Geometric phases play a central role in a variety of quantum phenomena, especially in condensed matter physics. Recently, it was shown that this fundamental concept exhibits a connection to quantum phase transitions where the system undergoes a qualitative change in the ground state when a control parameter in its Hamiltonian is varied. Here we report the first experimental study using the geometric phase as a topological test of quantum transitions of the ground state in a Heisenberg XY spin model. Using NMR interferometry, we measure the geometric phase for different adiabatic circuits that do not pass through points of degeneracy.

When a quantum system is subjected to a cyclic adiabatic evolution, it returns to its original state but may acquire a geometric phase factor in addition to the dynamical one. Berry made this surprising discovery in 1984 [1], so that this is also known as Berry’s phase. Later this phase was generalized in various directions, to include a more general case of noncyclic and nonadiabatic evolution [2], and even the case of mixed states. Geometric phases (GP) have been observed in a wide variety of physical systems, e.g., in spin-polarized neutrons [3], nuclear magnetic resonance (NMR) [4] and superconducting systems [5]. Moreover, GP has found applications to many areas, such as molecular dynamics, many-body systems and quantum computation [6,7].

Very recently, the GP of many-body systems has been shown to be closely connected to quantum phase transitions (QPTs), an important phenomenon in condensed matter physics [8,9]. QPTs occur at zero temperature and describe abrupt changes in the properties of the ground state resulting from the presence of level crossings or avoided crossings [10]. Recently, different methods related to quantum information have been developed for characterizing QPTs, including the fidelity [11], quantum entanglement [12,13] and some other geometric properties [14]. The GP, which is a measure of the curvature of Hilbert space, can reflect the energy level structure (i.e., level crossing points) in a Heisenberg XY spin model. In our experiment, the system Hamiltonian changes adiabatically along a closed trajectory in parameter space while the system, which is in the ground state of the Hamiltonian, accumulates a GP. Depending on the region in parameter space, the resulting GP is zero or has a finite value. These regions in parameter space are separated by a line where the ground state of the system becomes degenerate [15]. Using adiabatic state preparation and NMR interferometry, we observe the transitions of GP on both sides of the level crossings point. This experiment might be viewed as a first meaningful step to use GP as a fingerprint for observing QPTs.

Consider a one-dimensional spin-1/2 XY model in a uniform external magnetic field along the z-axis:

\[ \mathcal{H}(\lambda, \gamma) = -\sum_j \left( \frac{1 + \gamma}{2} \sigma_j^x \sigma_{j+1}^x + \frac{1 - \gamma}{2} \sigma_j^y \sigma_{j+1}^y \right) - \frac{\lambda}{2} \sum_j \sigma_j^z, \]

where \( \sigma_j^k \) (k = x, y, z) denote the Pauli matrices for qubit k, \( \lambda \) is the strength of the external magnetic field, and \( \gamma \) measures the anisotropy of the coupling strength in the XY plane. This model is exactly solvable and can be diagonalized by the Jordan-Wigner transformation, Fourier transformation and then Bogoliubov transformation [16]. However, it still contains a rich phase structure [10]. Barouch and McCoy [17] investigated the statistical mechanics of this model in the thermodynamical limit and showed that a circle (\( \lambda^2 + \gamma^2 = 1 \)) separates the oscillatory phase (inside) from the para- or ferro-magnetic phase (outside). At the level crossing or avoided crossing between ground state and first excited state, the ground state changes discontinuously. As a result, the GP associated with the ground state also changes discontinuously. Theoretical work has demonstrated the close relation between GPs and the energy level structures, thereby revealing the ground state properties [8,9], even in the two-qubit case [15].

In this Letter, we report the first experiment that shows this important connection between the GP and the energy level structure (i.e., level crossing points) in a Heisenberg XY spin model. When a quantum system is subjected to a cyclic adiabatic evolution, it returns to its original state but may acquire a geometric phase factor in addition to the dynamical one. Berry made this surprising discovery in 1984 [1], so that this is also known as Berry’s phase. Later this phase was generalized in various directions, to include a more general case of noncyclic and nonadiabatic evolution [2], and even the case of mixed states. Geometric phases (GP) have been observed in a wide variety of physical systems, e.g., in spin-polarized neutrons [3], nuclear magnetic resonance (NMR) [4] and superconducting systems [5]. Moreover, GP has found applications to many areas, such as molecular dynamics, many-body systems and quantum computation [6,7].
\[ U_1^\dagger(\phi) \mathcal{H}(\lambda, \gamma, \phi) U_1(\phi) = \prod_k e^{-i \phi \sigma_z^k} \mathcal{N}. \]  
\( \tilde{\mathcal{H}} \) has the same spectrum as \( \mathcal{H} \), independent of \( \phi \). Here we study a minimal model of two qubits coupled by an XY-type interaction [15]. The eigenvalues of \( \mathcal{H} \) are \pm 1 and \pm r, where \( r = \sqrt{\lambda^2 + \gamma^2} \). The ground state is

\[ |\Psi_g(\phi)\rangle = \begin{cases} 
\frac{1}{\sqrt{2}}(|01\rangle + |10\rangle), & r < 1 \\
\cos \frac{\theta}{2} |00\rangle + \sin \frac{\theta}{2} e^{-i2\phi} |11\rangle, & r > 1 
\end{cases} \tag{1} \]

where \( \tan \theta = \gamma / \lambda \). For \( r < 1 \), the ground state is thus invariant; for \( r = 1 \), it is doubly degenerate; and for \( r > 1 \), it is spanned by the two states \(|00\rangle \) and \(|11\rangle \), with coefficients that depend on the angle \( \theta \).

If we let the Hamiltonian travel along a cyclic path in the parameter space \((\lambda, \gamma, \phi)\), we can consider the subspace spanned by \(|00\rangle \) and \(|11\rangle \), which contains the ground state, as a pseudo-spin 1/2, where \( r > 1 \), the ground state is thus invariant; for \( r = 1 \), it is doubly degenerate; and for \( r < 1 \), it is spanned by the two states \(|00\rangle \) and \(|11\rangle \), with coefficients that depend on the angle \( \theta \).

As shown in Fig. [1a], it is useful to represent the trajectory in a parameter space spanned by \( \gamma \cos(2\phi), \gamma \sin(2\phi) \) and \( \lambda \). Here, the sphere with radius \( r = 1 \) marks the points where the Hamiltonian is degenerate. Inside this sphere \((r < 1)\), the GP vanishes, while it has a finite value that depends on the opening angle of the cone subtended by the circuit. A special case is the XX spin model (i.e., \( \gamma = 0 \)). Here, the GP always vanishes, because the operation \( U_z \) does not change the Hamiltonian of the system. While we are considering here only a minimal two-spin model, the ground state and the ground state energy of the XY model in the thermodynamic limit are similar [17].

When the system undergoes the cyclic adiabatic evolution along \( \mathcal{H} \), there will also be an additional dynamic phase generated, relative to the instantaneous energy of the system, besides the GP. Hence, in order to acquire the pure geometric part, we have to eliminate the dynamical contribution. To eliminate the dynamical contribution to the phase shift, we combine two experiments with the closed paths \( C \) and \( \bar{C} \) [2], which generate the same geometrical phases, but opposite dynamical phases. The two trajectories have the same geometrical shape (cones), but their Hamiltonians \( \mathcal{H} \) and \( -\mathcal{H} \) and thus their dynamical phases add to zero. During the first period, the Hamiltonian \( \mathcal{H}(\lambda, \gamma, \phi) \) follows the closed curve \( C \) in the parameter space \( r = (r, \theta, \phi) \), with \( \phi \) changing from 0 to \( \pi \), as schematically shown by the the red circles (labeled by \( C \) in the upper part) for \( \lambda > 0 \) in Fig. [1a]. During the second period, the

\[ \text{FIG. 1: (Color online) (a) Parameter-space representation of the cyclic adiabatic evolutions that generate the GP. Two closed paths \( C \) and \( \bar{C} \), related by inversion symmetry, were combined for observing a purely GP. The cycles are horizontal, i.e., \( \lambda \) is constant and \( \gamma \) is constant. The observed GP depends on the angle \( \theta \) if the circles are outside the sphere \( r = 1 \) (shown in black) and vanish if the curves are inside the sphere. (b) Energy level diagram of the time-dependent \( \mathcal{H}_{ad}(s) \) for ASP (denoted by the dashed lines), and the optimal function of adiabatic parameter \( s(t) \) (denoted by the solid line) calculated for a constant adiabaticity factor, when \( \gamma = 0.5, \lambda = 0.9920 \). The black dots represent the experimental values for the discretized scan.} \]
all three spins are $T_2 \approx 1s$. The natural Hamiltonian of this system is $H_{NMR} = - \sum_{i=0}^2 \frac{\omega_i}{2} \sigma_i^z + \sum_{i<j} \frac{J_{ij}}{2} \sigma_i^x \sigma_j^x$, where $\omega_i$ is the Larmor frequency for spin $i$ and $J_{ij}$ are the coupling constants $J_{01} = 160.7$ Hz, $J_{12} = -194.4$ Hz and $J_{02} = 47.6$ Hz. As the sample is not labeled, the relative phase information on $^1H$ at the end of the quantum circuit was obtained through the $^{13}$C spectrum by a SWAP operation between $^{13}C$ and $^1H$ [13].

In the experiment, we first initialized the system into the pseudopure state (PPS) $|\psi_{000}\rangle = \frac{1}{\sqrt{2}}|1\rangle + \epsilon|000\rangle$ by spatial averaging [13], with the polarization $\epsilon \approx 10^{-5}$. Then we prepared the ground state of the Heisenberg XY Hamiltonian by an adiabatic passage: A rf pulse rotated the spins from the $z$- to the $x$-axis, i.e., to the ground state of $H_0 = \sum_i \sigma_i^x$, and then this Hamiltonian was slowly changed into the target XY Hamiltonian $H(\lambda, \gamma)$, always fulfilling the adiabatic condition $\kappa \ll 1$ [19]. This assures that the resulting final state is close to the desired ground state of the XY model. We optimized the time dependence of the transfer by choosing $H_{ad}(t) = [1 - s(t)]H_0 + s(t)H$ with $0 \leq s(t) \leq 1$. The solid line in FIG. 1(b) shows the corresponding time dependence for a constant $\kappa$. The time dependence of $s(t)$ was chosen such that the adiabaticity parameter $\kappa < 0.25$ at all times.

In the experiment, the adiabatic transfer was performed in discrete steps. The parameter $s(t)$ therefore assumes discrete values $s_m$ with $m = 0, \ldots, M_P$, and for each period of duration $\delta$, the corresponding Hamiltonian $H_{ad}[s_m]$ was generated by a multiple pulse sequence: $U_P(\delta) = e^{-iH_{ad}[s_m] \delta} = e^{-(1-s_m)H_0 \frac{\delta}{2}} e^{-i\lambda \gamma H_{ad}[s_m] \delta} e^{-(1-s_m)H_0 \frac{\delta}{2}} + O(\delta^3)$, via the use of Trotter’s formula. $\delta$ and $M_P$ were chosen by simultaneously considering this stepwise approximation and the adiabaticity criterion. The experimental values $s_m$ for the discretized scan are represented by black dots in FIG. 1(b). The theoretical fidelity of this stepwise transfer process was $\approx 0.99$, and the experimental fidelity was $> 0.98$.

After the preparation of the ground state, we applied the cyclic adiabatic variation $C$ or $\bar{C}$. The corresponding control operation $UC$ or $U\bar{C}$ was generated in the form of a discretized adiabatic scan, as described for the ASP part. Again, the parameters of the scan were optimized to keep the fidelity $> 0.99$. At the end of the scan, the accumulated phase was measured.

FIG. 3: (a) Experimental NMR spectra for two specific parameter sets, $P_1$ for $H(0.0, 0.5)$ and $P_2$ for $H(0.878, 0.5)$. From top to bottom, the spectrum corresponds to the initial ground state $|\psi_{x}(\lambda, \gamma)\rangle$, $U_C|\psi_{x}(\lambda, \gamma)\rangle$ for the adiabatic path $C$ and $U_C|\psi_{x}(\lambda, \gamma)\rangle$ for the adiabatic path $\bar{C}$. (b) Measured ground-state GP of the Heisenberg XY model (points) for different parameter sets $(\lambda, \gamma)$ compared to the theoretical expectations (solid curves).
are $\beta_t(C) \approx -62.6^\circ$ and $\beta_t(\tilde{C}) \approx 114.2^\circ$, corresponding to a GP of 25.8$^\circ$.

Fig. 3(b) shows the GP measured for different parameters $(\lambda, \gamma)$. The symbols show experimental data points, while the curves that connect the points show the theoretically expected GP as a function of the magnetic field strength $\lambda$, for a constant anisotropy parameter $\gamma$. In all cases, the observed GPs are compatible with the theoretically expected values: zero if the parameters $(\lambda, \gamma, \varphi)$ fall inside the sphere with radius $r = 1$, a sudden increase to the maximum value just outside the sphere, where the opening angle $\theta$ of the cone subtended by the circuit reaches a maximum, and then decreasing as the circuit $C$ is moved away from the origin. Increasing values of $\gamma$ correspond to larger circles $C$ and thus bigger values of $\theta$. The points marked $P_1$ and $P_2$ correspond to the spectra shown in the upper part of the figure.

The relevant sources of experimental errors mainly came from undesired transitions induced by the time-dependent Hamiltonian, inhomogeneities of rf fields and static magnetic fields, imperfect calibration of rotations and relaxation. We used a numerical optimization procedure to minimize undesired transitions during the adiabatic passage. The durations of individual experiments ranged from 30 ms to 90 ms, short compared to the relaxation time $T_2 \sim 1$s. The experimental error of the geometric phase was less than 3$^\circ$, involving the realizable single- and two-qubit logic gates technique, and the Heisenberg XY model has been efficiently simulated by a universal quantum circuit only involving the realizable single- and two-qubit logic gates.

Moreover, the diagonalization theory of the XY model shows a valid energy gap between the two lowest energies, which guarantees the viability of the cyclic adiabatic evolution to generate the ground-state GP, even in the thermodynamic limit $[8]$. Recent research also shows that a 10-qubit system already represents a good approximation to the thermodynamical limit $[23]$. Therefore, the present scheme is in principle applicable to larger spin systems, when the technical difficulties in building a medium-scale quantum computer are overcome. This significant connection between GPs and QPTs is not a specific feature of the XY model, but remains valid in a general case $[8, 9]$. We hope that this experimental work will contribute to an improved understanding of the ground-state properties and QPTs in many-body quantum systems.

We thank S. L. Zhu for helpful discussion. This work was supported by NNSFC, the CAS and NFRP, and by the DFG through Su 192/19-1.

FIG. 4: (Color online) Relevant properties of the quantum register. (a) The molecular structure of Diethylfluoromalonate and the oval marks the three spins used as qubits. (b) The relevant NMR parameters: the resonance frequencies of the nuclei, the J-coupling constants and the relaxation times. (c) NMR spectrum of the 13C isotope, while the signal from the 1H and 19F nuclei is observed only as small (0.5%) satellites. To effectively separate this signal from that of the dominant background, we selected the 13C nucleus, which we used as the quantum register, and worked at a concentration of about 1%. This nuclei was observed with the corresponding 1H and 19F spectra. Because we used an unlabeled sample, the molecules with a 13C nucleus, which we used as the quantum register, were present at a concentration of about 1%. The 1H and 19F spectra were dominated by signals from the 2-qubit molecules containing the 12C isotope, while the signals from the quantum register with the 13C nucleus appeared only as small (0.5%) satellites. To effectively separate this signal from that of the dominant background, we transferred the state of the 1H and 19F qubits to the 13C qubit by a SWAP gate and read the state through the 13C spectrum. The matrix representation of the SWAP operation for two spins \( \sigma_i \) and \( \sigma_j \) is shown in Fig. 5 together with the corresponding pulse sequence.

SUPPORTING ONLINE MATERIAL

Quantum simulator and characterization

For the quantum register for these experiments, we selected the 1H, 13C, and 19F nuclear spins of Diethylfluoromalonate dissolved in d-chloroform. The relevant system parameters are listed in Fig. 4. Experiments were carried out at room temperature, using a Bruker Avance III 400 MHz (9.4 T) spectrometer equipped with a QXI probe with pulsed field gradient.

Because we used an unlabeled sample, the molecules with a 13C nucleus, which we used as the quantum register, were present at a concentration of about 1%. The 1H and 19F spectra were dominated by signals from the 2-qubit molecules containing the 12C isotope, while the signals from the quantum register with the 13C nucleus appeared only as small (0.5%) satellites. To effectively separate this signal from that of the dominant background, we transferred the state of the 1H and 19F qubits to the 13C qubit by a SWAP gate and read the state through the 13C spectrum. The matrix representation of the SWAP operation for two spins \( \sigma_i \) and \( \sigma_j \) is shown in Fig. 5 together with the corresponding pulse sequence.

Experimental procedure

The experiment, summarized in Fig. 2(a) in the paper, includes three steps: (i) Adiabatic state preparation (ASP): to prepare the ground state of the XY spin model \( \mathcal{H}(\lambda, \gamma) \) at different points of the Hilbert parameter space \( (\lambda, \gamma) \) by adiabatic evolution; (ii) NMR interferometry: to generate the pure geometric phase (GP) on one of the two paths where an auxiliary spin is introduced; (iii) Phase measurement: to obtain the GP by measuring the relative phase between the two paths via quadrature detection in NMR.

1. Adiabatic state preparation

To prepare the system in the ground state of a Hamiltonian \( \mathcal{H}(\lambda, \gamma) \), the system can start with an initial Hamiltonian \( \mathcal{H}(0) = \mathcal{H}_0 \), whose ground state \( |\psi_g(0)\rangle \) is known and then it is adiabatically driven to the target Hamiltonian \( \mathcal{H}(T) = \mathcal{H}(\lambda, \gamma) \). A time-dependent Hamiltonian \( \mathcal{H}_{\text{ad}}(t) \) smoothly interpolates between \( \mathcal{H}(0) \) and \( \mathcal{H}(T) \):

\[
\mathcal{H}_{\text{ad}}(t) = [1 - s(t)]\mathcal{H}_0 + s(t)\mathcal{H}(\lambda, \gamma),
\]

where the function \( s(t) \) varies from 0 to 1 to parametrize the interpolation. If the quantum system starts in \( |\psi_g(0)\rangle \) and the variation of \( \mathcal{H}(t) \) is adiabatic, the final state reached will be close to the ground state of \( \mathcal{H}(T) = \mathcal{H}(\lambda, \gamma) \). To ensure that the system is prepared in the ground state of \( \mathcal{H}(\lambda, \gamma) \), the sufficiently slow variation of \( \mathcal{H}_{\text{ad}}(t) \) means that the traditional adiabatic condition \([?)\]

\[
\left| \langle \psi_g(t) | \psi_1e(t) \rangle \right| / \varepsilon_1e(t) - \varepsilon_2g(t) \ll 1
\]

is fulfilled, where \( |\psi_g(t)\rangle \) and \( |\psi_1e(t)\rangle \) refer to the instantaneous ground state and the first excited state, respectively, and \( \varepsilon_1(t), \varepsilon_2(t) \) are the corresponding energies.

To do this, we chose the initial Hamiltonian of the system \( \mathcal{H}_0 = \sigma_x^2 + \sigma_x^3 \), whose ground state \( |\psi_g(0)\rangle_{23} = \)
$\frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) \otimes \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$) is well-known. Starting from the thermal equilibrium state, the system was first initialized into a pseudopure state (PPS) $\rho_{000} = \frac{1 - \epsilon}{8} \mathbf{1} + \epsilon \langle 000 \rangle \langle 000 \rangle$ by spatial averaging \[25\], where $\mathbf{1}$ represents the unity operator and $\epsilon \approx 10^{-5}$ represents the thermal polarization. The $|0\rangle$ and $|1\rangle$ states correspond to the two eigenstates of $\sigma_z$ the spin-up and spin-down states, respectively. The normalized deviation density matrix of the PPS \[25\], $\rho_2 \equiv [p - (1 - \epsilon) \mathbf{1}/8]/\epsilon$ was reconstructed by quantum state tomography \[23, 25\], which involves the application of 7 readout pulses and recording of the spectra of all three channels to obtain the coefficients for the 64 operators comprising a complete operator basis of the three-spin system. The experimentally determined state fidelity was $F = \frac{\text{Tr}(\rho_{e}^{\text{obs}} \rho_{m})}{\sqrt{\text{Tr}(\rho_{e}^{\text{obs}} \rho_{m})} \times \text{Tr}(\rho_{m})^2} \approx 0.99$. Then the initial state $|0\rangle_1 \otimes \psi_0(0)_{2,3}$ was prepared by two pseudo-inverse-Hamadard gates, i.e., $|\pi/2\rangle_u - y$ pulses on the system qubits 2 and 3.

An optimal function of $s(t)$ determines the efficiency of ASP. To find the optimal interpolar function $s(t)$ for the adiabatic process, we rewrite the adiabatic condition of Eq. (4) as

$$\left| \frac{ds(t)}{dt} \right| \leq \frac{|\varepsilon_1 e^t - \varepsilon_2 e^{-t}|}{|\psi_1(t)|^2 \frac{\partial H_{\text{ad}}(t)}{\partial s} |\psi_1(t)|} = \chi, \quad (5)$$

which defines the optimal sweep of the control parameter $s(t)$ with the scan speed $\frac{ds(t)}{dt} / \chi$, represented by the solid line in Fig. 1 (b) in the paper for the Hamiltonian $H(\lambda, \gamma) = H(0.992, 0.5)$. The time dependence of $s(t)$ was chosen such that the adiabaticity parameter $\kappa < 0.25$ at all times.

For the experimental implementation, we have to discretize the continuous adiabatic passage into $M_p + 1$ segments (i.e., $s_m = \frac{s_0}{M_p} t_0$) with $m = 0, ..., M_p$, $s_0 = 0$ and $s(M_p) = 1$, and generate the instantaneous discretized Hamiltonian $\mathcal{H}_{\text{ad}}[s_m] = [1 - s_m \mathcal{H}_0 + s_m \mathcal{H}(\lambda, \gamma)]$ for a time $t$. The evolution operator for the $m$th step is given by

$$U_m = e^{-i \delta \mathcal{H}_{\text{ad}}[s_m]}, \quad (6)$$

where $\delta = t_0/(M_p + 1)$. The total evolution is

$$U_\mathcal{P} = \prod_{m=0}^{M_p} U_m. \quad (7)$$

Since $\mathcal{H}_0$ and $\mathcal{H}(\lambda, \gamma)$ in $\mathcal{H}_{\text{ad}}[s_m]$ do not commute, the operator $U_m(\delta)$ is approximately implemented by the use of Trotter’s formula \[24\]:

$$U_m = e^{-i \delta \mathcal{H}_{\text{ad}}[s_m]} = e^{-i \frac{\delta}{2}[1 - s_m] \mathcal{H}_0} \times e^{-i \delta s_m \mathcal{H}(\lambda, \gamma)} e^{-i \frac{\delta}{2}[1 - s_m] \mathcal{H}_0} + O(\delta^3). \quad (8)$$

For this stepwise approximation, the duration of each time step $\delta$ has to be chosen such that (i) the time $\delta$ is short enough that the Hamiltonian simulation holds and (ii) the adiabaticity criterion remains valid, i.e., the total time $T_\mathcal{P}$ is long enough. The experimental values $s_m$ for the discretized scan are represented by black dots in Fig. 2(b) in the paper, which keeps a high theoretical fidelity (more than 0.99) of the final state for this stepwise transfer process of our ASP. The two operations $e^{-i \frac{\delta}{2}[1 - s_m] \mathcal{H}_0}$ and $e^{-i \delta s_m \mathcal{H}(\lambda, \gamma)}$ can be precisely simulated: $e^{-i \frac{\delta}{2}[1 - s_m] \mathcal{H}_0}$ can be easily realized using NMR radiofrequency pulses, while we use quantum techniques to simulate the XY Hamiltonian:

$$e^{-i \delta s_m \mathcal{H}(\lambda, \gamma)} = V_d^\dagger e^{-i \delta s_m \mathcal{H}_d(\lambda, \gamma)} V_d,$$

where the diagonal matrix $\mathcal{H}_d(\lambda, \gamma) = V_d \mathcal{H}(\lambda, \gamma) V_d^\dagger$.

$$\mathcal{H}_d(\lambda, \gamma) = \begin{pmatrix} -\sqrt{\lambda^2 + \gamma^2} & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & \sqrt{\lambda^2 + \gamma^2} \end{pmatrix}$$

$$= -\sqrt{\lambda^2 + \gamma^2} + \frac{1}{2} \sigma_z - \frac{\sqrt{\lambda^2 + \gamma^2}}{2},$$

with

$$V_d = \begin{pmatrix} \cos(\theta/2) & 0 & 0 & -\sin(\theta/2) \\ 0 & 1/\sqrt{2} & -1/\sqrt{2} & 0 \\ 0 & 1/\sqrt{2} & 1/\sqrt{2} & 0 \\ \sin(\theta/2) & 0 & 0 & \cos(\theta/2) \end{pmatrix}$$

$$= e^{-i \frac{\theta}{2} \sigma_z/2} e^{-i \frac{\theta}{2} \sigma_y^2/2} e^{-i \frac{\theta}{2} \sigma_y^2/2}.$$
are shown in Fig. 7 along with the theoretical expectations. From the tomographically reconstructed density matrices, we determined the experimental fidelity for our prepared states: $F_{P_1}^{\text{exp}} = 0.98$, $F_{P_2}^{\text{exp}} = 0.99$. This proves that ASP prepared successfully the ground state of the XY model.

2. NMR interferometry: A purely GP generation by conditionally cyclic adiabatic variations of the Hamiltonians

Cyclic adiabatic evolution

The studied physical system is described by $\tilde{H}(\lambda, \gamma, \phi) = U_1^\dagger(\phi)H(\lambda, \gamma)U_1(\phi)$ with $U_1(\phi) = \prod_k e^{-i\frac{\phi}{2}\sigma^k_z}$, which has the same spectrum as $H(\lambda, \gamma)$, independent of $\phi$. Its matrix form is

$$\tilde{H}(\lambda, \gamma, \phi) = -\begin{pmatrix} \lambda & 0 & 0 & e^{i2\phi} \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ e^{-i2\phi} & 0 & 0 & -\lambda \end{pmatrix}. \quad (11)$$

Clearly we can consider the subspace spanned by $|00\rangle$ and $|11\rangle$, which contains the ground state, as a pseudo-spin 1/2, where the spin evolves in an effective magnetic field $B = r(\sin \theta \cos 2\phi, \sin \theta \sin 2\phi, \cos \theta)$ with $\tan \theta = \gamma/\lambda$, while the subspace spanned by $|01\rangle$ and $|10\rangle$ is independent of $\phi$. Here, we adiabatically vary the angle $\phi$, that is, the Hamiltonian depends on time through a set of parameters $R(t) = R(\theta, \phi(t)) = (\sin \theta \cos 2\phi(t), \sin \theta \sin 2\phi(t), \cos \theta)$. Thus we are interested in the adiabatic evolution of the system as $R(t)$ moves slowly along a path $C$ in the parameter space, i.e.,

$$C : [0, T] \rightarrow S^2 \text{ with points } R(t) \in C,$$

where the unit sphere $S^2 = \{R \in \mathbb{R}^3 : |R| = 1\}$ is the parameter space of the system. The quantum adiabatic theorem predicts that a system initially in one of its eigenstates $|n; R(0)\rangle$ will remain its instantaneous eigenstate $|n; R(t)\rangle$ of the Hamiltonian $\tilde{H}(R(t))$ throughout the process.

If the parameters $R(t)$ adiabatically traverse a closed path $C : [\phi(0) = 0, \phi(T) = \pi]$ and return, after some period $T$, to their original values:

$$C : R(0) \rightarrow R(t) \rightarrow R(T) = R(0),$$

then

$$\tilde{H}(R(T)) = \tilde{H}(R(0))$$

$$E_n(R(T)) = E_n(R(0))$$

$$|n; R(T)\rangle\langle n; R(T)| = |n; R(0)\rangle\langle n; R(0)|.$$

Here the Hamiltonian $\tilde{H}(R)$ has the spectral resolution

$$\tilde{H}(R(t)) = \sum_n E_n(R(t))|n; R(t)\rangle\langle n; R(t)|.$$

However, the basis vectors $|n; R\rangle$ themselves in general not be unique over the whole parameter space. A new set of eigenvectors $|n; R\rangle'$ can be obtained by gauge transformations:

$$|n; R\rangle' = e^{i\zeta_n(R)}|n; R\rangle,$$

where $\zeta_n(R)$ are arbitrary real phase angles. One can use different parameterizations over different patches of the parameter space. Here we require that the closed path $C$ is placed into one single patch $\mathcal{O} \subset \mathcal{M}$ and the basis functions $|n; R\rangle$ is smooth and single-valued.

Consequently, the cyclic adiabatic evolution along the closed path $C : [\phi(0) = 0, \phi(T) = \pi]$ let the Hamiltonian $\tilde{H}(R(t))$ and the adiabatically evolving state $|\psi(t)\rangle = |\psi(\phi(t))\rangle$ return to their original forms in the parameter space as time progresses from $t = 0$ to the period $t = T$. If our system starts with the ground state $|\Psi_g(0)\rangle = \cos \frac{\theta}{2}|00\rangle + \sin \frac{\theta}{2}|11\rangle$ of $\tilde{H}(R(0))$, the adiabatically evolving state at time $t$ is

$$|\psi(t)\rangle = e^{i(\beta_g + \beta_d)|\Psi_g(\phi)\rangle} = e^{i(\beta_g + \beta_d)U_1^\dagger(\phi)|\Psi_g(0)\rangle}. $$

The cyclic adiabatic evolution along the closed path $C$ will generate the dynamical phase

$$\beta_d = \int_0^T E_d(t)dt = \int_0^T -\sqrt{\lambda^2 + \gamma^2}dt = -T\sqrt{\lambda^2 + \gamma^2}$$

and the geometric phase (or Berry phase)

$$\beta_g = i\int_0^T \langle \Psi_g(\phi)|\partial_\phi|\Psi_g(\phi)\rangle = \pi(1 - \cos \theta).$$
Berry phase for the GP obtained in the adiabatic approximation is associated with a closed curve in the Hamiltonian parameter space. After the cyclic adiabatic evolution along the closed path $C$, the system state obtains the total phase $\beta_t(C) = \beta_d(C) + \beta_g(C) = \pi(1 - \cos \theta) - T\sqrt{\lambda^2 + \gamma^2}$, mixing the GP with the dynamical phase.

A purely GP generation: eliminating the dynamical phase

In order to obtain a purely GP, we have to design a reverse dynamical process to cancel out the dynamical phase but double the geometric one. This can be implemented by another closed path $\tilde{C} (\phi : \pi \rightarrow 2\pi)$ along the Hamiltonian $-\tilde{H}(\lambda, \gamma, \phi)$. In this case, the initial state $|\Psi_g\rangle = \cos \frac{\theta}{2} |00\rangle + \sin \frac{\theta}{2} |11\rangle$ is not the ground state of $-\tilde{H}(\lambda, \gamma, \phi)$, but the eigenstate of the Hamiltonian $-\tilde{H}(\lambda, \gamma, \phi)$ with the highest eigenvalue $\sqrt{\lambda^2 + \gamma^2}$. Therefore the adiabatic passage was performed on this eigenstate along $-\tilde{H}(\lambda, \gamma, \phi)$. Thus we have the dynamical phase

$$\beta_d(\tilde{C}) = \int_0^T \sqrt{\lambda^2 + \gamma^2} dt = T\sqrt{\lambda^2 + \gamma^2},$$

and the geometric phase

$$\beta_g(\tilde{C}) = i \int_0^\pi (\Psi_g(\phi)|\partial_\phi|\Psi_g(\phi)) = \pi(1 - \cos \theta),$$

which leads to the total phase $\beta_t(\tilde{C}) = \beta_d(\tilde{C}) + \beta_g(\tilde{C}) = \pi(1 - \cos \theta) + T\sqrt{\lambda^2 + \gamma^2}$.

The resulting effect of the two closed paths $C$ and $\tilde{C}$ is

$$\beta_t(\tilde{C}) + \beta_t(C) = 2\beta_g = 2\pi(1 - \cos \theta).$$

Consequently, the dynamic phase vanishes and we obtain a purely GP.

NMR interferometry

The phases generated can be detected by NMR interferometry, which consists of a Hadamard gate and a controlled-$U$ operation (see Fig. 2 (a) in the paper). The Hadamard gate is represented by the Hadamard matrix:

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

which maps the basis state $|0\rangle$ to $\frac{1}{\sqrt{2}} (|0\rangle + |1\rangle)$ and $|1\rangle$ to $\frac{1}{\sqrt{2}} (|0\rangle - |1\rangle)$. The auxiliary qubit $a$ was put into a superposition state $\frac{1}{\sqrt{2}} (|0\rangle + |1\rangle)$ from the $|0\rangle$ state by a pseudo-Hadamard gate $|\pi/2\rangle^a - y$.

Then the system state adiabatically traces out a closed path $C (\phi : 0 \rightarrow \pi)$ along the Hamiltonian $\tilde{H}(\lambda, \gamma, \phi)$, but only if the auxiliary qubit is in state $|1\rangle$; when the auxiliary qubit is in state $|0\rangle$, the system state is not affected. This can be realized by a controlled-$U$ operation: $U_C = |0\rangle\langle 0| \otimes 1 + |1\rangle\langle 1| \otimes \tilde{U}C$, where $1$ represents a $4 \times 4$ unit operator and the unitary operator $\tilde{U}C$ is the cyclic adiabatic evolution on the system qubits along the chosen path. It effectively introduces a relative phase shift between the initially prepared superposition with known phase of the states of the auxiliary qubit when the cyclic adiabatic evolution $\tilde{U}C$ creates a non-zero phase. The process of the interferometer can be described as

$$|0\rangle_a |\Psi_g\rangle_{12} \xrightarrow{H_a} \frac{1 + \sqrt{2}}{\sqrt{2}} (|0\rangle_a + |1\rangle_a) |\Psi_g\rangle_{12}$$

$$\tilde{U}C \rightarrow \frac{1}{\sqrt{2}} (|0\rangle_a + e^{|2\lambda|\phi} |1\rangle_a) |\Psi_g\rangle_{12}.$$

Likewise, for the closed path $\tilde{C}$, The process is

$$|0\rangle_a |\Psi_g\rangle_{12} \xrightarrow{H_a} \frac{1 + \sqrt{2}}{\sqrt{2}} (|0\rangle_a + |1\rangle_a) |\Psi_g\rangle_{12}$$

$$\tilde{U}C \rightarrow \frac{1}{\sqrt{2}} (|0\rangle_a + e^{|2\lambda|\phi} |1\rangle_a) |\Psi_g\rangle_{12}.$$

The resulting effect of these two experiments results in

$$|0\rangle_a |\Psi_g\rangle_{12} \longrightarrow \frac{1}{\sqrt{2}} (|0\rangle_a + e^{|2\lambda|\phi} |1\rangle_a) |\Psi_g\rangle_{12},$$

where the purely GP is obtained by summing the relative phases in these two experiments.

Experimental implementation for conditionally cyclic adiabatic evolutions along $C$ and $\tilde{C}$

The Hamiltonian $\tilde{H}(\lambda, \gamma, \phi)$ varies adiabatically along the trajectory $C$, i.e., $\phi$ changes slowly from 0 to $\pi$. Like in APS, the continuous Hamiltonian $\tilde{H}(\lambda, \gamma, \phi)$ is discretized into $M + 1$ steps in the range of $\phi : 0 \rightarrow \pi$ in the actual implementation. Likewise, we numerically optimized the adiabatic steps $M + 1$ and evolution time $T$ to achieve a high fidelity of the instantaneous state of the system. In experiment, we chose $M < 6$ and $T \sim 10$ which results in a theoretical fidelity of $> 0.99$ for both trajectories $C$ and $\tilde{C}$.

The unitary operation of the $m$th adiabatic step for a constant $\phi_m$ can be realized by the following decomposition:

$$\tilde{U}_C^m = e^{-i\frac{1}{2}(1^a - \sigma^{\phi_m}_a) \otimes \tilde{H}(\lambda, \gamma, \phi_m) \tau} = 1^a \otimes U_1^z(\phi_m) e^{-i\frac{1}{2}(1^a - \sigma^{\phi_m}_a) \otimes \tilde{H}(\lambda, \gamma, \phi_m) \tau} 1^a \otimes U_2(\phi_m)$$

$$= 1^a \otimes U_1^z(\phi_m) V_1^z e^{-i\frac{1}{2}(1^a - \sigma^{\phi_m}_a) \otimes \tilde{H}(\lambda, \gamma, \phi_m) \tau} 1^a \otimes V_2 U_2(\phi_m),$$

where $\tau = T/(M + 1)$. The total evolution is

$$U_C(T) = \prod_{m=0}^{M} \tilde{U}_C^m. \quad (12)$$
The quadrature detection in NMR serves as a phase register. For the trajectory \( C \), we have the input state of the auxiliary qubit: 
\[
|\varphi_m\rangle = \begin{cases} 
1 \text{ or } 2 \quad (k \neq j), & \text{for } k = 1 \text{ or } 2, \quad j = 1 \text{ or } 2, 
\end{cases}
\]
and \( C \) is determined by tan \( \frac{\beta}{2} \) out of phase with each other. Thus, the phase angle \( \beta_C + \beta_d \) of the signal can be determined by tan \( \frac{1}{2}(IM/RE) \). Quadrature detection combined with Fourier analysis thus gives all the necessary information on the magnetic resonance signal components, i.e., amplitude, phase, and frequency [23]. Taking the input state of \( \frac{1}{2}(|0\rangle_a + |1\rangle_a)\Psi_{12} \) as the reference spectrum, we measured the relative phase information by the phase of the Fourier-transformed spectrum. Fig. [9] shows a simple example for the phase measurement by the Fourier-transformed spectra.

### Experimental results and data analysis

Fig. [10] shows the experimental NMR spectra for a set of experiments \( H(\lambda, \gamma) \) with varying magnetic field strength \( \lambda \) (0 \( \rightarrow \) 1.7) and a constant anisotropy parameter \( \gamma = 0.5 \). The parameter \( \lambda \) was varied by a hyperbolic sine function [30], but avoiding the level crossing points. From these spectra, we measured the phase shifts accumulated by the two trajectories \( C \) and \( C \) listed in Table I. The pure GP was then obtained by summing the two phase shifts from \( C \) and \( C \): \( \beta_g = (\beta(C) + \beta(C))/2 \). A set of the experimental spectra are shown in Fig. 3 in the paper.

Our experimental errors of the geometric phases are less than 3°. These errors result from the imperfection of the initial ground state by ASP, the diabatic effect, and other experimental imperfections such as the inhomogeneity of the radio frequency field and the static magnetic field, and the imperfect calibration of the radio frequency pulses. The decoherence from spin relaxation was small, since the total experimental time of less than 90 ms was short compared to the shortest relaxation time of 1.0 s.

The error contributed by the imperfection of the initial ground state of ASP can be evaluated by the use of the measured input density matrices \( \rho_{ini}^{exp} \) after ASP, e.g., shown in Fig. [7]. Therefore we have the input state
\[
\rho_{ini} = |0\rangle_a \langle 0| \otimes \rho_{ini}^{exp}.
\]
FIG. 10: Experimental $^{13}$C spectra for the XY Hamiltonian $H(\lambda, \gamma)$ with $\gamma = 0.5$ and the variable $\lambda$ from 0 to 1.7. The red ones are the spectra of the initial states prepared by ASP as the references. The upper plot is the spectra for the trajectory $C$ when $\lambda$ scans while the lower plot is for $\bar{C}$. We extract the phase information from these spectra using quadrature detection.

TABLE I: The extracted phase values from the NMR signals for $\gamma = 0.5$. $\beta_C^{exp}$ and $\beta_{\bar{C}}^{exp}$ are the phases obtained by the NMR interferometry with the related adiabatic evolution trajectories $C$ and $\bar{C}$. $\beta_g^{exp} = \frac{\beta_C^{exp} + \beta_{\bar{C}}^{exp}}{2}$ is the geometric phase. The corresponding experiment spectra are showed above.

| ExpNo. | $\lambda$ | $\beta_C^{exp}$ (°) | $\beta_{\bar{C}}^{exp}$ (°) | $\beta_g^{exp}$ (°) | $\beta_g^{th}$ (°) |

| 3      | 0.6592    | 173.8                | -174.2                 | -0.3              | 0                |
| 4      | 0.74      | 168                  | -170                   | -1                | 0                |
| 5      | 0.7922    | 172.2                | -171                   | 0.6               | 0                |
| 6      | 0.8275    | 174.6                | -176.2                 | -0.8              | 0                |
| 7      | 0.8541    | 170.4                | -171.6                 | -0.6              | 0                |
| 8      | 0.878     | -62.6                | 114.2                  | 25.8              | 23.6             |
| 9      | 0.9045    | -60                  | 107.6                  | 23.8              | 22.5             |
| 10     | 0.9399    | -60.2                | 106.4                  | 23.1              | 21.1             |
| 11     | 0.992     | -69.8                | 111.4                  | 20.8              | 19.3             |
| 12     | 1.0729    | -70.4                | 108.6                  | 19.1              | 16.8             |
| 13     | 1.2009    | -79.6                | 109                    | 14.7              | 13.8             |
| 14     | 1.4051    | -75.6                | 95.4                   | 9.9               | 10.4             |
| 15     | 1.7321    | -81.1                | 96.6                   | 7.7               | 7.1              |

Then we input the state to an ideal NMR interferometer, i.e., a perfectly implemented Hadamard gate and controlled evolution process simulated on a classical computer to get the theoretical output:

$$\rho_f = \frac{1}{2} \left( \rho_{\text{ini}}^{\exp} \rho_{\text{ini}}^{\exp + \rho_{\text{ini}}^{\exp \dagger} U_{\alpha}(T) \rho_{\text{ini}}^{\exp \dagger}} \right),$$

where $\alpha \ (\alpha = C \ or \ \bar{C})$. As a result, the measurement on the auxiliary qubit by the quadrature detection gives

$$\langle \rho_f \sigma_a \rangle = \frac{1}{2} \text{Tr}[U_{\alpha}(T)\rho_{\text{ini}}^{\exp \dagger}].$$

Thus we achieved the simulated phases $\beta_{\alpha}^{\text{sim}} = \arg(\rho_f \sigma_a) = \arg(\text{Tr}[U_{\alpha}(T)\rho_{\text{ini}}^{\exp \dagger}]).$ Thus the simulated geometric phase starting from the experimental initial state is $\beta_g^{\text{sim}} = \frac{\beta_C^{\text{sim}} + \beta_{\bar{C}}^{\text{sim}}}{2}$. We found that the errors contributed by the imperfection of the prepared initial state is about $1^\circ$.
