see e.g. Cole et al. 1994; Percival et al. 2001; Lahav & Suto 2004; Percival et al. 2007; Slepian et al. 2017). So far, this has mainly been possible thanks to extensive observational campaigns such as the Sloan Digital Sky Survey (SDSS, York et al. 2000), dedicated to measure angular positions and spectroscopic redshifts (spec-zs hereafter) of a large number of extragalactic objects over big cosmological volumes.

However, spectroscopic observations have their limitations in terms of sky coverage and number density of tracers for which redshifts can be measured in practice. Currently, the number of available spec-zs is about 3 million, and this quantity is unlikely to grow by more than an order of magnitude in the coming years (Peacock 2016). Photometric datasets, on the other hand, already include \(\sim 10^9\)
extragalactic sources, and this number is expected to increase dramatically in the next decade thanks to the ongoing and planned imaging surveys (e.g. The Dark Energy Survey Collaboration 2005; Ivezić et al. 2008; Laureijs et al. 2011; Chambers et al. 2016). This difference stems from the comparatively longer observation time required to measure spectra, whereas sparse sampling is required to guarantee efficient selection of spectroscopic targets at moderate to large redshifts. As a result, outside of the local volume of $z < 0.1$, spec-z campaigns map only specific, colour-selected sources, such as luminous red galaxies, emission line sources, or quasars (e.g. Blanton et al. 2017). This results in a low number density, limited completeness of tracers, and high shot-noise.

Another important difference between photometric and spectroscopic surveys is their typical sky coverage. The former are usually (much) wider than the latter, since spectroscopic observations require a trade-off between area and depth. As a result, wide, almost full-sky, spectroscopic datasets like the 2MASS Redshift Survey (2MRS, Huchra et al. 2012) or the IRAS PSCz (Saunders et al. 2000) are much shallower and contain fewer objects than their full-sky photometric counterparts, such as the catalogues based on the 2-Micron All-Sky Survey (2MASS, Skrutskie et al. 2006) or on the Wide-Field Infrared Survey Explorer (WISE, Wright et al. 2010) measurements (e.g. Kovács & Szapudi 2015; Bilicki et al. 2016).

While spectroscopic surveys remain the primary datasets for three dimensional (3D) clustering analyses, the availability of wide and deep photometric catalogues allows us to perform studies of 2D, i.e. angular, clustering over much larger volumes. Indeed, two-point angular correlation functions and angular power spectra (APS hereafter) were historically the first statistics used to investigate the properties of the large scale structure of the Universe (e.g. Peebles 1973; Hauser & Peebles 1973; Peebles & Hauser 1974; Davis et al. 1977). In particular, the APS is the natural tool to analyze full-sky catalogues since spherical harmonics constitute the natural orthonormal basis on the sphere. This consideration applies to wide spectroscopic samples too, in which case the Bessel functions are included to trace clustering along the radial direction. The so-called Fourier-Bessel decomposition (Fisher et al. 1994; Heavens & Taylor 1995), has been however seldom applied so far due to the computational cost of the technique (e.g. Tadros et al. 1999; Percival et al. 2004; Leistedt et al. 2012).

The APS has been used to quantify the 2D clustering properties in many existing photometric catalogues (e.g. Blake et al. 2004, 2007; Padmanabhan et al. 2007; Thomas et al. 2011; de Putter et al. 2012; Ho et al. 2012, 2015; Seo et al. 2012; Hayes & Brunner 2013; Leistedt et al. 2013; Leistedt & Peiris 2014; Nusser & Tiwari 2015). Although cosmological information can be extracted from purely 2D samples (e.g. Blake et al. 2004; Nusser & Tiwari 2015), much more stringent tests can be performed if some knowledge of clustering in the radial direction is also available. This is, in essence, the idea behind the tomographic approach, in which 2D clustering analyses are performed in different radial shells, both in terms of auto- as well as cross-correlations between the bins. The better the proxy for the radial distance, the thinner the shells, the closer to a full 3D study the tomographic analysis is (e.g. Blake & Bridle 2005; Asorey et al. 2012; Salazar-Albornoz et al. 2014). The tomographic approach to angular clustering is in particular possible thanks to the availability of photometric redshifts (photo-$z$) estimated from multi-wavelength broad-band photometry (Koo 1985). Indeed, most of the tomographic clustering analyses have focused on the SDSS galaxy and quasar photometric catalogues, i.e. targeting objects at relatively large redshifts ($z > 0.4$) and using much less than full-sky (less than [or approx. 1] steradians). The sky coverage aspect is rather crucial, since APS errors scale with the square root of the employed area (e.g. Peebles 1980; Dodelson 2003). This is one of the reasons why surveys like Euclid (Laureijs et al. 2011) and the Large Synoptic Survey Telescope (LSST, LSST Science Collaboration et al. 2009), designed to map large portions of the sky at large depths, will adopt the tomographic analysis of APS as one of their main cosmological probes.

In the recent years, photo-$z$ catalogues covering the full extragalactic sky have become available (Bilicki et al. 2014, 2016). Although relatively local, as compared to for instance SDSS, these samples are much deeper than what is available from spectroscopic full-sky datasets such as 2MRS and PSCz, while giving access to much larger sky areas than SDSS or other ongoing photometric campaigns, such as the Dark Energy Survey (The Dark Energy Survey Collaboration 2005). It is thus finally possible and timely to attempt a tomographic angular clustering analysis in the local Universe. This is the motivation behind the present work.

We aim at applying the tomographic technique to the very local, but almost all-sky 2MASS Photometric Redshift catalogue (2MPZ, Bilicki et al. 2014). Its parent dataset, 2MASS, was already used for APS measurements, but to a much more limited extent than we present here. In particular, Frith et al. (2005) have measured the APS of a 2MASS subsample of $5 \times 10^5$ objects over 65% of sky to infer cosmological parameters, whereas Ando et al. (2017) estimated the APS of the much shallower, but spectroscopically complete, 2MRS sub-catalogue to constrain parameters of the galaxy halo occupation distributions. In none of these cases a tomographic approach was adopted.

In this paper we present the first all-sky tomographic measurement of APS in the relatively local Universe ($z < 0.24$) using 2MPZ. This dataset encompasses ~ 1 million 2MASS sources within its completeness flux limit of $K \leq 13.9$ mag, and provides precise and accurate photo-$z$s for all the contained sources. We thus extend the earlier tomographic analyses based on SDSS material down to very small redshifts and to wider angular scales, as well as add tomography to those studies which used the low-redshift all-sky data without any $z$-binning. Finally, our analysis also complements 3D clustering analyses applied to other $z \sim 0$ samples, such as from the 2dF Galaxy Redshift Survey (2dFGRS, Percival et al. 2001; Cole et al. 2005), the 6dF Galaxy Survey (6dFGS, Beutler et al. 2011, 2012), or the SDSS Main Galaxy Sample (Zehavi et al. 2011; Ross et al. 2015; Howlett et al. 2015).

We perform a likelihood analysis and derive constraints on cosmological parameters such as the matter mean density, the universal baryon fraction and the galaxy bias in different redshift bins. Our results, although not competitive with respect to the precision obtained from e.g. CMB experiments (Planck Collaboration et al. 2016), illustrates the efficiency
Cosmological information from the 2MPZ catalogue

2 THE 2MASS PHOTOMETRIC REDSHIFT CATALOGUE

2.1 Description

The 2MASS Photometric Redshift catalogue\(^1\) (Bilicki et al. 2014) is an almost all-sky flux-limited galaxy sample of 934,844 objects in the photo-z range \(z_p \in (0, 0.4)\) with 90% of the sources within \(z_p < 0.15\), and with mean redshift \(\langle z_p \rangle = 0.07\). 2MPZ is the most comprehensive all-sky sample of the Universe in this redshift range to date. It can be regarded as an extension of the Two Micron All-Sky Survey (2MASS, Skrutskie et al. 2006) Extended Source Catalogue (XSC, Jarrett et al. 2000).

2MPZ was constructed by cross-matching 2MASS XSC with two additional all-sky data-sets, SuperCOSMOS XSC (Hamblly et al. 2001; Peacock et al. 2016) and WISE (Wright et al. 2010). Photo-z have been estimated for all the sources common to the three catalogues, using the ANNz photo-z software (Collister & Lahav 2004). Highly accurate photo-z calibration was possible thanks to very comprehensive spectrophotometric subsets of 2MASS, based on the 2MRS, 6dFGRS (Jones et al. 2009), 2dFGRS (Colless et al. 2003), and SDSS DR9 (Ahn et al. 2012). They altogether encompass one-third of the whole 2MASS XSC and provide a very complete redshift training sample, especially thanks to SDSS. The resulting photo-z in 2MPZ are constrained to excellent precision and accuracy, with an overall mean bias of \((\delta z) \sim 10^{-5}\) and random photo-z error of \(\sigma_{z_p} \sim 0.013\) (see Sect. 2.3 for a more comprehensive photo-z error characterization). 2MPZ is flux-limited to \(K \leq 13.9\) (Vega) which correspond roughly to the all-sky completeness limit of 2MASS XSC. Within this limit, 2MPZ includes 94% of the 2MASS XSC objects. The missing sources are mostly located in areas not suitable for extragalactic science such as regions of high Galactic extinction, Magellanic Clouds, vicinity of bright stars, etc.

MNRA S000, 1–?? (0000)
Northern (equatorial) part of the survey ($\delta > 12^\circ$) is deeper than the Southern one. This difference should be small at $K = 13.9$, though not necessarily negligible.

SuperCOSMOS is based on digitized scans of photographic plates from two hemispherical surveys, POSS-II and UKST, the split being at $\delta = 2.5^\circ$. The two input samples were collected with different instruments, and colour-based calibration was essential to put the all-sky SuperCOSMOS magnitude measurements on a common scale. This calibration was fully completed only after the publication of the 2MPZ catalogue (Peacock et al. 2016). What is more, after the 2MPZ sample had been published, it was recognized that the colour terms applied to SuperCOSMOS magnitudes in 2MPZ were partly incorrect (Bilicki et al. 2016), as were the extinction corrections in one of the hemispheres. These issues do not influence the sample selection itself (as it was based on 2MASS only), but can matter for the photo-$z$ estimation, which was calculated using eight photometric bands from 2MASS+WISE+SuperCOSMOS. We note however that the photo-$z$s in 2MPZ were trained independently in the two hemispheres to self-calibrate such issues, so we expect them to be not significant.

We believe that none of the systematic errors described above should be large enough to affect our clustering analysis. However, to guarantee that this is indeed the case, we have run a series of sanity checks in which we compare the APS measured in different sky areas (e.g. North vs. South hemispheres). The results of these tests are presented in Appendix C.

### 2.2 2MPZ galaxies: angular and redshift distribution

In Fig. 2 we show $\texttt{Healpix}$-based Mollweide projections of 2MPZ galaxy surface overdensity, $\delta_i = N_i/\bar{N} - 1$, where $N_i$ denotes the number of galaxies per pixel and $\bar{N}$ is the mean counts computed in three photo-$z$ intervals, indicated in the plots. Large scale features, corresponding to clusters and filaments, can be clearly identified, despite the thickness of the shell and projection effects. A simple visual inspection reveals therefore that a tomographic clustering analysis of 2MPZ galaxies should be indeed possible.

The width of redshift shells has been set equal to $\sim 5$ times the average photo-$z$ error. This choice represents a tradeoff between the need to preserve clustering information along the line of sight (which requires narrow intervals) and that to minimize the contamination from objects in neighbouring redshift shells (which requires wide bins) (Crocce et al. 2011; Ross et al. 2011). In Table 1 we list the width of each redshift shell, the number of 2MPZ galaxies after masking, their surface density in the unmasked region, and the mean photometric galaxy redshift. The same quantities are also shown for the full 2MPZ sample (first row). The last column lists the (Poisson) shot-noise correction that we apply to the APS estimated in each interval, as detailed in Sect. 3.4.

We believe that none of the systematic errors described above should be large enough to affect our clustering analysis. However, to guarantee that this is indeed the case, we have run a series of sanity checks in which we compare the APS measured in different sky areas (e.g. North vs. South hemispheres). The results of these tests are presented in Appendix C.
Cosmological information from the 2MPZ catalogue

Table 1. Catalogue statistics in the photo-z bins considered in this analysis. The first row shows the full sample.

| Redshift bins | $\langle z_p \rangle$ | $N_{\text{gal}}$ | $\overline{N_{\text{gal}}}$ per deg$^2$ | Shot noise |
|---------------|----------------------|-----------------|----------------------------------------|------------|
| Full          | (0.024)              | 0.07            | 700222                                 | 24.8       | $1.23 \times 10^{-5}$ |
| z-bin 1       | (0.08)               | 0.056           | 353530                                 | 12.1       | $2.53 \times 10^{-5}$ |
| z-bin 2       | (0.08, 0.16)         | 0.109           | 297318                                 | 10.7       | $2.83 \times 10^{-5}$ |
| z-bin 3       | (0.16, 0.24)         | 0.187           | 49374                                 | 1.7        | $1.66 \times 10^{-4}$ |

2.3 2MPZ galaxies: redshift distribution and errors

Within the $K = 13.9$ magnitude limit, $\sim 38\%$ of 2MPZ galaxies have both spectroscopic, $z_s$, and photometric redshifts measured. We use this overlap subsample to illustrate the effect of photo-z errors on the measured clustering in Fig. 4. The plot shows two “pie diagrams” representing the position of 2MPZ galaxies in a slice $|\delta| \leq 10^\circ$ thick in declination, and $75^\circ$ wide in right ascension. On the left hand side the radial position is assigned using the photo-z as distance indicator. On the right hand side we use spectroscopic redshifts. Errors on photo-z obliterate the clustering signal on scales up to $50$ Mpc $h^{-1}$ along the line of sight, erasing prominent structures such as the Sloan Great Wall (Gott et al. 2005) at $z_s \sim 0.08$. This observation qualitatively justifies the choice of photo-z binning described in Sect. 2.2.

Because of the photo-z errors, the observed redshift distribution of galaxies, $dN/dz$, is different from the true one, $dN/dz_s$. The relation between the two quantities is (e.g. Sheth & Rossi 2010):

$$\left( \frac{dN}{dz_s} \right)_i = \int_0^{\infty} W(z_p) \frac{dN}{dz_p} P(z_s|z_p) dz_p.$$  (1)
where $W_i(z_p)$ defines the photo-$z$ bin, which in our case is a top-hat function. $P(\delta z|z_p)$ is the conditional probability (zPDF hereafter) of $\delta z$ given $z_p$. To infer $dN/d\delta z$ (which is an input of our analysis) from the observed $dN/dz_p$ we then need to estimate the zPDF. To do so, we consider the 2MPZ overlap subsample that have both $z_p$ and $z_i$. In order to highlight possible photo-$z$ systematic errors, in Fig. 5 we show, as green histograms, the zPDF as a function of $\delta z(z_p) = z_i - (z_i|z_p)$, where $(z_i|z_p)$ is the mean spec-$z$ in a given bin of photo-$z$. In each bin we measure the rms scatter $\sigma^2_i(z_p) = (z_i - \langle z_i|z_p \rangle)^2$, which quantifies random errors. These are well fitted by $\sigma^2_i(z_p) = 0.03 \tanh^{-1}(20.78 z_p^2 + 7.76 z_p + 0.05)$. They increase with the photo-$z$ from a value of $\sim 0.006$ at $z_p \sim 0$ to $\sim 0.02$ at $z_p \sim 0.24$.

The dashed blue curves in Fig. 5 represent Gaussian distributions with zero mean and a width $\sigma_G(z_p) \approx 0.9 \sigma_i(z_p)/(1 + z_p)$, which provides a good fit around the peak but fails to reproduce the extended tails of the distributions. Similarly as in Bilicki et al. (2014), we also find that the function

$$P(\delta z|z_p) \propto \left[1 + \left(\frac{\delta z}{2\sigma_G(z_p)}\right)^2\right]^{-3/2},$$

provides a better fit to the zPDF in all redshift bins, as is shown by the dot-dashed red curves in that Figure.

The impact of photo-$z$ errors on the 2MPZ galaxy redshift distribution can be appreciated in Fig. 6. The top panel shows the $dN/dz$ and $dN/d\delta z$ measured in the overlap subsample (filled and dotted histograms). The short-dashed curve illustrates the effect of convolving $dN/dz_p$ with a Gaussian zPDF (Eq. 1) with fixed width equal to 0.015. The inferred $dN/d\delta z$ underestimates the true one at small redshifts. The continuous curve shows the effect of using a Gaussian zPDF with redshift-dependent width $\sigma_G(z_p)$. The match with the observations improves considerably.

Using the zPDF from Eq. (2) does not improve the quality of the fit further. As a consequence, we will model the zPDF as a Gaussian with redshift-dependent width. In doing this, we implicitly assume that the $dN/dz_p$ of 2MPZ galaxies with both $z_p$ and $z_i$ measured is representative of the whole sample. This hypothesis is justified by the fact that a large part of the calibration data comes from SDSS, deeper and more complete than 2MPZ within their common area.

In the bottom panel of Fig. 6 we show the $dN/d\delta z$ of the full 2MPZ sample (black, continuous curve) and the inferred $dN/d\delta z$ (dashed, orange curve), together with the $dN/dz_p$ of the 2MPZ galaxies in the three photo-$z$ bins identified by the vertical dashed lines. As anticipated, the size of the bin guarantees an acceptable level of contamination from neighbouring redshift intervals.

### 2.4 Mock 2MPZ galaxy catalogues

Previous analyses (e.g. Blake et al. 2004, 2007; Thomas et al. 2011) have assumed that errors on the APS are Gaussian. In this work we check the validity of this hypothesis by computing errors and their covariance from a suite of synthetic 2MPZ catalogues matching the properties of the real one.

Since a large number of independent mock catalogues are required to measure the covariance matrix with good accuracy, we shall make some assumptions on the properties of these mocks. First of all, we assume that the mock galaxy density PDF is lognormal, which, as we have seen in Sect. 2, is a good approximation. Furthermore, we assume

---

Figure 4. Pie diagram of a subsample of 2MPZ galaxies which have both spectroscopic and photometric redshift measured. Left: galaxy positions in photo-$z$ space. Right: galaxy positions in spec-$z$ space. The colour coding reflects spec-$z$ from light blue for nearby objects to dark red for distant galaxies. Colour mixing in the left panel further illustrates the effect of the rms random photo-$z$ error $\sigma_i \sim 0.01$.

Figure 5. Distributions of the photo-$z$ errors, zPDF, as a function of $z_i - (z_i|z_p)$ in photo-$z$ bins of width $\Delta z = 0.018$. The central redshift values of the bins, $z_p$, are indicated in the plot. Histograms: measured zPDF. Dashed curve: best fit Gaussian model with the same variance as the measured zPDF. Dot-dashed curve: empirical zPDF model of Eq. (2).

---

3 We are not aware of any existing $N$-body simulations which would allow us to select sufficiently many independent 2MPZ-like realizations for such an analysis.
Cosmological information from the 2MPZ catalogue

3 THE ANGULAR POWER SPECTRUM OF 2MPZ GALAXIES

In this Section we introduce the theory behind the model of the 2MPZ angular power spectrum and its estimator. The formalism and mathematical details can be found in, e.g. Peebles (1980); Peacock (1999).

3.1 Modeling the angular power spectrum

The APS of galaxies with spec-z in a given bin $i$ can be obtained from the harmonic decomposition of the observed surface density fluctuations around the mean $\sigma_i$. In case of a partial sky coverage, quantified by a binary angular mask $M(\hat{\Omega})$, the effective mean density depends on the direction: $\sigma_i(\hat{\Omega}) = \sigma_i(M(\hat{\Omega}))$, where $\sigma_i = N_i/\Delta \Omega$ is the mean surface density of $N_i$ over the unmasked area $\Delta \Omega$. The harmonic coefficients of the galaxy surface density fluctuation $\delta_{gal}(\hat{\Omega})$ are

$$d_{lm}^{\delta(s)}(\hat{\Omega}) = \int d_{gal}(\hat{\Omega}) Y_{lm}^{*}(\hat{\Omega}) d\hat{\Omega} = \int d^2 s \phi_i(s) \delta_{gal}(s) Y_{lm}^{*}(\hat{\Omega}),$$

where in the second expression the integral is in redshift space $s = z(s, \hat{\Omega})$, $\phi_i(s) = \phi_i(s)M(\hat{\Omega})$ is the survey selection function in the $i$-th redshift bin$^4$ and $\delta_{gal}(s)$ is the 3D galaxy density fluctuation. The first equality in this expression will be implemented to design the estimator of APS. The second one provides the starting point for the theoretical modeling of the APS.

Gravitational lensing, integrated Sachs Wolfe effect, and peculiar velocities modulate the observed galaxy density $\delta_{gal}$. These effects need to be taken into account to obtain unbiased estimates of $d_{lm}^{\delta(s)}$ (e.g. Challinor & Lewis 2011). At the low redshifts of the 2MPZ galaxies the dominant effect is peculiar velocities inducing RSD (e.g. Kaiser 1987; Fisher et al. 1994; Heavens & Taylor 1995; Hamilton & Culhane 2000).

We Monte-Carlo sample the maps to obtain a distribution of discrete objects in two steps: first, we assign photo-z to an object according to the measured $dV/dz_p$; second, this object is assigned an angular position according to the angular surface density, which varies depending on the redshift bin in which the object is located. The number of mock objects in each redshift bin is drawn from a Poisson deviate with mean equal to the number of objects in the real sample.

Spec-z are assigned following the results from Sec. 2.3. We repeat the procedure until we generate 1000 2MPZ mock catalogues that we use to estimate errors in the measured angular spectrum and its covariance matrix.

Public codes such as FLASK (Xavier et al. 2016) can generate log-normal mock catalogues with correlation among different bins. In our likelihood analysis we verify that neglecting cross-correlation among photo-zs in the 2MPZ clustering analysis does not affect significantly our results, thus justifying our choice for the construction of the mock catalogues.

Figure 6. Redshift distributions of 2MPZ galaxies. Top panel (a): 2MPZ galaxies in the overlap subsample with both spectroscopic, $z_s$, and photometric redshifts, $z_p$. Dotted, blue histogram: $dV/dz_p$. Filled, olive-green histogram: $dV/dz_s$. Red solid, long-dashed blue and dot-dashed green curves: $dV/dz_s$, obtained respectively a Gaussian error distribution zPDF with variable width (baseline), Gaussian with fixed width, and the empirical model of Eq. (2). Bottom panel (b): 2MPZ galaxies in the full sample. Black solid curve: $dV/dz_s$. Orange dotted curve: $dV/dz_s$, inferred using the baseline zPDF. Other curves: $dV/dz_s$ of galaxies in the three photo-z bins identified by the vertical dashed lines, obtained using the baseline zPDF.

that the $\ell$-modes of the mock 2MPZ angular spectrum measured over the full sky are all independent (i.e. we assume that mode-to-mode correlation is only induced by the geometry mask). Finally, as we are interested in measuring the angular spectrum in different redshift bins, we shall ignore any cross-correlation along the radial direction.

We generate the 2MPZ mock catalogues with the following procedure:

- We assume a fiducial cosmological model and compute the APS in the three redshift bins. We implement the public code CLASSgal (Di Dio et al. 2013), which includes the non-linear component of the dark matter power spectrum and corrections due to redshift space distortions (more details in Sect. 3).
- We modulate the amplitude of the angular spectra to match the observed one (described in Sect. 3.4). With this procedure we implicitly determine the large-scale bias of the mock galaxies.
- We generate Gaussian realizations of the angular spectrum in the three redshift bins and produce the corresponding Healpix surface density maps with a resolution matching of the 2MPZ map described in Sect. 2.2.
- We perform a lognormal transformation which preserves the angular spectrum and obtain a lognormal PDF.
- We impose the geometry of the 2MPZ sample represented by the mask described in Sec. 2.1.
needs to be evaluated for many different cosmological models and no explicit parametrization of the RSD is done in terms of the linear redshift-space distortion parameter $\beta$ (the ratio of the matter growth rate to the galaxy bias; e.g. Kaiser 1987). We use the options ‘density’ and/or ‘rad’ in order to account for real-space or redshift-space estimates of the angular power spectrum.

In general, the angular cross-spectrum between any two redshift bins $i$ and $j$ is:

$$C_{ij}^{\ell} = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} \langle d^b_{im} d^b_{jm} \rangle \equiv R^{ij}_\ell C_{ij}^\ell,$$

(4)

where $R^{ij}_\ell$ denotes the so-called mixing matrix, which quantifies the effect of the geometry mask on the true power spectrum $C_{ij}^\ell$, the latter being expressed as

$$C_{ij}^\ell = b_i b_j \int_0^\infty P(k) k^2 F_i^\ell(k) F_j^\ell(k) dk.$$

(5)

In this expression $P(k)$ is the three-dimensional, primordial matter power spectrum, $b_i$ is the linear bias of survey galaxies at $z = z_i$. The kernels $F_i^\ell(k)$ incorporates the effect of the survey selection function $\phi_i$, the matter transfer function $D(k, z)$ and RSD (see e.g. equation 2.7 of Di Dio et al. 2013). The version of these kernels written in terms of the parameter $\beta$ can be found, e.g. in equation 28 of Podmaniczky et al. (2007).

### 3.2 2MPZ angular mixing matrix

The mixing matrix in Eq. (4) can be expressed in terms of the 3-j-Wigner symbols:

$$R_{\ell\ell'} = \frac{2(2\ell+1)}{4\pi} \sum_{\ell''} (2\ell'' + 1) W_{\ell\ell'}^{000} \left( \ell \ell' \ell'' \right)^2,$$

(6)

where $W_{\ell\ell'}$ represents the APS of the geometry mask. In Fig. 7 we show some elements of the $R_{\ell\ell'}$ for the full 2MPZ mask (the light-coloured histogram in all panels) as well as those that refer to various half-sky samples (dark-coloured histograms in the different panels). The values of $\ell$ and $\ell'$ are indicated in the panels. Departures from $\delta$-Dirac shape indicate power leakage from $\ell$ to $\ell' \neq \ell$. For the full 2MPZ case, and for the multiplies used in our analysis, ~75% of power is preserved at the scale $\ell$ and ~90% is preserved in the range $\ell \pm 6$. When only Northern and Southern hemispheres are used, the power preserved at the same multipole drops to ~37% in Galactic coordinates (upper panels) and to ~35% in Equatorial coordinates (bottom panels). This comparison highlights the importance of using an all-sky survey for such an analysis. The precise figures are listed in Table 2 together with the fraction of the unmasked sky, $f_{\text{sky}}$, and the number of objects that it contains, $N_{\text{gal}}$.

### 3.3 Limber approximation and redshift space distortions

The implementation of Eq. (5) involves the evaluation of spherical Bessel functions, which are computationally demanding. This is a potentially serious issue, since Eq. (5) needs to be evaluated for many different cosmological models when comparing observations with theory. Several methods have recently been proposed to mitigate this problem (e.g. Campagne et al. 2017; Assassi et al. 2017). Perhaps the most common approach is that of adopting the so-called Limber approximation (e.g. Limber 1953; Loverde & Afshordi 2008), valid for $\ell \gg 1$. In this approximation Eq. (5) can be shown to reduce to

$$C_{ij}^\ell = \frac{b_i b_j}{N_i N_j} \int_0^\infty \frac{dN_i}{dz} \frac{dN_j}{dz} P_{\text{rad}} \left( \frac{\ell}{r(z)} \right) H(z) \frac{dz}{r^2(z)}$$

(7)

where $H(z)$ is the Hubble function, $N_i = \int dN_i/dz$ is the expected number of galaxies in the $i$-th redshift bin and $P_{\text{rad}}(k, z) = P(k) D^2(k, z)$ is the matter power spectrum. The accuracy of this approximation depends on the angular scale, the cosmological model and the characteristics of the target galaxy sample such as the depth of the redshift shell and selection effects. The impact of using the Limber approximation for our study is shown in the top panels of Fig. 8, in which we plot the ratio of the exact expression for the angular spectrum for 2MPZ galaxies (Eq. 5) and the one evaluated with Eq. (7), in the three redshift bins considered.

### Table 2. Some characteristic of the 2MPZ angular mixing matrix, for hemispherical divisions in two coordinate systems, for the full photo-z range.

| Hemisphere          | $N_{\text{gal}}$ | $f_{\text{sky}}$ | Fraction of power at $\ell$ |
|---------------------|------------------|------------------|----------------------------|
| Full 2MPZ           | 700222           | 0.69             | 75%                        |
| Northern Galactic   | 360972           | 0.35             | 38%                        |
| Southern Galactic   | 339250           | 0.34             | 36%                        |
| Northern Equatorial | 359507           | 0.35             | 37%                        |
| Southern Equatorial | 346715           | 0.34             | 36%                        |
in our analysis, for the fiducial cosmological model. Both spectra have been convolved with the same mixing matrix. The offset is mostly within 5% (except for the outer redshift bin) and approaches unity for $\ell > 10$, which is the smallest multipole that we shall use in our analysis. This systematic difference is significantly smaller than the Gaussian random error (see Eq. 13) that we adopt in our study (see Sect. 4.2).

Redshift space distortions modify the APS on the same scales as affected by the Limber approximation. To compare the respective amplitudes of the two effects we show, in the bottom panels of Fig. 8, the amplitude of the RSD signal, computed as the ratio between the 2MPZ angular spectra in real and redshift space, as obtained from CLASSgal. The amplitude of the RSD effect is comparable to the systematic error introduced when the Limber approximation is adopted. From this comparison we conclude that i) the Limber approximation in Eq. (7) provides fair estimates of the real space APS for $\ell \geq 10$, and ii) in this $\ell$-range, the APS is not affected by RSD, either in the first and second redshift bins. In the third redshift bin the RSD signal is comparable to the random error, but only below $\ell \sim 10$.

Following the above results, in order to avoid unnecessary approximations, in our likelihood analysis we shall implement the exact expression for the APS with RSD, despite the computational cost.

### 3.4 The angular power spectrum estimator

In this work we use the estimator of APS introduced by Peebles (1973) (see also Hauser & Peebles 1973; Wright et al. 1994; Wandelt et al. 2001), and employed in many analyses, including tomographic ones similar to ours (e.g. Blake et al. 2004, 2007; Thomas et al. 2011). The estimator implements Eq. (3) as

$$k_{\ell}^i = \frac{1}{\bar{f}_{\text{sky}}(2\ell+1)} \sum_{m=-\ell}^{m=\ell} \hat{a}_{\ell m}^i \hat{a}_{\ell m}^* - \frac{1}{\bar{\sigma}^2} \delta_{\ell i}.$$

where the second term represents the Poisson shot-noise correction. We verified that such a model for the shot-noise is adequate for the 2MPZ catalogue as it matches the angular spectrum of a random distribution of objects with the same surface density. Comparisons with model predictions use the ensemble average of Eq. (8)

$$\langle \delta_{\ell}^i \rangle = \frac{1}{\bar{f}_{\text{sky}}(2\ell+1)} \sum_{m=-\ell}^{m=\ell} \bar{R}_{\ell m} c_{\ell m}^i,$$

which includes the mixing matrix $R_{\ell m}$ (Eq. 6).

The practical implementation of the estimator consists of two steps. First of all we use the HealPix package to estimate the harmonic coefficients of a pixelized galaxy surface density map,

$$\hat{a}_{\ell m} = \Delta \Omega \sum_{k=1}^{N_{\text{pix}}} \left( \frac{N_k - \bar{N}_i}{\bar{N}_i} \right) Y_{\ell m}(\hat{\Omega}).$$

where $N_k$ is the number of 2MPZ galaxies in the $k$-th pixel and $\bar{N}_i$ its mean in the $i$-th redshift shell. All the pixels have equal area $\Delta \Omega$. The resolution matches that of the angular 2MPZ mask and corresponds to $\ell_{\text{max}} = 256$. We average the measurements obtained from Eq. (8) as

$$\hat{c}_{\ell m} = \frac{1}{\Delta \Omega^2} \sum_{k} \left( \Delta \Omega \sum_{\ell m} \right) \delta_{\ell m}^i,$$

where we have chosen $\Delta \ell = 6$ in order to minimize the number of elements of the covariance matrix, while reducing the effect of the window function by keeping about $\sim 90\%$ of the original signal in the $\ell$ bin, as discussed in Sect. 3.2. The bin-average mixing matrix is computed as

$$R_{\ell m, \ell', m'} = \frac{(2\ell'+1)}{4\pi} \sum_{\ell} (2\ell'' + 1) W_{\ell'} W_{\ell''} W_{\ell m, \ell', m'},$$

where $W_{\ell m, \ell', m'}$ denotes the 3-j-Wigner symbols averaged as in Eq. (11).

Other estimators based on the harmonic decomposition have been used to estimate angular spectra of galaxies (e.g. Blake et al. 2004, 2007; Thomas et al. 2011). We compare one of them with the estimator used here in Appendix A, observing no significant difference between the two results. There are also alternative approaches to measure the APS from a galaxy sample, such as the maximum likelihood (e.g. Huterer et al. 2001; Tegmark et al. 2002; Blake et al. 2004; Seo et al. 2012; Hayes & Brunner 2013). In particular, Blake et al. (2004) showed that the harmonic analysis (as the one we adopted here) and the maximum likelihood estimator yield estimates of APS that are in good agreement, when applied on samples with large sky coverage, as is the case of 2MPZ. Also, publicly available codes such as PolSpice (Chon et al. 2004) have been implemented to obtain APS in order to perform homogeneity tests in the 2MPZ sample (Alonso et al. 2015). We have developed our own APS code, H-GAPS (Healpix-based galaxy angular power spectrum), which we release together with this paper.\(^5\)

4 RESULTS

In this Section we present the main results of the measurement of 2MPZ APS in the three adopted redshift bins, both for auto- and cross-power spectra. We then validate them by computing the errors (covariance matrices) using three different approaches.

4.1 The measurements of the 2MPZ angular power spectrum

In the upper panel of Fig. 9 we show the measurements of the \( \ell \)-binned, angular auto-power spectra of 2MPZ galaxies in three photo-z bins, illustrated with three different symbols. In the multipole range shown here the signal dominates over the shot-noise error in the first two redshift bins. In the third photo-z-bin the shot-noise becomes larger than the signal for \( \ell \geq 70 \). The middle panel of Fig. 9 shows the angular cross-spectra between galaxies in different bins. Not surprisingly, the amplitude of the cross-spectrum is significantly smaller than that of the auto-spectrum, especially in the case of the first vs. third redshift bin (red triangles). The error bars show Gaussian errors which, as we will show in Sect. 4.3, provide a good estimate of the uncertainties. The bottom panel shows the elements of the mixing matrix obtained with Eq. (12), showing how the signal from a given \( \ell \)-bin is spread towards neighbouring bins due to partial sky coverage\(^6\).

Focusing on the auto-spectra, we see that the spectral amplitude decreases from redshift bin 1 to redshift bin 2, and then increases again in redshift bin 3. This apparently anomalous behaviour reflects the interplay between the evolution of galaxy clustering and its luminosity dependence in a dataset such as 2MPZ. Evolution lowers the amplitude of the clustering signal as a function of redshift, provided that the same population of objects is selected. This is basically the case when moving from redshift bin 1 to bin 2. The second effects dominates in the third redshift bin in which, because of the flux-limit, the selected 2MPZ galaxies are intrinsically brighter, more biased and, consequently, more clustered than in the first two redshift bins.

In general, the shape of the angular spectrum is well-approximated (in the range \( 20 \leq \ell \leq 100 \)) by a power-law \( C_\ell = A\gamma_\ell \). For the \( K \leq 13.9 \) limit we obtain \( A = (4.6 \pm 0.8, 6 \pm 1.25 \pm 0.6) \times 10^{-2} \) and \( \gamma = (1.35 \pm 0.04, 1.51 \pm 0.05, 1.18 \pm 0.06) \) in the first, second, and third redshift bin, respectively.

The bias induced by the flux-limit is more evident in Fig. 10, where we illustrate and quantify the shape of the APS for various values of the \( K \)-magnitude cut, ranging from our fiducial value \( K \leq 13.9 \) to the limiting value defining the 2MRS spectroscopic sample (\( K \leq 11.75 \)). In order to use approximately the same population of objects, we focus on the first photo-z redshift bin. The APS at the original cut \( K \leq 13.9 \) is shown in all the panels for reference, as well as different values of \( A \) and \( \gamma \) for each apparent magnitude limit.

4.2 Error analysis

Most of the previous APS analyses of photo-z samples (e.g. Blake et al. 2004; Thomas et al. 2011; Alonso et al. 2015) have assumed Gaussian errors, showing that they were adequate for the level of accuracy required in those studies. Similarly, we now assess the goodness of the Gaussian hypothesis for a sample like 2MPZ and compare it with two alternative, and arguably more reliable, error estimates: those obtained from the 2MPZ mock catalogues described in Sect. 2.4, and those derived from the so-called jackknife technique.

4.2.1 Gaussian Errors

Under the assumption that, in the \( i \)-th redshift bin, the spherical harmonic coefficients \( a_{\ell m} \) are Gaussian random distributed variables, the covariance matrix of the angular cross-power spectrum is diagonal, with a variance given by (e.g. Kamionkowski et al. 1997):

\[
\sigma_{\ell,i}^2 = \frac{2}{(2\ell+1) S_k} \left[ \sigma_i^2 (\sigma_i^2 + 2 \gamma_i^2) \sum_{j} \left( C_{\ell,j}^i + S_{\ell,j}^i \right) \right]^{1/2}, \tag{13}
\]

where \( S_k \) is the shot-noise of the APS measured in the \( i \)-th redshift bin. The expression for the auto-power spectrum error is obtained for \( i = j \).

4.2.2 Covariant errors from the 2MPZ mock catalogues

A better estimate of the errors which also accounts for their covariance can be obtained by exploiting the mock 2MPZ catalogues described in Sect. 2.4. In this case the accuracy of the error estimate depends on the number of available mocks and their similarity to the real sample.
The relation between the accuracy and the number of mocks $N_M$ is not trivial and depends on the number of free parameters in the analysis, $N_p$, and the number of bins in which the clustering measurement is performed, $N_K$. If $\sigma_0^2$ are the ideal values of the diagonal element of a covariance matrix obtained from an arbitrary large number of mock catalogues, then the additional variance $\sigma_{ad}^2$ induced by using a limited number $N_M$ of mocks to estimate the covariance matrix is $\sigma_{ad}^2 = (N_K - N_p)/(N_M - N_K)$ (e.g. Dodelson & Schneider 2013). In our case we use $N_K \sim 10 \ell$-bins to constrain $N_p = 4$ cosmological parameters. Therefore we need $\gtrsim 700$ mocks in order to guarantee that the additional variance is below $\sim 1\%$.

The similarity between mock and real samples has been discussed in Sect. 2.4. Here we stress the fact that in the mocks the APS multipoles are all independent, despite the fact that a lognormal PDF is assumed. To estimate covariance errors we compute the binned angular spectra in the three redshift bins of each mock and compute the covariance matrix as:

$$C_{\ell'} = \frac{1}{N_M - 1} \sum_{j=1}^{N_M} (C^{(j)}_{\ell'} - \bar{C}_{\ell'}) (C^{(j)}_{\ell} - \bar{C}_{\ell}).$$

where $N_M = 1000$. $\bar{C}_{\ell}$ denotes the sample mean.

### 4.2.3 Jackknife errors

The jackknife (JK) resampling (Tukey 1958) techniques allows one to estimate random errors from the dataset itself, with no need to use mock catalogues. This approach has been extensively applied to multiple galaxy clustering analyses (see e.g. Cabrè et al. 2007; Norberg et al. 2009, 2011; Escoffier et al. 2016). Its implementation for a 2D sample consists of dividing the observed sky into non-overlapping, equal-area regions and computing the relevant quantity (APS for the present work) after removing one of such regions at a time. The various regions are represented by a set of low resolution $N_{\text{side}}$ pixels (patches hereafter). Because of the 2MPZ geometry mask, the number of unmasked small pixels (used for the clustering analysis) varies from patch to patch. Therefore, in order to have a minimal number of JK patches $N_{JK}$, we have only considered those in which the scatter in the number of unmasked pixels deviates by less than 20% from the mean. After measuring the APS in each of these $N_j = \{N_{\text{side}}\}$ JK replicates, where $d$ is the number of masked-out sky patches, we compute the error covariance matrix as:

$$C_{\ell'} = \frac{N_{JK}}{N_d} \sum_{j=1}^{N_j} (C^{(j)}_{\ell'} - \bar{C}_{\ell'}) (C^{(j)}_{\ell} - \bar{C}_{\ell}).$$

where $\bar{C}_{\ell}$ is the mean among the $N_j$ replicates. In general, the results depend on the patch size, set by the resolution $N_{\text{side}}$, and the number of masked-out regions $d$. We have explored different combinations of $N_{\text{side}}$ and $d$ and found that the mean of the $N_j$ JK replicates $\bar{C}_{\ell}$, and the diagonal elements of the associated covariance matrix (Eq. 15) obtained from the configuration ($N_{\text{side}} = 4$, $d = 1$) agree, within $\sim 1\%$ and $\sim 10\%$ respectively, with the same quantities obtained from the ensemble of mocks. With these parameters we obtain a set of $N_j = N_{JK} = 119$ JK replicates.

### 4.3 Error comparison

Figure 11 summarizes and compares the results of the various error estimates. We focus here on the angular auto-spectra. The three columns show the results obtained in the three redshift bins. The top panels compare the measured APS of 2MPZ galaxies (green dots) with those obtained from the 1000 2MPZ mock catalogues (overlapping grey curves). The angular spectra of the mocks are in good agreement with those of the real 2MPZ catalogue, demonstrating that the procedure described in Sect. 2.4, based on a log-normal probability distribution, generates realistic mocks. The scatter among the mocks also matches the Gaussian error bars.

The plots in the second row of Fig. 11 compare the off-diagonal elements of the covariance matrices computed using the mock catalogues (the upper half of each panel) and the jackknife method (lower half). Each bin represents one element of the matrix, colour-coded according to its amplitude, normalized to the diagonal elements. In both cases the amplitude of the off-diagonal elements is less than 20% of the diagonal elements. Off-diagonal terms arise from the mode-coupling induced by the geometry mask and by the nonlinear evolution. The latter is ignored in the mock catalogues. This partly explains why these terms are larger in the JK matrices than in the mock matrices. Another source of mismatch comes from the fact that JK error estimate is less accurate than that obtained from the 1000 mocks (e.g. Norberg et al. 2009).

The third row of Fig. 11 compares the amplitude of the diagonal errors computed using the three methods. The amplitude of the Gaussian errors is very similar to that of the diagonal errors obtained from the mocks, except at very...
small $\ell$ values (green dashed curves). This result is consistent with the small amplitude of the off-diagonal elements which, in turns, is a manifestation of the large sky coverage of the 2MPZ catalogue. The orange solid curve shows that, instead, JK errors are systematically larger than the ones obtained from the mocks. The effect is stronger in the first redshift bin, where the amplitude of the mismatch can be as large as $30\%$, reducing to $10\% - 15\%$ at higher redshift. This redshift dependence is not surprising and mainly reflects the impact of nonlinear effects which, at small redshifts, can propagate to large angular scales.

It is worth noticing that the larger amplitude of the JK error is contributed by objects in a limited number of sky patches in which the clustering amplitude is significantly larger than the mean signal. We plan to investigate deeper the significance of these effects and the properties of 2MPZ galaxies residing in these areas in a follow-up paper (see e.g. Alonso et al. 2016, for a related approach).

In the bottom panels of Fig. 11 we compare the elements of the correlation matrices for the bin centred at $\ell = 100$ for the JK (solid line histograms) and the 2MPZ mock errors (filled, red histograms). The amplitude of the terms which are far from the diagonal is larger in the JK case, whereas terms close to the diagonal are larger in the mock case.

These results show that differences in the random errors computed using different methods are smaller than the error amplitudes, and that off-diagonal elements are small. Therefore, in the likelihood analysis, we assume random Gaussian errors with no covariance. We demonstrate in Appendix C1 that this choice does not have an impact on the results of the likelihood analysis.

Figure 11. 2MPZ angular power spectrum error comparison. Top panels: 2MPZ angular spectra (green dots) vs. individual mock spectra (grey curves). Vertical bars represent Gaussian errors. Second row: Covariance matrix elements estimated from the mocks (upper half) and from jackknife (lower half), both normalized to their diagonal elements. The colour code represents the amplitude. Third row: comparison between diagonal elements: mocks vs. JK (orange solid) and mocks vs. Gaussian (green dashed). Bottom panels: histograms representing the amplitude of the correlation matrix elements centred at $\ell = 100$. JK (empty histograms) vs. mocks (filled histograms). Results in the three columns refer to the three 2MPZ redshift bins indicated in the labels.
5 LIKELIHOOD ANALYSIS

In this Section we compare the measured 2MPZ angular auto- and cross-spectra with the theoretical predictions of the ΛCDM model to estimate a set of cosmological parameters \( \theta \). To do this, we sample the posterior conditional probability of \( \theta \) given the measured angular spectrum \( \hat{C}^{ij}_{\ell,M} \), using a MonteCarlo Markov-Chain approach. The Bayes theorem guarantees that \( \mathcal{P}(\theta|\hat{C}^{ij}_{\ell,M}) \propto \mathcal{P}(\theta) \mathcal{L}(\hat{C}^{ij}_{\ell,M} | \theta) \). For a flat prior \( \mathcal{P}(\theta) \) we sample the likelihood which is assumed to be Gaussian \( \mathcal{L}(\hat{C}^{ij}_{\ell,M} | \theta) \propto e^{-\chi^2_{ij}/2} \), where

\[
\chi^2_{ij} = \left( \hat{C}^{ij}_{\ell,M} - C^{ij}_{\ell,M} \right) C^{-1} \left( \hat{C}^{ij}_{\ell,M} - C^{ij}_{\ell,M} \right),
\]

(16)

where \( C^{ij}_{\ell,M} \) is the model power spectrum of Sect. 3.1, which includes the effect of the mixing matrix, and \( C^{-1} \) is the inverse of the covariance matrix of Sect. 4.2.1. Following the conclusions of that Section, we ignore off-diagonal terms.

To sample the posterior probability we use the publicly available code MontePython (Audren et al. 2013). To combine measurements from different bins we simply multiply the respective posteriors, i.e., we assume no correlation among the redshift bins. Finally, to obtain the 2D and 1D confidence intervals we marginalize the posterior over all the other parameters.

We focus on the same cosmological parameters as determined in previous tomographic analyses, namely, the mass density parameter of the dark matter component \( \Omega_{cdm} \in [0,0.7] \), the baryon energy density parameter \( \Omega_b \in [0,0.09] \), the amplitude of the primordial power spectrum (at a pivot scale of 0.05 h Mpc \(^{-1} \)), \( 10^9 A_S \in [0.1,10] \) and the linear galaxy bias in each redshift bin \( b_i \in [0,1,10] \). The values in the parentheses are ranges of the (flat) priors. We map this parameter space into the set \( \{ f_b, \Omega_{mat}, \sigma_8, b \} \) where \( \Omega_{mat} = \Omega_{cdm} + \Omega_b \) is the total matter energy density parameter, \( f_b = \Omega_b/\Omega_{mat} \) is the baryon fraction, and \( \sigma_8 \) is the rms of the matter distribution on spheres of radius \( 8 \) Mpc \( h^{-1} \) (at \( z = 0 \)), which is related to \( A_S \) and normalizes the linear power spectrum (see e.g. Komatsu et al. 2009). Except for the galaxy bias, all parameters are specified at \( z = 0 \).

To compare model and data we need to indicate the multipole range considered in the analysis. We set the minimum value at \( \ell = 10 \) to minimize the impact of the systematic errors induced by the geometry mask, which we discuss in details in Appendix B. For the maximum \( \ell \) we choose a conservative value that accounts for both the map resolution (i.e. the pixel size) and that of shot-noise. The effect of pixel size is redshift-independent and, as shown in Appendix B, becomes important for \( \ell \sim 100 \). The impact of shot-noise depends on the redshift due to the flux-limited nature of the sample and can be appreciated in Fig. 12 by comparing the shot-noise level (horizontal long-dashed lines) with the measured 2MPZ APS (points with Gaussian error bars).

We point out that in the \( \ell \)-ranges considered here, departures from the linear model are significant in the first two redshift bins. This can be approximately justified by Fig. 12, where the orange solid curves in each panel show the model of the APS for the fiducial cosmological setup, for the three redshift bins. This model has been obtained using CLASSgal and includes Halo-Fit (Smith et al. 2003; Takahashi et al. 2012, with the 1-halo and 2-halo terms represented by the dashed and the dot-dashed curves, respectively) to account for non-linear evolution of the underlying dark matter. The linear APS (computed with the same set of fiducial parameters) is also plotted for reference (dashed and dot-dashed curves). This model assumes the fiducial cosmology. The linear model (dotted curve) is also shown for reference. Model spectra have been boosted up by linear bias factors, as discussed in the text. The horizontal long-dashed-dotted curve indicates the shot-noise level in each redshift bin.

**Figure 12.** The 2MPZ binned angular auto-power spectrum (red dots with Gaussian error bars) in three bins of increasing redshift (from top to bottom). The orange continuous curve is the Halo-fit model spectrum and its 1-halo and 2-halo contributions (dashed and dot-dashed curves). This model assumes the fiducial cosmology. The linear model (dotted curve) is also shown for reference. Model spectra have been boosted up by linear bias factors, as discussed in the text. The horizontal long-dashed-dotted curve indicates the shot-noise level in each redshift bin.

Note that by using Halo-Fit to model the underlying matter power spectrum, we can attempt to generate individual estimates on the parameters \( \sigma_8 \) and \( b \), which are degenerated in the linear regime. Finally, as commented in Sect. 3.3, and in order to be as general as possible, our APS model includes the effects of RSD.
5.1 Individual redshift bins

In this Section we estimate the cosmological parameters $f_b$ and $\Omega_m$ that determine the shape of the angular spectra, and the combination $\sigma_b f_b(z = z_i)$ that represents the linear $rms$ galaxy density fluctuation in the $i$-th redshift bin and sets its amplitude. All the other cosmological parameters are fixed at their fiducial values. The upper panels of Fig. 13 show the 68% and 99% confidence regions in the $\{f_b, \Omega_m\}$ plane obtained after marginalizing over $\sigma_b f_b$. The blue dot represents the best fit values and the error bars show the 68% confidence interval on each parameter after marginalizing over the other. These values are listed in the first two columns of Table 3. Dashed lines with grey bands illustrate the fiducial parameter values with their 1$\sigma$ errors.

Our results agree with those obtained by Blake et al. (2007) and Thomas et al. (2011) who performed a similar, tomographic analysis at larger redshift using SDSS-based MegaZ-DR4 and MegaZ-DR7 catalogues of LRGs, respectively. Our errors are, however, about twice as large as theirs. This difference, which quantifies the difficulty in carrying out a tomographic analysis in the local Universe, has several causes. First, 2MPZ is wider than SDSS but the galaxy surface density of the former ($\sim 24$ galaxies per deg$^2$) is approximately 3 times smaller than in the LRG sample. As a consequence, shot-noise affects larger angular scales, especially in the outer redshift bin of the survey where the galaxy number density drops quickly. Second, non-linear effects in both the underlying dynamics and galaxy evolution processes also affect larger scales in the local Universe. Finally, 2MPZ galaxies are significantly less biased, and therefore less clustered, than LRGs. The net result is a significant reduction both in the $t$-range useful for the likelihood analysis and in the clustering amplitude with respect to the analysis of the Planck mission.

![Figure 13. 68% and 99% confidence contours for the parameters $f_b$ and $\Omega_m$ derived for z = 0 from 2MPZ auto-power spectra in the three redshift bins (top panels), obtained after marginalizing over $b(z)$ and $\sigma_b$. Bottom panels show the same confidence contours for $b(z)\sigma_b$ and $\Omega_m$. Blue dots and error bars indicate the best fit values and their 68% confidence intervals in each parameter, obtained after marginalizing over the rest of varied parameters. Dashed lines and grey bands illustrate the analysis of the Planck mission.](image)

![Figure 14. Mean values of the parameters $\Omega_m$ and $f_b$ with their 68% confidence intervals obtained from auto-power spectra in the first (red squares) and second (black circles) redshift bins, as a function of the maximum scale $\ell_{\text{MAX}}$ used in the likelihood analysis. The values from the second redshift bin have been placed at $\ell_{\text{MAX}} + 3$. Triangles show the results obtained by extending the analysis to the range $[0, 70]$ for the first (green triangles placed at $\ell_{\text{MAX}} + 6$) and the second redshift bin (blue triangles placed at $\ell_{\text{MAX}} + 9$). The horizontal line and the shaded area represents respectively the Planck values and their 1$\sigma$ error bars.](image)
shift bin is as expected and reflects the different bias factors of 2MPZ galaxies in the three redshift shells, as discussed in Sect. 4. The best fit values for the effective linear bias parameters $b_{\text{eff}}$ are listed in Table 3 together with their 68% confidence interval. The relative errors are in the range 20–30%, to be compared with typical 10% errors in the estimate of the LRG galaxies obtained by Thomas et al. (2011). Our results are also in good agreement with the 2MPZ galaxy linear bias parameters obtained by cross-correlating galaxy catalogues with CMB Planck maps to search for the integrated Sachs Wolfe effect (Stößner et al. 2017).

5.2 Robustness to the choice of $\ell$-range

We have tested the robustness of our result to the choice of the $\ell$-range considered in the APS analysis. We performed two different sets of tests. First, we fixed $\ell_{\text{MIN}}$ to its fiducial value ($\ell_{\text{MIN}} = 10$) and changed $\ell_{\text{MAX}}$. The goal was to assess the impact of nonlinear and shot-noise effects by pushing the analysis to smaller angular scales. Figure 14 shows the estimated value of $f_b$ (top) and $\Omega_m$ (bottom) as a function of $\ell_{\text{MAX}}$. The results do not change significantly (i.e. within the 1–σ error bars) with respect to the fiducial case $\ell_{\text{MAX}} = 70$. In particular, results in the second redshift bin (black dots) are remarkably robust to $\ell_{\text{MAX}}$. In the first bin (red squares), pushing the analysis to $\ell_{\text{MAX}} = 100$ reduces the size of random errors by ∼20% but modifies the best fit values of both parameters. We interpret this result as an indication that, in this case, nonlinear effects do play a role and bias our results. For this reason we chose to set $\ell_{\text{MAX}} = 70$ in the analysis. As for the third bin, we did not explore the case $\ell_{\text{MAX}} = 100$ since that regime is shot-noise dominated and found that setting $\ell_{\text{MAX}} = 50$ has the only effect to increase random errors.

In the second test we set $\ell_{\text{MAX}} = 70$ and extend the analysis down to the first $\ell$-bin (containing modes in the range $\ell \in (0,6)$). The results are shown in the same plot for both the first and the second photo-$z$ bins (green and blue triangles). Although we notice that including large scale modes induces a shift in the mean of the posterior distributions towards lower values of $\Omega_m$ (high values of $f_b$), the constrained values are consistent within 1–σ with the fiducial value $\ell_{\text{MIN}} = 10$.

5.3 Multiple redshift bins

In this Section we first combine the auto-correlation analyses performed in each bin to improve the constraints on the cosmological parameters. Then, we include the results obtained by cross-correlating 2MPZ galaxies in nearby bins, i.e. we also compute the angular cross-spectra between bins 1 and 2, and also 2 and 3. The cross-correlation between bins 1 and 3 is consistent with zero and will be ignored.

To combine these results we assume no correlation along the radial direction and test the goodness of this hypothesis a posteriori. With this hypothesis we can compute the combined posterior probability $P_{ij}(\theta_{\text{cosmo}}, \hat{C}_{ij})$ where $\theta_{\text{cosmo}} = [f_b, \Omega_m, \sigma_8]$ in three steps: 1) We compute the posterior probability for each auto- or cross-angular spectra. 2) We marginalize each probability over the bias parameter (or bias parameters in case of cross-spectra) in the redshift bin. 3) We compute $P_{ij}(\theta_{\text{cosmo}}, \hat{C}_{ij})$ by multiplying the var-

\[ P_{ij}(\theta_{\text{cosmo}}, \hat{C}_{ij}) = \prod_i \prod_j P_{ij}(\theta_{\text{cosmo}}, \hat{C}_{ij}) \]

Figure 15. 68% and 99% confidence intervals for $f_b$ and $\Omega_m$ obtained after marginalizing over $\sigma_8$ and the bias parameters $b_i$. In the upper four panels we combine the auto-spectra from various redshift bins. The lower panels illustrate the effect of additionally using the cross-spectra for the constraints. Dotted vertical and horizontal lines show the Planck results and their 1-σ errors (shaded region).

Figure 16. Similar as Fig.15 but for the set of parameters $\sigma_8$ and $\Omega_m$.

Table 3. Best-fit values of the relevant cosmological parameters and their 68% confidence intervals obtained by: i) performing auto-correlation analyses in each photo-z bin (first three columns), ii) combining the results of different bins (columns 4 to 7) and iii) from the cross-correlation analysis in different bins (last two columns).

| photo-z bin combination(s) | Auto-power spectra | Combined auto-power spectra | Adding cross-power spectra |
|----------------------------|-------------------|----------------------------|---------------------------|
|                            | $(z_p) = 0.05$    | $(z_p) = 0.1$              | $(z_p) = 0.19$            |
| $f_b$                      | 0.14$^{+0.10}_{-0.11}$ | 0.17$^{+0.10}_{-0.12}$ | 0.12$^{+0.10}_{-0.10}$ |
| $\Omega_m$                | 0.36$^{+0.16}_{-0.16}$ | 0.29$^{+0.15}_{-0.13}$ | 0.28$^{+0.12}_{-0.12}$ |
| $b_{\text{eff},i}$        | 1.14$^{+0.35}_{-0.40}$ | 1.49$^{+0.30}_{-0.30}$ | 2.07$^{+0.33}_{-0.48}$ |

Table 3. Best-fit values of the relevant cosmological parameters and their 68% confidence intervals obtained by: i) performing auto-correlation analyses in each photo-z bin (first three columns), ii) combining the results of different bins (columns 4 to 7) and iii) from the cross-correlation analysis in different bins (last two columns).

ious posterior probabilities together. The results are summarized in Fig. 15, where we show the confidence levels in the $(f_b, \Omega_m)$ plane, analogous to those plotted in the upper panels of Fig. 13. To clarify the notation $i$ & $j$ indicates that we combine information from auto-spectra in redshift bins $i$ and $j$, whereas $i \times j$ indicates that the cross-spectra between bins $i$ and $j$ have been included in the analysis. The upper four panels consider auto-spectra only and, among them, the bottom-right panel uses information from all the three redshift bins. The four bottom panels are analogous to the upper ones except that they include cross-spectrum information. The values of the best fit parameters and their uncertainties are summarized in Table 3.

Combining information from the different redshift bins does have an impact on the analysis. The errors on the estimated $\Omega_m$ are reduced by a factor of about two. The largest improvement is obtained when the auto- and cross-spectra of 2MPZ galaxies in the outer redshift bin are included in the analysis. A similar, significant improvement has also been found by Thomas et al. (2011). By comparison, the improvement on the baryon fraction error is less spectacular. Error bars are reduced by 10-30% (again, the largest improvement is obtained using galaxies in the outer redshift bin) with no much benefit obtained by including cross-spectrum measurements.

By analogy with Fig. 15, in Fig. 16 we show the confidence contours in the $(\sigma_8, \Omega_m)$ plane, this time for auto-spectra only. The fact that we obtain a constraint on $\sigma_8$ may seem in contradiction with the fact that, in the linear regime and with no RSD information from low multipoles (which, as emphasised earlier, we do not use), this parameter is fully degenerate with the linear bias parameters. In fact, as anticipated, this degeneracy is broken by the fact that we use Halo-fit to model the APS and that nonlinear contributions are not negligible at $\Omega_{\text{MAX}} = 70$, especially in the first redshift bin. Not surprisingly, these constraints are not competitive with those obtained by CMB, 3D clustering analyses and cluster counts. We rather consider this measurement as a sanity check showing that the values of $\sigma_8$ obtained from our analysis (e.g. $\sigma_8 = 0.79^{+0.25}_{-0.19}$ from the combined analysis) are consistent with that obtained from Planck (grey strips) that have been used to infer the 2MPZ galaxy bias values.

We note that in the current implementation of CLASS-\text{gal}, cross-power spectrum can be computed by modeling the galaxy $dN/dz$ with either a Gaussian or a top hat function. We chose the first option despite the fact that, as can be deduced from Fig. 6, it does not provide a good fit to the galaxy redshift distribution, but it is certainly closer to reality than the top-hat option. We show in Appendix C2 that this choice does not introduce significant systematic errors.

6 DISCUSSION AND CONCLUSIONS

In this work we have performed a tomographic analysis in the spherical harmonic space to investigate the clustering properties of galaxies in the 2MASS Photometric Redshift catalogue (2MPZ) in the local ($z < 0.24$) Universe. Tomographic analyses have emerged as a complementary tool to investigate the LSS of the Universe when photometric, rather than spectroscopic, redshifts are available and a full study of the three dimensional distribution of objects is not possible. Despite the fact that a significant amount of information is lost along the radial direction because of considerable photo-z errors as compared to spectroscopy, the number of objects in photometric surveys is significantly larger than in spectroscopic ones. The former thus offer the possibility of densely sampling the LSS of the Universe over very large volumes which will not be easily available for the latter.

Several studies have explored the potential of the tomographic technique, its pros and cons, and demonstrated that it can already be applied to existing datasets to constrain cosmological parameters. While these constraints are not tight, they have the advantage of being complementary to those obtained from spectroscopic samples (Percival et al. 2001; Cole et al. 2005; Sánchez et al. 2009; Zehavi et al. 2011; Beutler et al. 2012; Ross et al. 2015; Howlett et al. 2015). As a result, the tomographic technique is now regarded as one of the most promising tools to apply to next generation photometric redshift surveys like Euclid (Laureijs et al. 2011) and LSST (LSST Science Collaboration et al. 2009) and new strategies are being proposed on how to combine information from spectroscopic and photometric samples (see e.g. Percival & Bianchi 2017 for a recent example).

In this work we have used this technique to analyze galaxy clustering in the local Universe. We are aware that this application stretches the method to its limits, since the
combination of nonlinear effects, limited volume, uneven sky coverage, and other related issues severely limits the power of the method. Nevertheless, we decided to proceed because of the availability of the new, wide 2MPZ galaxy photo-z dataset built upon the 2MASS photometric survey (Bilicki et al. 2014). Wide coverage is of paramount importance in local studies to maximize the volume of the survey and mitigate the impact of the unavoidable cosmic variance. Good photo-z calibration and small random errors are also highly desirable to efficiently slice up the volume in independent redshift shells. 2MPZ satisfies both these requirements since it allowed us to sample about $2.8\pi$ steradians, covering both the northern and southern hemispheres, with $\sim 700,000$ galaxies divided in three equal sized narrow redshift bins of width $\Delta z = 0.08$.

The results of our analysis can be summarized as follows:

- 3D clustering analyses have already been carried out in spectroscopic samples (2dFGRS, 6dFGS and SDSS) that partially overlap with 2MPZ. With these results available, the first goal of the tomographic analysis is to provide a clustering-based, independent validation of the 2MPZ catalogue itself. The presence of anomalous features in the clustering statistics (APS in this case) would indicate potential issues in e.g. the survey photometry, redshift calibration etc, that should be further investigated.

The imprint of these potential systematic errors is expected to display a characteristic north-south pattern, both in Equatorial and in Galactic coordinates. We extensively searched for smoking gun signatures by comparing results obtained independently in the various hemispheres and found no evidence of them in any of the statistics considered, namely the 1-point galaxy density probability distribution function, the APS and the cosmological parameters (baryon fraction, mass density, and galaxy rms number density fluctuations).

We checked that these tests are significant in the sense that the various hemispheres we have divided the 2MPZ into have similar areas and window functions, and therefore provide a similar amount of information.

- Performing a tomographic analysis in the local Universe has its own peculiarities. It should be designed as a balance between minimizing the contamination and maximizing the number of bins to take the full advantage of the tomographic approach (e.g. Blake & Bridle 2005; Asorey et al. 2012). We have investigated this issue with the help of the 2MPZ mock galaxy catalogues and found that considering objects in the redshift range $z = [0,0.24]$ and dividing the sample into three equally spaced bins represents good compromise. The residual contamination effect is accounted for in the likelihood analysis using different approaches that, as we have verified, provide very similar results.

- To estimate the statistical errors and their covariance we have created 1000 catalogues of mock 2MPZ galaxies with a lognormal density distribution function, Halo-fit angular power spectrum of a ΛCDM model, Gaussian photo-z errors, and the same geometry as the real survey. The angular power spectra measured in each of the 1000 mocks for each redshift bin were used to compute the covariance matrices of the angular auto- and cross-power spectra. This is a rigorous but computationally intensive approach that, for the sake of accuracy, should be repeated for any cosmological model considered in the likelihood analysis. To check whether other, less time-consuming approaches could be adopted without compromising the quality of the results, we have computed errors with two alternative methods: a jackknife resampling technique and the analytic Gaussian assumption. In our analysis we compared the errors and addressed the robustness of the likelihood analysis to the type of error estimate. We found that the three methods provide very similar error estimates. The exception is the jackknife technique, which systematically overestimates the uncertainties, by $\sim 20\%$, although in the first redshift bin only.

As a result we decided to use Gaussian errors, similarly as in the previous tomographic analyses of SDSS samples by Blake et al. (2007) or Thomas et al. (2011).

- We have used the public code MontePython to Monte Carlo sample the posterior probability of selected cosmological parameters, namely the baryon fraction, the mean
mass density and the combination of galaxy bias and rms mass density fluctuation, given the estimated angular auto- and cross-spectra in the three redshift bins. Flat priors were set on the dark matter density, baryon density, primordial spectral amplitude and effective linear galaxy bias at the mean redshifts of the three bins. All remaining cosmological parameters were fixed at their Planck values (Planck Collaboration et al. 2014).

From the analysis of the auto-spectra in each redshift bin independently, we measured \( f_b \) and \( \Omega_\text{m} \), and found that they are in agreement with the reference LCDM model. However, uncertainties are large; 1-\( \sigma \) errors on \( \Omega_\text{m} \) are of the order of 50\%, and even larger for the baryon fraction.

Combining different auto-spectra under the hypothesis of no radial correlation among the bins significantly improves the results and reduces the relative errors to \( \sim 25\% \) for \( \Omega_\text{m} \) and to \( \sim 50\% \) for \( f_b \). Additional information from the cross-spectra does not bring significant improvements (1-\( \sigma \) errors on \( \Omega_\text{m} \) drop to 20\%), which indicates that cross-power is indeed small and the hypothesis of negligible radial correlation among the bins is indeed a reasonable one.

Our error bars are about twice as large as in the similar tomographic analysis of the SDSS samples such as Thomas et al. (2011). This is not entirely unexpected: it reflects the large cosmic variance which is typical of cosmological investigations of the local Universe, further exacerbated by the limited multipole range accessible to our analysis. A denser sampling of a more linear density field over a significantly larger volume, as in the SDSS case, would significantly improve the quality of the analysis. This is the key to the success of the tomographic analyses that will be performed on forthcoming datasets like the Euclid photometric catalogue (Laureijs et al. 2011) and the LSST galaxy sample (LSST Science Collaboration et al. 2009). We note however that such studies could be also attempted with already existing deep wide-angle photo-\( c \) datasets, such as WISE \( \times \) SuperCOSMOS (Bilicki et al. 2016) or SDSS DR12 (Beck et al. 2016).

Driven by the need to keep the number of free parameters small, we have restricted our analysis to the regime in which galaxy bias is close to the linear model. As a result, from the APS in each redshift bin we have constrained the combination \( h \sigma_8 \), which we used to estimate the effective bias parameters of 2MPZ galaxies after fixing \( \sigma_8 \) to its Planck value. We were able to estimate such effective bias parameters with fairly good precision (15–20\%) and found that \( h_{\text{eff}}(z) \) increases by \( \sim 60\% \) from the first redshift bin of median photo-\( c \) of \( \langle z_p \rangle = 0.05 \) to the third one with \( \langle z_p \rangle = 0.19 \). This rapid change simply reflects the apparent magnitude-limited nature of the catalogue, which selects objects increasingly brighter intrinsically at larger redshifts.

Bias parameters can be marginalized over when combining auto- and cross-spectra measured in different redshift bins and thanks to the nonlinearities quantified by the 1-halo term within the Halo-Fit framework, which breaks the degeneracy between \( b_h \) and \( \sigma_8 \). The resulting \( \sigma_8 \) value, though not at all competitive with those obtained with other probes, is nevertheless in agreement with the Planck value. This constitutes a useful sanity check for our analysis and justifies a posteriori our procedure to estimate the galaxy bias.

The 2MPZ APS contains not only the cosmological in-

Together with the estimator \( \hat{\mathcal{K}} \) defined in Eq. (8), Peebles (1973) also introduced an estimator for the APS of the form:

\[
\hat{D}_\ell^i = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} \int d\Omega \, \hat{Y}_m^i(\Omega) \hat{Y}_m^j(\Omega),
\]

where \( \hat{Y}_m^i \) represent the spherical harmonic coefficients defined in Eq. (3), the second term is the shot-noise correction and

\[
J_{lm} = \int M(\Omega) \hat{Y}_m^i(\Omega) \hat{Y}_m^j(\Omega) \, d\Omega.
\]

Figure A1. Ratio between the APS of the 2MPZ sample (full red shift range) measured with the estimator \( \hat{D} \) defined by Eq. (A1) and that obtained with the estimator \( \hat{K} \) from Eq. (8), for different hemispheres and coordinate systems. The error bars represent the rms scatter of the 2MPZ mock catalogues described in Sect. 2.4.

\[
\hat{C}_\ell = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} \sum_{m'=-\ell}^{\ell} \int d\Omega \mid Y_m^i(\Omega) M(\Omega) Y_{m'}^j(\Omega) \mid^2,
\]

which, unlike the mixing matrix of Eq. (6), cannot be written in terms of 3j Wigner symbols. It is important therefore to use the mixing matrix appropriate to the estimator adopted.

At the level of a likelihood analysis, an incorrect choice might lead to a systematic effect in the constraints of cosmological (or astrophysical) parameters. Such systematic is clearly reduced as long as the sample covers larger fractions of the sky, in which case the measurements obtained with the estimators \( \hat{D} \) of Eq. (A1) and \( \hat{K} \) come to closer agreement. Given the sky fraction covered by the 2MPZ galaxy catalogue, the difference between these two estimators are below the error bars assigned to the measurements, as is shown in Fig. A1.

\[
\hat{K}_\ell = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} \sum_{m'=-\ell}^{\ell} \int d\Omega \mid Y_m^i(\Omega) M(\Omega) Y_{m'}^j(\Omega) \mid^2,
\]

Figure B1. Panel (a) shows the input power spectrum \( \epsilon_{\text{input}}^\ell \) (solid red line) and the \( 10^4 \) Gaussian realizations (overlapping light green curves). The short-dashed blue line illustrates the mean of the convolution of the \( 10^4 \) full-sky APS with the 2MPZ mixing matrix (\( \hat{C}_\ell \)). The long-dashed orange line presents the APS from the \( 10^4 \) maps upon which the 2MPZ mask has been imposed (\( \hat{C}_\ell^m \)). Panel (b) shows the percentage difference between these spectra (exactness), and panel (c) provides the difference among these spectra in units of the statistical error.

- For each realization, a full-sky overdensity map \( \delta_\ell(\hat{\Omega}) \) is created using the \texttt{alm2map} routines in \texttt{ Healpix}. We measure the power spectrum for each of these \( 10^4 \) full-sky maps and estimate its mean (\( \hat{C}_\ell^m \)) and variance.
- In parallel, for each realization we use Eq. (4) to compute the the convolved APS, \( \hat{C}_\ell^m \), using the mixing matrix described in Sect. 3.2.
- We apply the geometry mask \( M(\hat{\Omega}) \) to the full-sky map.
to obtain the masked overdensity field and estimate its APS \( \tilde{C}_\ell \).

Panel (a) in Fig. B1 shows the different power spectra obtained with this procedure. Panel (b) shows the relative differences between the three APS. The most relevant is the red solid curve that compares the masked and the convolved spectrum. Panel (c) shows these differences in units of statistical errors, \( \sigma \), estimated from the scatter among the mocks. From these comparisons we conclude that:

- The effect of the 2MPZ mixing matrix, quantified by the difference between \( \tilde{C}_\ell^{\text{input}} \) and \( \tilde{C}_\ell \) (dashed curves), is significant on large scales. Its amplitude of 10\% at \( \ell = 2 \) decreases with \( \ell \) and drops to 1\% at \( \ell = 50 \). This systematic effect is however small, less than 10\%, compared to the statistical error.
- The difference between the masked power \( \tilde{C}_\ell \) and the convolved \( \tilde{C}_\ell \) (solid line in Fig. B1 panel b) is \( \leq 1\% \) and much smaller than the statistical errors. We conclude that the estimated mixing matrix and its convolution with the true power spectrum do match the APS measured from the mock 2MPZ map.
- The comparison between the input power spectrum \( C_\ell^{\text{input}} \) and the measured full-sky spectrum \( C_\ell^{\text{obs}} \) quantifies the impact of the map resolution. As expected the effect is significant on the angular scales of the pixel (i.e., \( \ell \gtrsim 120 \)). Its amplitude of \( \sim 1\% \) at \( \ell \sim 80 \) increases with \( \ell \) and matches the statistical error at \( \ell \sim 140 \).

These results can be used to set the multipole range in which to compare the model and measured APS. To be conservative, we discard the multipoles below \( \ell = 10 \) (i.e., we discard our first two \( \ell \)-bins), where the impact of the mask is significant, and multipoles above \( \ell = 100 \), to avoid map resolution effects. Other effects like shot-noise and nonlinearity will further decrease this upper limit.

**APPENDIX C: ROBUSTNESS TESTS FOR THE LIKELIHOOD ANALYSIS**

In this Section we check the sensitivity of the results to the input of the likelihood analysis, namely the covariant errors in the binned spectra and the galaxy redshift distribution used to model the angular spectra. We also check the robustness to splitting the samples into two hemispheres. Instead, the sensitivity to the minimum and maximum multipoles used in the analysis is discussed in the main text.

**C1 Sensitivity to the estimated errors**

In our analysis we have used three different methods to estimate the error of the 2MPZ power spectrum and their covariance: analytic Gaussian errors, jackknife procedure, and covariance matrix from the lognormal mock catalogues. As we have discussed in Sec. 4.3, we decided to adopt Gaussian errors having verified that the results do not change significantly when adopting any of the two other methods. Here we show that the estimated cosmological parameters are robust to the type of error considered.

Figure C1 shows the confidence contours in the \( f_b-\Omega_m \) plane together with their best fit values (dots) and the marginalized 1-\( \sigma \) error bars. We only show the results obtained in the second redshift bin since they are representative for the other two bins. The black dot and dashed contours refer to the baseline model of Gaussian errors. In the left panel the blue dot and the filled contours show the results obtained when the likelihood is computed using the full covariance matrix from the mocks. They are remarkably similar to the baseline case, showing that ignoring covariance does not introduce any appreciable difference, apart from slightly reducing the size of the errors. The same considerations apply to the jackknife errors (panel to the right).

We conclude that our choice to adopt Gaussian errors is entirely justified and does not introduce significant systematic effects.

**C2 Sensitivity to the galaxy redshift distribution**

To model the APS in the generic redshift bin one needs to specify the true (i.e, spectroscopic) galaxy redshift distribution in that bin. In Sect. 2.3 we described the procedure to
In Sect. 2.1 we discussed that 2MPZ is potentially prone to north-south systematic effects both in Galactic and Equatorial coordinates. In the main text we searched for such effects in the 1-point overdensity PDF. Here we extend that search and look for systematic differences in the estimated cosmological parameters. The results are shown in Fig. C3. We find no significant differences between the \( \{ f_b, \Omega_m \} \) values estimated in the full sample and those obtained from the four hemispheres.

**Figure C3.** The \( f_b-\Omega_m \) parameters obtained in four hemispheres: North Galactic (top left), South Galactic (top right), North Equatorial (bottom left), South Equatorial (bottom right). The dashed curves show the reference case of the all-sky 2MPZ sample. All contours are computed in the second redshift bin.
