Polar van der Waals chalcogenophosphates exhibit unique properties, such as negative electrostriction and multi-well ferrielectricity, and enable combining dielectric and 2D electronic materials. Using low temperature piezoresponse force microscopy, we revealed coexistence of piezoelectric and non-piezoelectric phases in CuInP$_2$Se$_6$, forming unusual domain walls with enhanced piezoelectric response. From systematic imaging experiments we have inferred the formation of a partially polarized antiferroelectric state, with inclusions of structurally distinct ferrielectric domains enclosed by the corresponding phase boundaries. The assignment is strongly supported by optical spectroscopies and density-functional theory calculations. Enhanced piezoresponse at the ferrielectric/antiferroelectric phase boundary and the ability to manipulate this entity with electric field on the nanoscale expand the existing phenomenology of functional domain walls. At the same time, phase-coexistence in chalcogenophosphates may lead to rational strategies for incorporation of ferroic functionality into van der Waals heterostructures, with stronger resilience toward detrimental size-effects.

aryed thiophosphates, with a general composition of CuInP$_2$Q$_6$ (Q = S, Se)\(^1\), have recently gained attention as candidate materials for two-dimensional\(^2\)–4 (2D) or few-layered ferroelectrics\(^5\)–\(^7\). The sulfur\(^6\) and selenium\(^8\)–\(^10\) compounds have similar structure of individual layers and a concomitant ferrielectric (FE) ordering, with Cu\(^{2+}\) and In\(^{3+}\) ions counter-displaced within individual layers, against the backbone of P$_2$Q$_6^\text{2−}$ anions. The spontaneous polarization of the sulfide can range from ~5 μC/cm\(^2\) to ~12 μC/cm\(^2\)\(^11\) vs ~2.5 μC/cm\(^2\)\(^12\) in the selenide, in part due to larger off-centric Cu displacement in the sulfide. Despite the structural similarity, the reported properties of their phase transitions are quite different\(^10\). Other than the difference in the transition temperatures (~230 K\(^8\),\(^9\) in the selenide vs ~305 K in the sulfide\(^6\),\(^10\)), CuInP$_2$Se$_6$ exhibits a broader transition window compared to CuInP$_2$S$_6$ as evidenced by macroscopic dielectric, caloric and thermal characterization\(^5\)–\(^10\). It was proposed that this anomaly is evidence for the coexistence of ferrielectric and antiferroelectric (AFE) ordering, and an incommensurate phase that precedes ferroelectric ordering\(^9\). The properties of the intermixed S–Se compound are even more interesting, possibly involving a Lifshitz transition as well as polar glassy phases\(^13\). The apparent compatibility of chalcogenophosphates with a variety of polar orderings signifies comparatively weak dipolar correlations in the lattice. This property may be particularly pertinent toward prospective application of these materials as functional components of van der Waals heterostructures.

Indeed, recently, Song et al.\(^12\) proposed that ultrathin films of CuInP$_2$Se$_6$ develop an antiferroelectric ground state, with the ferrielectric-antiferroelectric crossover occurring at a thickness of ~6–8 layers. The primary driving force for the crossover is the depolarizing field that favors the antiferroelectric with net zero polarization. This feature is in contrast to perovskite oxides, such as the canonical BaTiO$_3$, which become non-polar in the ultrathin film limit\(^14\). However, at present, most nanoscale properties in CuInP$_2$S$_6$, CuInP$_2$Se$_6$ and Cu$_0.4$In$_1.2$P$_2$S$_6$ remain to be understood, with respect to the mechanisms that screen spontaneous polarization at the interfaces, polarization switching, and the structure of the domains and their domain walls\(^1\) as well as the scalability down to the single-layer limit. Understanding these behaviors will also help to identify the possible mechanisms by which these materials can be functional in van der Waals heterostructures.

Here, we report the structure of polarization domains in bulk CuInP$_2$Se$_6$ utilizing quantitative imaging of nanoscale piezoelectric properties. Contrary to the expectation of ferrielectric ordering analogous to CuInP$_2$S$_6$, we reveal a fundamentally different domain structure, with two markedly different values of piezoresponse. Moreover, the domain boundaries exhibit the strongest piezoelectric response, with up to fourfold enhancement compared to domain surfaces. CuInP$_2$Se$_6$ on the other hand, features an expected domain structure, with nearly uniform value of piezoresponse within domains, alternating polarization orientation and domain walls with vanishing piezoresponse\(^15\)–\(^17\). Despite the more complex polar structure of CuInP$_2$Se$_6$, the domains can be flexibly manipulated with applied fields. We explain the phenomena observed in CuInP$_2$Se$_6$ by considering the real-space domain structure of an antiferroelectric that is partially polarized in finite electric field. Our arguments are supported by Raman spectroscopy and DFT calculations indicating the possible coexistence of ferrielectric and antiferroelectric states. FE/AFE coexistence presents an intriguing opportunity for few-unit-cell thiophosphates, particularly within van der Waals heterostructures. At the same time, piezoelectric domain walls, which are polar phase boundaries in this case and can be readily manipulated by applied electric fields, present a new functional element for the domain-wall electronics paradigm\(^18\),\(^19\).

## Results and discussion

Piezoresponse force microscopy does not exhibit any significant signal on the surface of CuInP$_2$Se$_6$ at room temperature in the paraelectric state, as expected. On a crystal cooled below 200 K, the piezoresponse phase and amplitude images (Fig. 1a, b) reveal domains of various forms and sizes (the measured response is defined by the normal components of the piezoelectric coefficient $d_{3j} = 2e_0e_{3j}Q_{3j}P_j$, where the $Q_{3j}$ are components of electrostrictive tensor, $P_j$ is the normal polarization component, and $e_{33}$ is the normal component of the dielectric constant). Despite structural similarity, however, there is a stark contrast between CuInP$_2$Se$_6$ and Cu$_0.4$In$_1.2$P$_2$S$_6$ as shown in Fig. 1. In Cu$_0.4$In$_1.2$P$_2$S$_6$, the contrast of the piezoelectric signal comprises the non-polar dielectric phase In$_{4/3}$P$_2$S$_6$, with negligible piezoresponse, and the ferrielectric phase CuInP$_2$Se$_6$, whose piezoresponse is comparable to a ferroelectric: domains of opposite polarization have opposite signs of piezoresponse, with nearly zero signal at the domain wall in between (Fig. 1b, d)\(^20\),\(^21\). Cancellation of piezoresponse at the domain wall is a mutual consequence of nearly zero polarization at the wall, and possibly the mechanical cancellation effect due to opposite direction of surface deformation in the adjacent domains separated by the domain wall\(^1\). In CuInP$_2$Se$_6$, extended regions of negligible piezoresponse and extended regions of uniform piezoresponse also exist. However, in contrast to Cu$_0.4$In$_1.2$P$_2$S$_6$, CuInP$_2$Se$_6$ crystals studied here are nearly stoichiometric, excluding the existence of a non-ferroelectric phase, such as In$_{4/3}$P$_2$S$_6$ in Cu$_0.4$In$_1.2$P$_2$S$_6$. Moreover, the regions of finite piezoresponse appear only below the transition and can be flexibly manipulated with applied fields (shown below in Fig. 2j). At the same time, the piezoresponse signal across a boundary separating the two distinct regions in CuInP$_2$Se$_6$ has maximum rather than minimum piezoresponse signal. These observations imply that CuInP$_2$Se$_6$ below the ferroelectric transition intrinsically exhibits at least two distinct structural phases. The imaging results are reproduced for a variety of tips, cleaved surfaces and are also observed irrespective of the underlying topography (Supplementary Fig. 1). By using PFM in ultrahigh vacuum on freshly cleaved and nearly atomically flat surfaces, as well as invoking the band-excitation methodology for piezorespose\(^22\), we have further ruled out simple experimental artifacts such as the underlying topography\(^23\), electrochemistry\(^24\), or mechanical properties of the contact\(^25\).

Further insight as well as confirmation of the above assignments is evidenced from the electric-field dependence of the measured piezoresponse (Fig. 2). It was previously pointed out that it is essential to check local electromechanical measurements for possible artefacts, such as the contribution of extrinsic electrostatics\(^24\). As seen in Fig. 2, the dominant effect of applied bias is to impose an offset on the measured signal in both Cu$_0.4$In$_1.2$P$_2$S$_6$ and CuInP$_2$Se$_6$, while keeping the contrast between entities largely unchanged.

This conclusion is further confirmed by analysis of select 1D profiles from the data in Fig. 2, as shown in Fig. 3. Indeed, relative enhancement of piezoresponse is maintained irrespective of applied field (Fig. 3a, c), while domain walls in Cu$_0.4$In$_1.2$P$_2$S$_6$ reveal approximately average signal between up and down-oriented domains (Fig. 3b). At the same time, at both −3 V (Fig. 2f) and +2 V (Fig. 2j), the domain structure of CuInP$_2$Se$_6$ begins to evolve in applied field, respectively shrinking and growing the regions of finite piezoresponse.

Given all of the above measurements, we propose that CuInP$_2$Se$_6$ exhibits coexistence of antipolar and polar regions, identified, respectively, by zero and finite piezoresponse signals. The domain walls are then the boundaries separating these
regions. Given the propensity of CuInP₂Se₆ toward antiferroelectric ordering (12 and see below), the polar and antipolar regions would correspond to ferrielectric and antiferroelectric phases, respectively.

This scenario of phase separation can be rationalized by considering the real-space structures underpinning the hallmark property of antiferroelectrics—a double-hysteresis switching loop (Fig. 3d)26–28. Double hysteresis corresponds to the switching of antiferroelectric configuration with net zero polarization to ferroelectric structure with nonzero polarization. Uniform antiferroelectric structure is, therefore, expected only in a very small range of applied fields27. At finite field, the system exhibits a state of finite polarization. In the real space, the structure with finite polarization can manifest as two distinct states: either the system is uniformly polarized in an applied field, or it exhibits nonuniform distribution of polarization (schematically shown in the inset of Fig. 3d), such that local regions of ferrielectric and antiferroelectric phases emerge. We believe the second case is the appropriate representation of CuInP₂Se₆ in our measurements.

Our argument for the coexistence of ferrielectric and antiferroelectric phases in CuInP₂Se₆ is supported by Raman spectroscopy and DFT calculations. Both Raman and SHG
The peaks at 203 and 219 cm\(^{-1}\) are best captured by a combination of the calculated signature of the AFE state. It is negligible for the calculated signatures, while prominent in the experimental conditions.

Further, we compared the experimental Raman spectra to those calculated by DFT in the ferrielectric and antiferroelectric ground states, as shown in Fig. 4c. The AFE state in these calculations corresponds to an alternating displacement of Cu atoms along the b (or a) crystallographic direction, between opposite sides of each layer (Supplementary Fig. 4b), consistent with prior work \(^{12}\), under zero strain, all bulk AFE structures have a higher energy than the bulk FE structure. Meanwhile, calculated energies of all three types of AFE/FE boundaries are small, within 2 meV/nm\(^2\) of each other, while the energy of a FE/FE domain wall is much higher, 21 meV/nm\(^2\) (Fig. 5). This result indicates that the formation of the observed mixed AFE/FE state is largely governed by the energetics of the respective domains and that there is a high likelihood of formation of AFE/FE boundaries.

**Discussion**

The complete analysis of phase coexistence CuInP\(_2\)Se\(_6\) falls outside the scope of this manuscript. However, we have carried out analytical modeling of the mixed free energy functional within the Landau–Ginzburg–Devonshire framework (Supplementary Discussion). The functional incorporates the contributions to the free energy from ferroelectric, antiferroelectric, antiferrodistortive order parameters, as well as coupling and striction terms. Importantly, although the coexistence of antiferroelectric and ferroelectric order parameters is intuitively simple, its detailed functional is very complicated. The variation of the order parameter across the domain wall is opposite for the ferroelectric and antiferroelectric states (Supplementary Fig. 4), it is likely that uniform states of either kind can be preferred depending on specific experimental conditions.

Further insight into the structure and energetics of the AFE and FE phases and the AFE/FE domain walls has been gained using DFT calculations of large supercells, which accommodate such boundaries. The energetics and structures of several possible AFE configurations are shown in Supplementary Fig. 4. Consistent with prior work \(^{12}\), under zero strain, all bulk AFE structures have a higher energy than the bulk FE structure. Meanwhile, calculated energies of all three types of AFE/FE boundaries are small, within 2 meV/nm\(^2\) of each other, while the energy of a FE/FE domain wall is much higher, 21 meV/nm\(^2\) (Fig. 5). This result indicates that the formation of the observed mixed AFE/FE state is largely governed by the energetics of the respective domains and that there is a high likelihood of formation of AFE/FE boundaries.
antiferroelectric end-states: in ferroelectrics, polarization drops to zero at the domain wall \( x = x_0 \) in Supplementary Eq. (18)), while the antiferroelectric order parameter \( A \) increases at the domain wall \( x = y_0 \) in Supplementary Eq. (19)). Our experimental observable is strain, and specifically piezoresponse measured as a voltage derivative of strain. In the case of the FE/AFE boundary we do indeed predict a maximum strain at the wall within the approximations of the model (Supplementary Fig. 7). This behavior can be rationalized by analogy with double-hysteresis strain loops in macroscopic antiferroelectric switching (schematic in Fig. 3d). Upon onset of polarization (transition from AFE to FE phase), the lattice experiences maximum deformation (expansion in perovskite oxides\(^{29,30}\) that exceeds subsequent deformation in the ferroelectric state (due to piezoresponse). In our interpretation, the AFE–FE domain boundary in CuInP\(_2\)Se\(_6\) is precisely the region of phase separation. The result of the LGD modeling, showing maximum strain at the boundary, supports the analogy between AFE/FE transition due to electric field (in macroscopic double-hysteresis loops) and due to phase separation in real-space (in our measurements). Although we cannot yet model the piezoresponse (dynamic strain), it is also maximized in the macroscopic hysteresis loops at the AFE/FE switching, and could therefore be maximum in our measurements in Fig. 1 and 2. Based on these results, piezoelectric domain walls should also be generally found in partially polarized antiferroelectrics.

Using quantitative piezoelectric microscopy, combined with DFT calculations and optical spectroscopy, we have revealed unusual domain-wall properties in polar CuInP\(_2\)Se\(_6\), where domain walls exhibit maximum piezoresponse at the domain walls in contrast to the expectations for ferroelectrics. Whereas polar walls were previously detected in in antiferroelectric PbZrO\(_3\)\(^{31}\) and in ferroelastic CaTiO\(_3\)\(^{32,33}\), we have inferred that in CuInP\(_2\)Se\(_6\) the domain walls separate regions of antiferroelectric and ferrielectric ordering. These domain walls should be general for antiferroelectrics while being distinct from domain walls in either ferroelectric or antiferroelectric phases, thus emerging as a new entity in the context of domain-wall electronics\(^{19}\). Meanwhile, the observation of antiferroelectric state confirms theoretical modeling of very small energy differences between ferrielectric and antiferroelectric states in CuInP\(_2\)Se\(_6\). The ability to define and control locally polarized, mesoscale regions in an otherwise non-polar matrix may provide a path to integrate ferroic and electronic functionality via van der Waals interfaces, which is complementary to ferroelectric materials and that may persist down to single layer\(^{12}\).

**Methods**

**Crystal growth.** The single crystal CuInP\(_2\)Se\(_6\) was grown from gas phase by chemical transport reactions. Iodine has been used as transport agent with concentration of 4–5 mg/cm\(^3\). The temperature of evaporation zone was 870 K, and for the crystallization zone temperature equals 850 K. The duration of the growth process was 330 h. The resulting product was thin single crystal plates with dimensions near 10 × 5 × 0.1 mm\(^3\). Cu\(_2\)Zn\(_4\)P\(_2\)Se\(_6\) single crystals were synthesized through the vapor transport method. Starting materials, sealed in fused silica ampoules, were heated to 750–775 °C at a rate of 30 °C/h and held at that temperature for 4 days and then cooled at a rate of 20 °C/h.

**PFM imaging.** Ultrahigh vacuum contact PFM imaging and polarization switching were performed on an Omicron AFM/STM, interfaced with a Nanonis controller package. The chamber pressure was 1 × 10\(^{-10}\) mbar or better. The samples were mounted on a standard Omicron sample plate and affixed with a silver conductive epoxy (Epo–Tek EJ2189–LV). A clean surface was prepared by Scotch tape method.
stands for ferrielectric and AFE for antiferroelectric order. Marzhauser) under the microscope of the micro-Raman setup. The cryostat was 293 K. Raman spectra were sampled with 10 K step from 100 to 250 K, and also a liquid He-cryostat (MicrostatHiResII, Oxford Instruments) with a temperature and equipped with a 1800 groves/mm grating and a CCD camera (Pixis 256BR, Princeton Instruments). Before entering the monochromator, the SHG light was passed through a short-pass cutoff filter (650 nm) and a polarizer to filter out the fundamental excitation light at 800 nm and select the SHG polarization parallel to that of the excitation light. The low-temperature SHG measurements were conducted using the same liquid He-cryostat, which was used for Raman measurements.

DFT calculations. The DFT calculations (relaxations and 1-point phonon frequencies) in this study use the VASP 5.3.5 computational package and are carried out under the Perdew-Burke-Ernhol generalized gradient approximation (GGA) and the the DFT-D2 method as developed by Grimme. The recommended VASP PAW pseudopotentials were used. All calculations used a 600 eV energy cutoff. Raman frequencies and intensities are calculated using the package developed by Fonari and Stauffer. The calculations were performed on two phases of CuInP$_2$Se$_6$: a 20-atom ferroelectric (FE) phase, and a 40-atom 1 × 2 × 1 antiferroelectric (AFE) phase. The setup for the Cu atoms in the AFE unit cell is the same as that found by Song et al. For phonon calculations, both structures were relaxed so that the forces are less than 5e$^{-5}$ eV/Å to eliminate residual spurious forces. The FE/FE and FE/AFE domain-wall calculations are performed using 8 × 2 × 1 supercells containing 160 atoms. These calculations use a Γ-centered Monkhorst-Pack (MP) k-point grid of 1 × 4 × 2. All atoms were relaxed until all forces were smaller than 0.02 eV/Å. The domain boundary energy per unit area is calculated as

$$E_{\text{boundary}} = (E_{\text{total}} - E_{\text{phase}})/2S,$$

where $E_{\text{total}}$ is the supercell energy, $E_{\text{phase}}$ and $E_{\text{plane}}$ are the energies for the requisite number of atoms in those phases, and $S$ is the cross-sectional area of the boundary.

Data availability

Source data for the scanning probe images, results of optical spectroscopy and first principles calculations presented in this manuscript will be shared upon reasonable request.

Code availability

The data analysis was carried out with widely accepted commercial and open source software without any significant code customization.

Second harmonic measurements. Second harmonic generation (SHG) measurements were conducted using a 50 fs Ti:sapphire laser (Mira Coherent) at 800 nm and 80 MHz repetition rate. The laser beam was passed through a half-wave plate mounted in a rotation stage and was directed into an upright microscope (Olympus) and focused onto a sample surface using a ×50 microscope objective (Numerical Aperture: NA = 0.5) to a few micron spot. The laser energy at the sample surface was ~0.1 W. The SHG light was collected in backscattering configuration using the same objective and was directed to a monochromator (Spectra Pro 2300i, Acton, f = 0.3 m) that was coupled to the microscope and equipped with a 150 groves/mm grating and a CCD camera (Pixis 256BR, Princeton Instruments). Energy (meV/nm$^2$) of the scattered Raman light was analyzed by a spectrometer equipped with a 150 grooves/mm grating and a CCD camera (Pixis 256BR, Princeton Instruments). The Raman spectra were measured in a custom-built micro-Raman setup. The excitation light was an 800 nm and 80 MHz repetition rate. The laser beam was passed through a half-wave plate mounted in a rotation stage and was directed into an upright microscope (Olympus) and focused onto a sample surface using a ×50 microscope objective.
