(Dated: March 20, 2002)

It has been known theoretically that localized states exist around zigzag edges of a graphite ribbon and of a carbon nanotube, whose energy eigenvalues are located between conduction and valence bands. We found that in metallic single-walled zigzag carbon nanotubes two of the localized states become critical, and that their localization length is sensitive to the mean curvature of a tube and can be controlled by the Aharonov-Bohm flux. The curvature induced mini-gap closes by the relatively weak magnetic field. Conductance measurement in the presence of the Aharonov-Bohm flux can give information about the curvature effect and the critical states.

Prior theoretical studies on zigzag carbon nanotubes clarified that they can exhibit either metallic or semiconductor properties of the edge state have been investigated theoretically and experimentally that even in “metallic” zigzag single-walled carbon nanotubes (SWCNTs) a finite curvature opens small energy gaps. Therefore, any zigzag SWCNTs have finite energy gaps.

On the other hand, Fujita et al. theoretically showed that localized states (edge states) emerge at graphite zigzag edges. The edge states are plane wave modes along the edge and their energy eigenvalues are in between the valence band and the conduction band (zero-energy states). Since the graphite sheet with zigzag edges can be rolled to form a zigzag SWCNT, the edge states are supposed to be localized at both edges of the zigzag SWCNT. In this case, a zigzag nanotube has not only bulk (extended) states with a finite energy gap but also zero-energy localized edge states. Although several properties of the edge state have been investigated, physical relationship between electrical properties of bulk states and edge states remains to be clarified.

In this paper, to investigate this relationship, we study an effect of the Aharonov-Bohm (AB) flux along the metallic zigzag nanotube axis. Among the Fujita’s edge states of metallic zigzag SWCNTs, we will show that there exist “critical states”. Their wave functions, in particular their localization length, are sensitive to the following two perturbations: the curvature and the Aharonov-Bohm (AB) flux. These perturbations are new ingredients for cylindrical geometry, absent in the flat graphene sheet. The main purpose of the paper is to clarify the dependence of the critical states on the AB flux and the relationship between the wave functions at the bulk and at the edge. This dependence can be examined by a conductance measurement in the presence of the AB flux. We note that such AB flux applied along the SWCNT axis (see Fig. 1) has already been realized in experiments.

Because the unit cell is composed of two sublattices, A and B, we write the wave functions as $|\Psi_k\rangle = \hat{\xi} (\psi_A(k), \psi_B(k))$ where $k$ is a discrete wave vector around the tubule axis. By fixing the chiral vector as $C_h = (n, 0)$, we obtain $k = 2\pi \mu/|C_h| (|C_h| = \sqrt{3a_{cc}n})$ where $\mu = 1, \cdots, n$ is an integer and $a_{cc} \approx 1.42\text{Å}$ is the carbon-carbon bond length. We analyze the system using the nearest-neighbor tight-binding Hamiltonian, $H = \sum_{a=1,2,3} \sum_{i j \in A} (V_a + \delta V_a) a_i^\dagger a_j + h.c.$. “$A$” (in the summation index) denotes an A-sublattice, $a_i$ and $a_i^\dagger$ are canonical annihilation-creation operators of the electron at site $i$, and site $i+a$ indicates the nearest-neighbor sites ($a = 1, 2, 3$) of site $i$. We include curvature effect as the bond direction-dependent hopping integral, $V_\pi + \delta V_\pi$.

We ignore the electron spin for simplicity.

The energy eigen equation, $H|\Psi_k\rangle = E|\Psi_k\rangle$, becomes

$$\epsilon \phi_A^{J+1} = \phi_B^{J+1} + g \phi_B^{J+1} \quad (J = 0, \cdots, N - 1),$$

$$\epsilon \phi_B^{J+1} = \phi_A^{J+1} + g \phi_A^{J+1} \quad (J = 0, \cdots, N - 1),$$

$$\epsilon \phi_A^{J+1} = g \phi_B^{J+1}, \quad \epsilon \phi_B^{J+1} = g \phi_A^{J+1},$$

where we define

$$\epsilon \equiv \frac{E}{(V_\pi + \delta V_\pi)} \quad g \equiv \frac{2(V_\pi + \delta V_\pi)}{(V_\pi + \delta V_\pi) \cos \frac{\pi(\mu - n \phi)}{n}}.$$

Here, we write the wave function at site $(I, J)$ of A(B) sublattice as $\psi_{(A,B)}(k) = \exp(2\pi i \mu/n)\phi_{(A,B)}(\mu)$ (see Fig. 1). We assume $\delta V_\pi = \delta V_\pi$ in the Hamiltonian because of the mirror symmetry along the axis of a zigzag nanotube. The effect of the AB flux is included in $g$ of Eq. 1 by the replacement, $\mu \rightarrow \mu - n \phi$, where $n \phi \equiv \Phi/\Phi_0$ is the number of flux quantum, $\Phi_0$.

By solving Eqs. 1, 2, and 3, we obtain an analytical form of the energy eigen function as

$$\phi_A^J = \left(\frac{1}{g} \sin \phi \right) \left(\sin \frac{(J+1)\phi}{\sin \phi}\right) \phi_A^J,$$

$$\phi_B^J = \left(\frac{\sin \frac{(J+1)\phi}{\sin \phi}}{\sin \phi}\right) \phi_B^J \quad (J = 0, \cdots, N),$$

where $\phi$ satisfies

$$2 \cos \phi = \frac{\epsilon^2 - g^2 - 1}{g} \equiv \kappa.$$
The energy eigenvalue is determined by the boundary condition of Eq. (8). Using Eqs. (3) and (4), we get

$$\sin(N+1)\phi + g \sin(N+2)\phi \sin \phi = 0.$$  \hspace{1cm} (8)

This equation corresponds to vanishing wave function at fictitious A sites of $J = N + 1$, i.e., $\phi_A^{N+1} = 0$. Most of the solutions for $\phi$ in Eq. (8) are real, as we explain later. Such real solutions represent extended states and satisfy $\kappa^2 \leq 4$.

In addition, there can be localized states, where $\phi$ has an imaginary part and $\kappa^2 > 4$. Their localization length is proportional to the inverse of the imaginary part of $\phi$. We examine if the boundary condition allows such a localized state. The complex solutions of Eq. (8) can be written as $\phi = i\varphi$ or $\phi = \pi + i\varphi$ where $\varphi$ is a real number. The former case, $\phi = i\varphi$, corresponds to $\kappa > 2$. In this case, Eq. (8) becomes

$$\sin(N+1)\varphi + g \sin(N+2)\varphi = 0.$$  \hspace{1cm} (9)

Due to $|\sin(N+2)| > |\sin(N+1)|$, we obtain $-1 < g < 0$. The latter case, $\phi = -i\varphi$, corresponds to $\kappa < -2$ and $0 < g < 1$. When $|g| \geq 1$, on the other hand, Eq. (8) does not allow complex solutions and therefore there is no localized state in this region. Because the boundary condition implies $g = -e^{i\varphi} + O(e^{2N\varphi})$ for $\varphi < 0$ ($-1 < g < 0$) and $g = e^{-i\varphi} + O(e^{-2N\varphi})$ for $\varphi > 0$ ($0 < g < 1$), the energy eigenvalues for localized states are $\epsilon = \pm O(e^{-N|\varphi|})$, exponentially small as a function of nanotube length.

By a more elaborated analysis, for a fixed $k$, we can analytically show that, (i) for $|g| \geq \frac{N+1}{N+2}$, all the $2(N+1)$ states are extended, (ii) for $0 < g < \frac{N+1}{N+2}$, there are $2N$ extended states and two localized states with $\text{Re}\phi = \pi$, and (iii) for $-\frac{N+1}{N+2} < g < 0$, there are $2N$ extended states and two localized states with $\text{Re}\phi = 0$. For each wave vector $k$ satisfying $|g| < \frac{N+1}{N+2}$, the two localized states have energies with opposite signs, $\epsilon = \pm O(e^{-N|\varphi|})$. Each of the two states is localized near both two edges. In the left (right) edge, it is localized in the $A$ ($B$) sublattice. Henceforth we consider the length $N$ of the nanotube to be large; the localized states are then allowed for $|g| < 1$.

The critical condition, $\kappa^2 = 4$, separates the extended and the localized states. We plot the lines of the critical condition in the $(g, \epsilon)$ plane in Fig. 2(a). The shadow regions satisfy $\kappa^2 > 4$, representing localized states. By applying the AB flux, each state moves and makes a trajectory in the $(g, \epsilon)$ plane. Suppose one extended state, located outside of the shaded region, comes across the boundaries $\kappa^2 = 4$ between the empty and shaded regions. It means that the extended state turns into a localized state. On the verge of the transition the state becomes "critical", when $g = \pm \frac{N+1}{N+2} \approx \pm 1$ and $\epsilon = \pm \frac{1}{N+2}$. If we assume $\delta V_0 = 0$ and there is no external magnetic field, this condition for $g$ is satisfied only in metallic zigzag nanotubes, namely, when $n$ is a multiple of 3 and $\mu_1/n = 1/3$ or $2/3$ (see Eq. (4)). When it is satisfied, the states with $g = \pm 1$, $\epsilon \approx 0$ are located very close to the critical line $\kappa^2 = 4$, and thus can be easily controlled by external perturbations as we see later.

The cylindrical geometry of nanotubes yields a finite mean curvature and induces a change of the hopping integral $\delta V_{2k}$. The scaling of the curvature gives $\delta V_{2k} / V_e \approx O(a_0^3/|C_0|^2)$. The values of $g$ are then driven

---

**FIG. 1:** Lattice structure of a zigzag carbon nanotube. The filled (open) circle indicates the $A$ ($B$) sublattice. Both the left and right edges are Fujita’s edges.

**FIG. 2:** (a) Region for localized states $\kappa^2 > 4$ shown as shaded area in the $(g, \epsilon)$ plane. Whether localized states are allowed depends on the boundary condition. If the figure is rewritten in terms of $k$ and $\epsilon$, the empty region reproduces the well-known band structure for the graphene sheet. (b) When we ignore the curvature effect, there are states with $g = -1$ in the absence of the AB flux. The curvature effect displaces the states onto the line $g = -(1 + (\delta V_2 - \delta V_1)/V_e)$. The AB flux changes the value of $g$, and eigenstates will make trajectories like the dashed curves in the figure. Two extended states (filled circles) become localized as they run into the shadow region. Eigenstates except for these two states remain extended (open circles).
away from \( g = \pm 1 \) to

\[
g \approx \pm \left( 1 + \frac{\delta V_2 - \delta V_1}{V_\pi} \right) + \sqrt{\frac{\pi n}{n}} n_\phi. \tag{10}
\]

From an experimental data of the mini-gap in metallic zigzag nanotubes, we estimate \( \delta V_2 - \delta V_1 = 0.9 \pm 0.2 \text{eV} \), but, in the absence of the AB flux, these states have \( |g| > 1 \), and are not critical but extended. However, the AB flux can make one of \( g \) within \( |g| < 1 \), which implies that two extended states become localized (see Fig. 2(b)). Other extended states remain extended even with this external magnetic field.

One of the important questions is whether the AB flux required for such a transition is experimentally accessible or not. We calculate the magnetic field required to close the curvature-induced mini-gap. From Eq. (10), we find \( n_\phi = \pi / (8\sqrt{3} n) \) is necessary to close the mini-gap for \( g = -1 \) (for \( g = 1 \), \( -n_\phi \) is necessary). This AB flux corresponds to the magnetic field \( B \approx 2 \times 10^7 \text{T} \). Thus, \( B \) is accessible if \( n \geq 20 \). For a zigzag nanotube with \( C_h = (n, 0) \), the flux quantum \( \Phi_0 \) corresponds to the magnetic field \( B_n = B_n / n^2 \text{T} \) \( (B_n \approx 8.5 \times 10^5 \text{T}) \), and therefore experimentally accessible magnetic flux corresponds to \( |n_\phi| \ll 1 \). For instance, we have \( B_n \approx 10^4 \text{T} \), which is well beyond an accessible magnetic field \( \approx 10^2 \text{T} \), and we can attain \( |n_\phi| \approx 10^{-2} \) at most.

Here, we plot the localization length of the critical state for metallic zigzag nanotubes with different diameters. We define the localization length \( L \) by \( |\phi^A|^2 / |\phi^A|^2 \approx \exp(-3a_{cc} J / 2L) \), where \( a_{cc} / 2 \) is the distance between \( J \) and \( J + 1 \) lines (Fig. 1). We obtain for \( n_\phi > n_\phi \)

\[
L \approx \frac{1}{4\pi n_\phi - \frac{\pi}{2\sqrt{3}n}} = \frac{1}{2\pi n_\phi} - \frac{\pi}{2\sqrt{3}n}. \tag{11}
\]

In Fig. 3 we plot \( L / |C_h| \) for \( n = 30 \) taken as the largest diameter for a SWCNT and \( n = 51 \) taken as a shell in a multi-walled carbon nanotube (MWCNT). The curvature-induced energy gaps are \( E_{gap} = 7.4 \text{meV} \) and \( 2.6 \text{meV} \), respectively, where we use \( V_2 = 2.7 \text{eV} \), \( n_\phi \) is estimated as \( 7.1 \text{T} \) for \( n = 30 \) and \( 1.4 \text{T} \) for \( n = 51 \). If we neglect the interlayer interaction in a MWCNT, a zigzag SWCNT in a MWCNT is the most suitable to examine the behavior of the critical states, because one does not need strong magnetic field to close the curvature-induced mini-gap.

The curvature effect and the modulation of localization length can be experimentally proved by conductance measurements as a function of the gate voltage for various values of the AB flux. We plot the conductance for different \( n_\phi \) in Fig. 4 where we assume ideal contacts and zero temperature. Such measurement is attainable, as conductance of well-contacted individual SWCNTs was measured in the ballistic regime by Kong et al.\(^a\). In Fig.4(a), the solid curve represents conductance in the absence of the AB flux, \( n_\phi = 0 \). The zero conductance state corresponds to the curvature-induced mini-gap. In (b), conductance changes according to the AB flux. Near the Fermi level, only one channel \( (g \approx -1) \) contributes to the transport and gives a unit of quantum conductance \( G_0 \). In (c), when \( n_\phi = n_\phi \), the zero conductance state disappears and the critical states start to localize. Even when further AB flux is applied, there remains a finite conductance at Fermi level due to the critical states as is depicted in (d). However, because further AB flux quickly reduces the transmission probability from Fig. 3, the conductance at the Fermi level decreases.

![FIG. 3: Localization length of the critical state for (a) \( n = 30 \) and (b) \( n = 51 \) zigzag nanotubes. The horizontal axis is a magnetic field, \( B \), (a) \( 7.5 \leq B \leq 30 \) and (b) \( 1.6 \leq B \leq 30 \).](c1)

![FIG. 4: Theoretical result of conductance with a metallic zigzag nanotube. We plot conductance as a function of gate voltage, \( V_g \), for several values of the AB flux.](c2)
zero, while other extended states open up the gap again. Such zero-energy states cannot be obtained by solving the Weyl equations with a uniform energy gap. Instead, it is known that by modulating locally the energy gap, there appear localized states called Jackiw-Rebbi (JR) states. The edge states in the nanotube induced by the AB flux resemble the JR states, in that they have zero energy and are localized; meanwhile they are different from ours because these edge states are induced by a uniform AB flux, and not by a local modulation. We note that related states can appear when we introduce a local geometrical deformation in the nanotube.

Throughout this paper, we have examined zigzag nanotubes having two Fujita’s edges. Even for zigzag nanotubes with open edges, one can consider other cases with one or two edges being the Klein’s edge. If one of the edges is Klein’s edge and the other is Fujita’s edge, there are still localized states, whereas their properties are distinct from the previous case for two Fujita’s edges. Such a nanotube can be made by attaching A-sites at the right edge of the zigzag nanotube in Fig. 1. The boundary condition for the right edge is $c_{N,A} = \phi_{N}$. For localized states we obtain $\epsilon = 0$ and $\phi_{A} = (-1)^{J} \phi_{A}$, $\phi_{B} = 0$ ($J = 0, \cdots , N$). Thus, the localized states have exactly $\epsilon = 0$ for every value of $g$, and they have amplitude only on the A sublattice. Such states are localized near the right (left) edge when $|g| > 1$ ($|g| < 1$). Furthermore, there are no transitions between localized and extended states, even when we apply a magnetic field. Meanwhile, when $g$ passes $g = \pm 1$, the localized state with $\epsilon = 0$ comes on the critical boundary of $\kappa^{2} = 4$ in Fig. 2(a), and the corresponding localized state will move from the right edge to the left or vice versa, and can be detected experimentally. On the other hand, when both edges are the Klein’s edges, the situation is somewhat similar to the case with two Fujita’s edges. For this case, localized states are realized when $|g| > 1$ instead of $|g| < 1$, and the AB flux induces a transition from localized to extended states.

Similar phenomena are expected also in nanotubes with other chiral structures except for armchair nanotubes. Nakada et al. showed numerically that localized states appear not only in the zigzag edges but also in edges with other shapes. We expect that such localized states will undergo transition with extended states in the presence of the AB flux.

Finally let us mention the Coulomb charging energy for the localized states. A typical energy scale of the charging energy for an edge state is $E_{c} \approx e^{2}/L_{\text{edge}}$, where $L_{\text{edge}}$ is the typical length for the edge states. This energy should be compared with that of the extended states evaluated as $E_{c} \approx e^{2}/L_{\text{sys}}$, where $L_{\text{sys}}$ is the system size. Since $L_{\text{sys}} \gg L_{\text{edge}}$, the Coulomb energy $E_{c}$ for the edge states are much bigger than that of the extended states, and may hinder localization. To lower this Coulomb charging energy, the spins of the localized states at each edge will align ferromagnetically.

In addition to the edge states, the bulk states can also have interesting phenomena due to the AB flux in SWCNTs. Namely, the AB flux induces a persistent current around the tube axis, and gives an orbital magnetic moment. The persistent current is caused by a splitting of the van Hove singularities by the AB flux. Quite recently, the splitting was observed in semiconducting nanotubes as the splitting of the first-subband magnetoresistance peak and also in small-bandgap (not curvature related) nanotubes as a temperature dependence of conductance. These experiments were intended to observe that the AB flux can make asymmetry between two energy bands composed of the extended (bulk) wave functions near the Fermi level. By means of doping in addition to the AB flux, an interference between many energy bands takes place. This interference affects magnetic and transport properties of the system, and is helpful to get insight into the bulk electronic states.

In summary, the Aharonov-Bohm effect of carbon nanotubes will be suited to examine not only the bulk electrical properties but also the properties of the edge states. We point out that there are two critical states in metallic zigzag nanotubes. Although the critical states became extended due to the curvature effect in the absence of magnetic field, the Aharonov-Bohm flux can make a transition from the extended states into localized edge states. This transition can be seen as a characteristic feature of conductance.
