ABSTRACT

Objective: Mutations in SCN1A gene encoding the alpha 1 subunit of the voltage gated sodium channel are associated with several epilepsy syndromes including genetic epilepsy with febrile seizures plus (GEFS+) and severe myoclonic epilepsy of infancy (SMEI). However, in most patients with SCN1A mutation, brain imaging has reported normal or non-specific findings including cerebral or cerebellar atrophy. The aim of this study was to investigate differences in brain morphometry in epileptic children with SCN1A mutation compared to healthy control subjects.

Methods: We obtained cortical morphology (thickness, and surface area) and brain volume (global, subcortical, and regional) measurements using FreeSurfer (version 5.3.0, https://surfer.nmr.mgh.harvard.edu) and compared measurements of children with epilepsy and SCN1A gene mutation (n = 21) with those of age and gender matched healthy controls (n = 42).

Results: Compared to the healthy control group, children with epilepsy and SCN1A gene mutation exhibited smaller total brain, total gray matter and white matter, cerebellar white matter, and subcortical volumes, as well as mean surface area and mean cortical thickness. A regional analysis revealed significantly reduced gray matter volume in the patient group in the bilateral inferior parietal, left lateral orbitofrontal, left precentral, right postcentral, right isthmus cingulate, right middle temporal area with smaller surface area and white matter volume in some of these areas. However, the regional cortical thickness was not significantly different in two groups.

Significance: This study showed large-scale developmental brain changes in patients with epilepsy and SCN1A gene mutation, which may be associated with the core symptoms of the patients. Further longitudinal MRI studies with larger cohorts are required to confirm the effect of SCN1A gene mutation on structural brain development.

1. Introduction

The SCN1A gene (MIM#182389), which encodes the alpha 1 subunit of the voltage-gated sodium channel, is the most clinically identified gene associated with epilepsy. The spectrum of epilepsy related to SCN1A mutation spans from milder phenotypes, such as genetic epilepsy with febrile seizures plus (GEFS+), to severe myoclonic epilepsy of infancy (SMEI), also known as Dravet syndrome (Gambardella and Marini, 2009). GEFS + is characterized by recurrent febrile seizure events beyond 5–6 years of age, even up to the teenage years, and can
develop a number of afebrile heterogeneous seizure types with remis-
sion in adolescence (Scheffer and Berkovic, 1997; Camfield and
Camfield, 2015). Dravet syndrome is a deleterious forms of childhood
epilepsy characterized by recurrent febrile and afebrile seizures in the
first year, followed by multiple seizure types resistant to various anti-
epileptic drugs, as well as cognitive, behavioral, and motor impairment
(Dravet, 2011). Mutation of SCN1A has been detected in 60–80% of
patients with Dravet syndrome and, in contrast, only 10% of patients with
GEFS+ (Brunklaus et al., 2012; Marini et al., 2011; Scheffer et al.,
2009).

Although it remains to be elucidated which modifying factors are
responsible for the different phenotypes of SCN1A mutation-related
epilepsy, (Brunklaus et al., 2012; Mistry et al., 2014; Zuberi et al.,
2011) previously published reports are largely in agreement on the role
of decreased excitability of GABAergic inhibitory interneurons leading
to an imbalance between excitation and inhibition in a selective area of
the brain as a pathogenesis of SCN1A mutation-related epilepsy (Yu
et al., 2006; Ogiwara et al., 2007; Cheah et al., 2012). Although this
altered synaptic activity might not be the only mechanism that shapes
connectivity patterns in brain, it will change the pattern of refinement
of activity dependent neural circuitry during brain development
(Tessier and Brodais, 2009; Flores and Mendez, 2014). We hypothe-
sized that there would be large-scale structural changes in the brains of
patients with SCN1A mutation as the result of altered synaptic activities
and brain development. However, few data are available on the neu-
roimaging and neuropathology of epileptic patients with SCN1A mu-
tation. Previous studies were unable to find specific or consistent neu-
roimaging findings related to SCN1A mutation (Brunklaus et al., 2012;
Guerrini et al., 2011; Striano et al., 2007; Moehring et al., 2013).
Furthermore, the majority of patients with SCN1A mutation exhibited
no gross structural brain abnormalities with the exception of a few
minor findings, including cerebral or cerebellar atrophy, cortical dys-
plasia, or hippocampal sclerosis (Brunklaus et al., 2012; Guerrini et al.,
2011; Striano et al., 2007). Therefore, quantitative neuroimaging ap-
proaches such as brain volumetry and cortical morphometry may be
useful in assessing the structural changes which could not otherwise be
seen by conventional brain magnetic resonance imaging (MRI), and in
understanding the pathogenesis of SCN1A mutation. Herein, we com-
pared brain volume and cortical morphology in patients with SCN1A
mutation-positive epilepsy and healthy control group as well as ana-
dized differences in the developmental patterns of their brains.

2. Methods

2.1. Subjects

Epileptic patients with SCN1A mutation were recruited from the
pediatric neurology clinics of three medical centers in Korea: Asan
Medical Center, Samsung Medical Center, and Seoul National
University Children’s Hospital. We included patients who satisfied
the following inclusion criteria: (i) epilepsy diagnosed by a pediatric neu-
rologist; (ii) genetically confirmed SCN1A mutation; (iii) normal brain
MRI. All patients underwent brain MRI for the diagnostic evaluation of
epilepsy, and all images were interpreted by one pediatric neuror-
diologist (HM Yoon), who confirmed that the images were free of any
brain abnormalities. We collected patients’ clinical information, in-
cluding age, sex, seizure onset, seizure phenotype, occurrence of status
epilepticus during follow-up, resistance to multiple antiepileptic drug,
cognitive and behavioral outcome, and SCN1A mutation type.

For each patient, two healthy control subjects matched in age and
gender and without alleged neurologic deficits were recruited. All MRIs
of the controls were reviewed and interpreted as normal by the same
pediatric neuroradiologist (HM Yoon). Our study protocol was ap-
proved by the Institutional Review Board of all participating institu-
tions (Asan Medical Center, Samsung Medical Center, Seoul National
University Children’s Hospital).

2.2. MRI acquisition

MRI scans were obtained on a Philips Achieva 3.0T scanner (Philips
Healthcare, Eindhoven, The Netherlands) (n = 53) and Siemens
MAGNETOM Verio 3.0T scanner (Siemens AG, Erlangen, Germany)
(n = 10). Three-dimensional whole brain T1 sequence imaging was ac-
quired with the following image parameters: echo time (TE) = 4.6 ms, re-
petition time (TR) = 9.8 ms, flip angle (FA) = 8.08, field of view (FOV) =
224 × 224 mm, matrix = 256 × 256, slice thickness = 1 mm, sagittal
images of the entire brain with in-plane resolution 1.0 mm × 1.0 mm or
TE = 5.1 ms, TR = 25 ms, FA = 30, FOV = 220 × 220 mm, matrix =
512 × 512, slice thickness = 1 mm, sagittal images of the entire brain
with in-plane resolution 1.0 mm × 1.0 mm on a Philips 3.0 T Achieva
scanner. On the MAGNETOM Verio scanner, images were obtained
with TE = 1.9 ms, TR = 1500 ms, FA = 90, FOV = 220 × 220 mm, matrix =
256 × 256, slice thickness = 1 mm, sagittal images of the entire brain
with in-plane resolution 1.0 mm × 1.0 mm. Before data processing,
all raw T1 sequencing images were visually inspected for common MR T1
weighted imaging artifacts, which can undermine segmentation accuracy,
by an experienced researcher (WH Shim) and neuroradiologist (HM Yoon).

2.3. Image analyses

All measurements, including cortical thickness, surface area, and
volume were obtained from T1 MRI scans using FreeSurfer (version
5.3.0, https://surfer.nmr.mgh.harvard.edu), a fully automated surface-
based analysis. The technical details of the procedures have been pre-
nviously described (Dale et al., 1999; Fischl et al., 1999; Fischl and Dale,
2000; Fischl et al., 2004). Briefly, the processing pipeline included
correcting of intensity variation, removal of non-brain tissue, segment-
tation of the gray matter/white matter (GM/WM) tissue, tessellation of
the cortical GM/WM boundary, inflation of the folded surfaces, and
automatic correction of topological defects to detect GM/WM and GM/
cerebropial fluid (CSF) boundaries. Cortical thickness was quantified
as the closest distance from the GM/WM boundary to the GM/CSF
boundary at each vertex. Subcortical volumes were calculated with
FreeSurfer’s automated procedure for volumetric measures. Each voxel
in the normalized brain volumes were assigned to one of 40 labels,
including cerebellum and brain stem (Fischl et al., 2004). Cortical
volume, cortical thickness, and surface area were estimated for 34 regions
per hemisphere according to the Desikan FreeSurfer atlas (Desikan
et al., 2006). To improve accuracy of imaging analysis, key inter-
mediate processing outputs (skull stripping, segmentation, parcellation)
of FreeSurfer were visually inspected and, if needed, brain masks and
inaccurate definitions of white matters were manually corrected by a
trained researcher (WH Shim) as described in FreeSurfer website.3

2.4. Statistical analyses

We compared age and gender distributions between groups using t-
tests and chi-square tests. FreeSurfer’s built-in general linear model
tool, QDEC, was performed to compare regional cortical thickness be-
 tween groups, controlling for age and gender. Cortical thickness data
were smoothed with a 10 mm full width at half maximum (FWHM)
Gaussian kernel. To correct for multiple comparisons, the false dis-
covery rate (FDR) was implemented using a cluster-wise correction
method with an initial cluster-forming threshold set at p < 0.01. Only
clusters with a corrected value of p < 0.05 were considered to be
significant. Analysis of covariance (ANCOVA) was performed using
SPSS version 18.0 (SPSS, Chicago, IL) to compare group differences in
the mean cortical thickness, mean surface area, and volume (global
volume and regional volume) with age and gender as covariates. In
surface area and volumetric analysis, total intracranial volume (TIV)

3 https://surfer.nmr.mgh.harvard.edu/fswiki/FrTtutorial/WhiteMatterEdits_freeview.
was included as a covariate to control the total brain size. Bonferroni correction for multiple comparisons was applied, and a \( p < 0.0015 \) was considered to be significant for both the cortical volume and surface area analysis for 34 regions \( (p < 0.05/34) \) as well as the analysis of 35 subcortical structural volumes \( (p < 0.05/35) \). We also assessed age-related group differences using QDEC (cortical thickness) and ANCOVA in SPSS (volume, surface area) after adjusting age and gender. The measurements in whole-brain analysis and age-related group differences were considered as significant with a value of \( p < 0.05 \).

### 3. Results

#### 3.1. Demographical and clinical characteristics

A total of 21 patients and 42 healthy control subjects were recruited. All demographic and clinical characteristic data from the patient and healthy control groups are shown in Table 1 and Inline Supplementary Table S1.

Inline Supplementary Table S1 can be found online at http://dx.doi.org/10.1016/j.nicl.2017.06.002.

#### 3.2. Whole-brain analysis

There was no significant difference in the total intracranial volume (TIV) between the two groups \( (p = 0.09) \). After controlling for age, sex, and TIV, the total brain, total GM, total cortical GM, subcortical GM, total cortical WM, and cerebellar WM, total cerebellar volumes of the patient group were significantly smaller than those of the healthy control group, while the cerebellar GM was not different (Table 2). The mean cortical surface area and cortical thickness were significantly reduced in the patient group, with a much larger discrepancy in surface area (difference between means: \(-5.5\%\), \( p < 0.001 \)) than in cortical thickness (difference between means: \(-2.4\%\), \( p = 0.045 \)).

#### 3.3. Effect of age on volume, cortical thickness and surface area

We compared the age effect on cortical thickness, global volume and surface area between the two groups. In comparison with the control group, there was no observed statistically significant difference in terms of age effect on total brain \( (p = 0.056) \), total GM \( (p = 0.076) \), total cortical GM \( (p = 0.077) \), total cortical WM \( (p = 0.097) \), cerebellar WM \( (p = 0.276) \) and cerebellar GM volume \( (p = 0.192) \), mean cortical thickness \( (p = 0.344) \) and mean surface area \( (p = 0.134) \). (Fig. 1).

The scatter plots show the age effect on total brain volume (A), total cortical gray matter volume (B), total gray matter volume (C), and total cortical white matter volume (D). CM, control male group; CF, control female group; PM, patient male group; PF, patient female group.

#### 3.4. Subcortical volume analysis

Subcortical volume analysis was performed to compare the volumes of the subcortical structures (thalamus, caudate, putamen, pallidum, hippocampus, accumbens area, CSF, and corpus callosum), cerebellum, and brainstem between the patient and control groups. After correction for multiple comparisons, the patient group showed significantly reduced volumes in bilateral putamen, caudate, accumbens area compared to the control group (corrected \( p \)-value < 0.05) (Table 3).

#### 3.5. Regional analysis of volume, surface area, cortical thickness

After correction for multiple comparisons, a regional surface area analysis of 34 parcelled regions per hemisphere found that patients had significantly decreased surface areas in the left lateral orbitofrontal and right middle temporal area (Table 4). Also, the patient group

4. Discussion

This study aimed to investigate morphometric brain abnormalities in patients with SCN1A mutation and related epilepsy. In the whole-brain analysis, we found significantly smaller total brain volume, total cortical GM volume, subcortical GM volume, total cortical WM volume and cerebellar WM volume in the patient group compared to the control group. These volume changes are consistent with previous studies, suggesting non-specific neuroimaging findings, such as atrophic change on cerebral and cerebellar area (Brunklaus et al., 2012; Guerrini et al., 2011; Striano et al., 2007) and brain morphometry analysis in patients with Dravet syndrome (Perez et al., 2014). Although the potential mechanism responsible for the volume change is uncertain, functional changes in GABAergic inhibitory interneurons, which are important in normal brain development, can alter the neural network formation (Flores and Mendez, 2014). One report also supports this hypothesis in that it has identified progressively reduced dendritic arborization and excessive spines in dentate gyrus granule cell of the mouse model (Scn1a<sup>E1099X/+</sup>) mimicking human Dravet syndrome (Tsai et al., 2015). This same study supports that this microstructural alteration likely results in neural network instability and has an impact on epileptogenesis and higher-order cognitive processing.

In our study, we identified brain developmental patterns in epileptic children with SCN1A mutation, which has not previously been shown by routine visual analysis. While patient group exhibited similar trajectories of global brain development of the normal controls, the total

Inline Supplementary Table S2 can be found online at http://dx.doi.org/10.1016/j.nicl.2017.06.002.
brain volume, GM and WM volume showed the largest discrepancy between the patients and controls during early childhood (Fig. 1). There is robust growth in human brain volume, mainly in the gray matter, through the first 2 years of life, with rapid elaboration of dendrites, spines, and synapses (Tau and Peterson, 2010). Synaptic overgrowth in early infancy is essential to ensure the complete wiring of the nervous system (Tessler and Brodie, 2009). Smaller GM volume during early childhood of patients with SCN1A mutation may be related to insufficient synaptogenesis and myelination in first 2 years of age, as well as an abnormal cortical pruning process through childhood (Tau and Peterson, 2010).

In our study, we also identified a smaller subcortical volume in the bilateral areas of putamen, caudate, accumbens area in the patients group compared to control group. The basal ganglia neural circuit connected with the cortex and the thalamus plays a key role in the modulation of motor control as well as cognitive and executive function and behavior (Bhatia and Marsden, 1994). The significant subcortical volume changes observed in this study could explain the epileptic seizures, motor impairments and cognitive declines of Dravet syndrome (Dravet, 2011).

In the regional analysis, the patient group exhibited a smaller GM volume in the bilateral inferior parietal, left lateral orbitofrontal, left precentral, right postcentral, right isthmus cingulate, right middle temporal area with the reduced surface area and WM volume in some of these areas. The inferior parietal, isthmus cingulate, and the middle temporal gyrus comprise the default mode network that in turn may cause the malfunction of these structures. Conversely, previous brain morphometric analysis in patients with Dravet syndrome revealed no difference in local GM volume (Perez et al., 2014). This discrepancy could be explained differences in the tools used for analysis and/or

### Table 4

| Parcellated region            | Surface area¹       | GM volume¹       | WM volume¹      |

L, left; R, right; GM, gray matter; WM, white matter.

Bold font indicates statistical significance (p < 0.05) after correction for multiple comparisons.

¹ Age, gender, and total intracranial volume were included as covariates in comparisons between the patient and control groups.
characteristics of the enrolled patients, such as the inclusion of younger patient groups irrespective of disease severity. As we noted, the younger patients showed a bigger difference in volume in this study (Fig. 1). However, present study could not clarify exact neuro-anatomical pattern correlated with phenotype since this study included too young patients (mean age at last follow up: 7.7 ± 2.9 years) to define the clinical diagnosis such as Dravet syndrome or GEFS+. Further study with larger patient group will be required to find the stratified results according to the phenotype.

Cortical volume is composed of two independent components, surface area and cortical thickness, which have different ontogenetic processes from one another, providing independent information on brain development (Vijayakumar et al., 2016). While cortical thickness depends on the numbers of cells in their intrinsic radial column, surface area is associated with the number of radial columns which can be affected by the inputs from subcortical structures (Rakic, 1988). Also, the volume is more highly correlated with area because volume is a quadratic function of surface distance and only a linear function of thickness (Winkler et al., 2010). In our study, patient group exhibited a much larger discrepancy in mean surface area than mean cortical thickness. Also, most of the regions with reduced GM volume were consistent with the region with smaller surface area in the patient group, while the cortex was not significantly thinner in the patient group than the control group according to the regional cortical thickness analysis. This result is in agreement with previous study suggesting that cortical thickness and surface area were found to be genetically independent (Winkler et al., 2010). The genetic influence of the SCN1A mutation may affect separately on cortical thickness and surface area during ontogenic processes.

Additionally, cerebellar WM volume was significantly smaller in patients with SCN1A mutations. The cerebellum is involved in motor coordination, balance, and posture, as well as in cognitive functions, such as memory, language, visuospatial skills, and attention (Tedesco et al., 2011; Fine et al., 2002). An experimental mouse model of Dravet syndrome revealed that the impairment of the sodium current and action potential firing in the GABAergic Purkinje neurons of the cerebellum may be responsible for motor coordination (Kalume et al., 2007) and that Purkinje neurons play an important role in cerebellar development and maturation (Fleming and Chiang, 2015). Thus, the core symptoms of Dravet syndrome, including ataxia, poor motor coordination, and autistic behavior, can be explained by these changes to the cerebellum linked to SCN1A mutation (Dravet, 2011; Battaglia et al., 2013).

This study has some limitations due to its small sample size and study design in that it is a cross-sectional study and may reflect cohort differences rather than true developmental trajectories. Furthermore, this study only examined linear age effects and interactions exclusively in patients 2–12 years of age, despite the fact that key cortical measures, such as cortical thickness, have been shown to have non-linear developing trajectory through their life (Shaw et al., 2008). Technically, the subjects have been scanned on two different scanners with different scanners with different parameters, which may influence the GM segmentation. However, all data used in our study were carefully visually inspected by a trained researcher, which may result in more reliable estimates (Iscan et al., 2015). Another limitation is the heterogeneity in patient characteristics in terms of frequency of seizures, developmental status, and genetic subtypes, which may be possible confounding factors. In the future, longitudinal studies with larger sample sizes and wider age ranges should be conducted to detect more accurate developmental trajectories after stratification by patient characteristics.

5. Conclusions

Using surface-based morphometric analysis, we found large-scale structural brain alterations associated with SCN1A mutation and related epilepsy, which may be linked to the core symptoms of SCN1A mutation-positive epilepsy. Children with SCN1A mutation-positive epilepsy showed smaller cortical and subcortical GM and surface area and exhibited changes in developmental trajectory compared to healthy control patients. Future longitudinal and in vivo functional studies of SCN1A mutation are needed to confirm the effect of SCN1A gene mutation on structural brain development.

Funding

This work was supported by an NRF-2016R1C1B2010078 and a grant (2016-703) from the Asan Institute for Life Sciences, Seoul, Korea.

Disclosure of conflicts of interest

None of the authors has any conflict of interest to disclose.

Acknowledgements

The authors would like to thank Sun-Ok Kim (Asan Medical Center) for conducting the statistical analyses and Joo Young Oh (Asan Medical Center) for completing the brain structural analyses.
